Centrifugal Water Chillers

One of the Equipment Series

A publication of
The Trane Company—
Worldwide Applied Systems Group

Preface

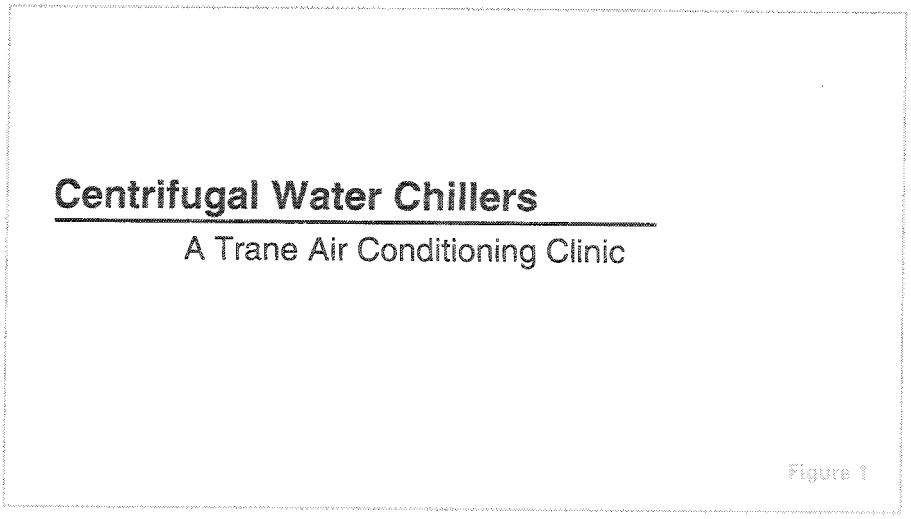

Figure 1

The Trane Company believes that it is incumbent on manufacturers to serve the industry by regularly disseminating information gathered through laboratory research, testing programs, and field experience.

The Trane Air Conditioning Clinic series is one means of knowledge sharing. It's intended to acquaint a nontechnical audience with various fundamental aspects of heating, ventilating, and air conditioning.

We've taken special care to make the clinic as uncommercial and straightforward as possible. Illustrations of Trane products only appear in cases where they help convey the message contained in the accompanying text.

This particular clinic introduces the concept of **centrifugal water chillers**.

Introduction

notes

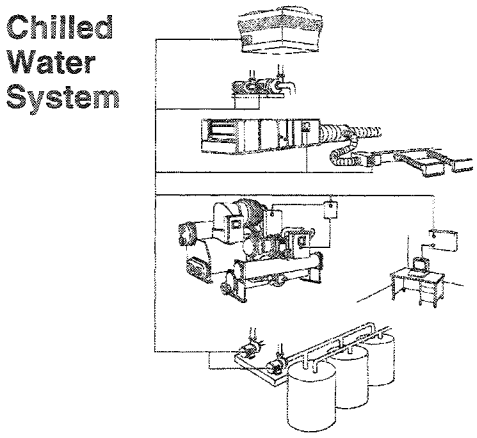

Figure 2

Water chillers are used in a variety of air conditioning and process cooling applications. They are used to make cold water that can be transported throughout a facility using pumps and pipes. This cold water can be passed through the tubes of coils to cool the air in an air conditioning application, or it can provide cooling for a manufacturing or industrial process.

Systems that employ water chillers are commonly called **chilled water systems**.

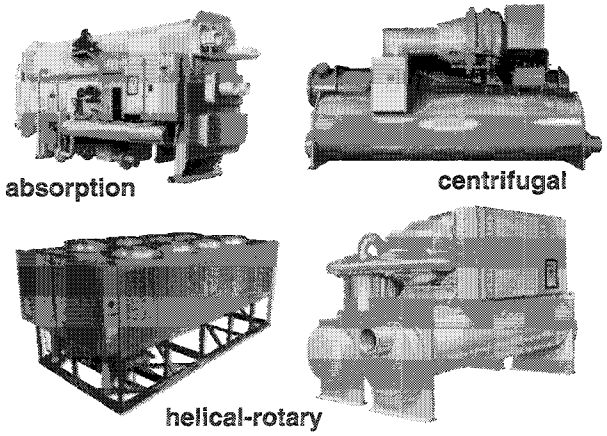

Figure 3

There are several types of water chillers. They differ from each other based on the refrigeration cycle or the type of compressor they use.

Absorption water chillers make use of the absorption refrigeration cycle and do not have a mechanical compressor involved in the refrigeration cycle.

Introduction

notes

Water chillers using the vapor-compression refrigeration cycle vary by the type of compressor used. Reciprocating and scroll compressors are typically used in small chillers. Helical-rotary (or screw) compressors are typically used in medium-sized chillers. Centrifugal compressors are typically used in large chillers.

As mentioned earlier, this particular clinic discusses **centrifugal water chillers**.

Centrifugal Water Chillers

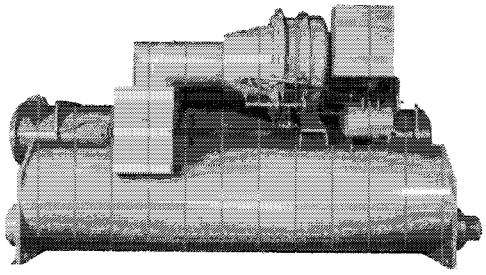

Figure 4

Centrifugal water chillers can also be divided into two types based on the method used to reject heat to the atmosphere: water-cooled or air-cooled. Since most centrifugal chillers are water-cooled, they are the primary focus of this clinic. Water-cooled centrifugal chillers are generally available from 100 to 3,000 tons [350 to 10,500 kW] as prefabricated machines, and up to 8,500 tons [30,000 kW] as built-up machines.

notes

Centrifugal Water Chillers

period one
Components

Figure 5

Many of the components of the centrifugal water chiller are similar to those of other chiller types.

components of a
Centrifugal Water Chiller

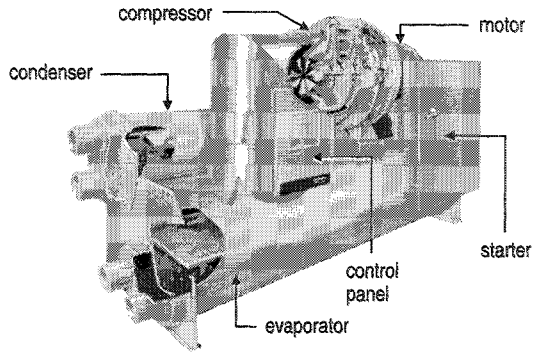

Figure 6

This particular centrifugal water chiller makes use of a shell-and-tube evaporator where refrigerant absorbs heat from the water flowing through the tubes. The compressor is made up of 1 or more centrifugal impellers. A second shell-and-tube heat exchanger serves as the water-cooled condenser, where refrigerant is condensed inside the shell and water flows inside tubes. Refrigerant is metered through the system using an expansion device such as a fixed orifice plate. An economizer can be used to enhance the efficiency of a chiller with multiple compressor impellers. A control panel is also provided on the chiller and a starter is either mounted on the chiller or located remotely.

period one
Components

notes

Compressor

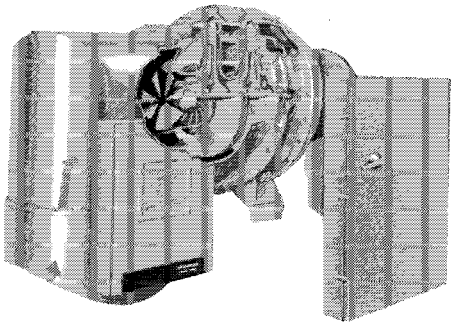

Figure 7

Compressor
The centrifugal compressor uses the principle of **dynamic compression**, which involves converting energy from one form to another, to increase the pressure and temperature of the refrigerant. It converts kinetic energy to static energy.

Impeller

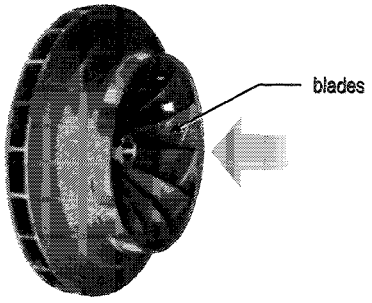

Figure 8

The core component of a centrifugal compressor is the rotating **impeller**. The center, or eye, of the impeller is fitted with blades that draw refrigerant vapor into radial passages that are internal to the impeller body.

period one
Components

notes

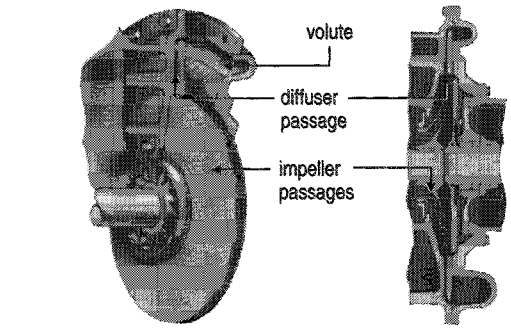

Figure 1

The rotation of the impeller causes the refrigerant vapor to accelerate within the **impeller passages**, increasing its velocity and kinetic energy.

The accelerated refrigerant vapor leaves the impeller and enters the **diffuser passages**. These passages start out small and become larger as the refrigerant travels through them. As the size of the diffuser passages increases, the velocity, and therefore the kinetic energy, of the refrigerant decreases.

The first law of thermodynamics states that energy is not destroyed—only converted from one form to another. Thus, the refrigerant's kinetic energy is converted to static energy or static pressure.

Refrigerant, now at a higher pressure, collects in a larger space around the perimeter of the compressor called the **volute**. The volute also becomes larger as the refrigerant travels through it. Again, as the size of the volute increases, the kinetic energy is converted to static pressure.

Due to its pressure and temperature, the refrigerant leaving the compressor is in a condition that allows its heat to be rejected from the chiller.

notes

centrifugal compressor
Energy Conversion

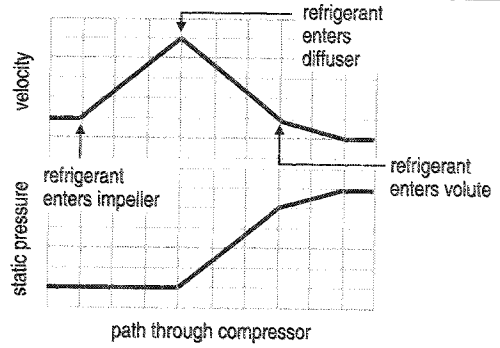

Figure 10

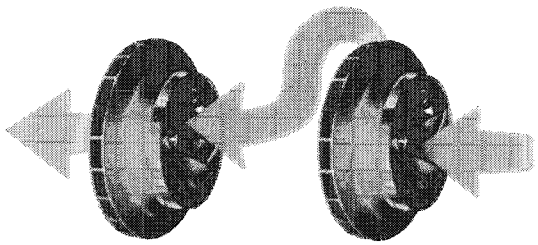
Again, in the passages of the rotating impeller, the refrigerant vapor accelerates, increasing its velocity and kinetic energy. As the area increases in the diffuser passages, the velocity, and therefore the kinetic energy, of the refrigerant decreases. This reduction in kinetic energy is offset by an increase in the refrigerant's static energy or static pressure. Finally, the high pressure refrigerant collects in the volute around the perimeter of the compressor, where further energy conversion takes place.

The resulting pressure and temperature of the refrigerant is now high enough that its heat can be rejected from the chiller.

Multistage Compressor



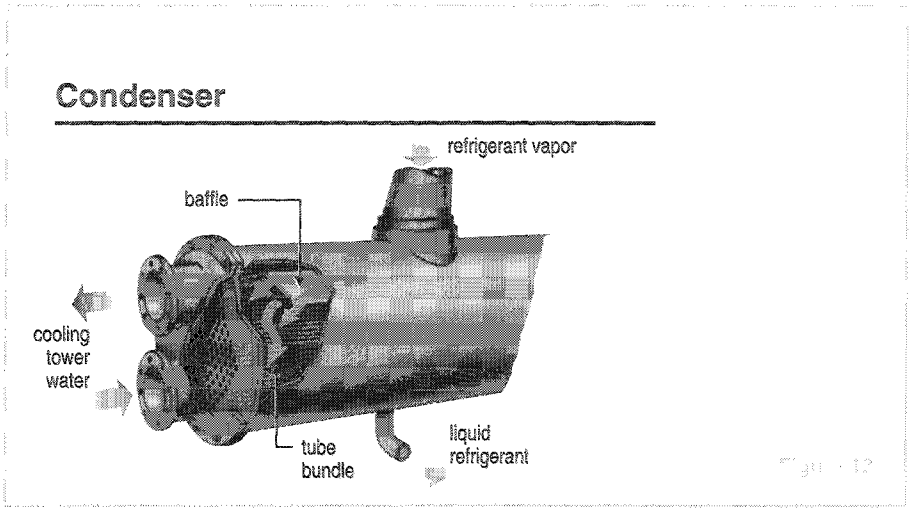


Figure 11

Centrifugal compressors use 1 or more impellers to compress the refrigerant. A **multistage compressor** uses 2 or 3 impellers to increase the pressure of the refrigerant in steps instead of performing the task within a single impeller. Compressed refrigerant vapor travels from the outlet of the first-stage compressor impeller to the inlet of the second-stage compressor impeller. After

notes

the accelerated refrigerant vapor leaves the last impeller, it collects in the compressor volute and travels on to the condenser.

Condenser

The high-pressure refrigerant vapor is discharged from the compressor into a heat exchanger that acts as a condenser.

In a water-cooled **condenser**, water is pumped through the tubes of the shell-and-tube heat exchanger while refrigerant vapor fills the shell space surrounding the tube bundle. A baffle inside the condenser helps distribute the refrigerant evenly. As heat transfers from the hot, high-pressure refrigerant vapor to the water, refrigerant condenses on the tube surfaces.

Cooling water flows first through the lower tubes and then through the upper tubes. This produces a nearly constant temperature difference between the downward-moving refrigerant and the tube surfaces, resulting in a uniform heat transfer rate within the tube bundle.

Condensed liquid refrigerant collects in the bottom of the shell and flows through the liquid line to the expansion devices and economizer.

period one
Components

notes

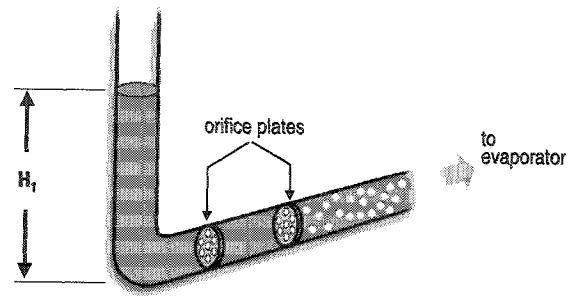

Figure 13

Expansion Device

An **expansion device** is used to maintain the pressure difference between the high-pressure (condenser) and low-pressure (evaporator) sides of the refrigeration system, as established by the compressor. This pressure difference allows the evaporator temperature to be low enough for the refrigerant to absorb heat from the water being cooled, and the condenser temperature to be high enough for the refrigerant to reject heat to water at normally available temperatures. High-pressure liquid refrigerant flows through the expansion device, causing a pressure drop that reduces the refrigerant pressure to that of the evaporator. This pressure reduction causes a small portion of the liquid to boil off, or "flash," cooling the remaining refrigerant to the evaporator temperature.

The expansion device is also used as a liquid refrigerant metering system, balancing the refrigerant flow rate with the evaporator load condition. In our example centrifugal chiller, the expansion device used is a set of 2 **orifice plates**. At full load, a large amount of refrigerant is moving through the chiller. The column of liquid refrigerant in the liquid line pressurizes the liquid at its base. During passage through the orifice plates, the liquid refrigerant undergoes a pressure drop equal to the head **(H_1)** before some of it flashes to vapor.

notes

expansion device
Orifice Plates

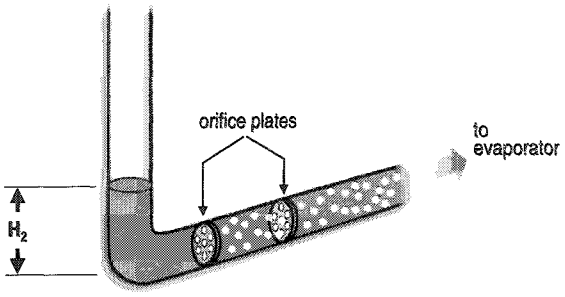

Figure 14

As the load decreases, less refrigerant moves through the chiller and the level of the liquid column drops. Now, as the liquid refrigerant passes through the orifice plates, it only undergoes a pressure drop equal to the lower head **(H_2)** before some of it flashes to vapor. This causes additional flashing at the orifice plate which, in turn, feeds less liquid to the evaporator.

Other types of expansion devices found in centrifugal chillers include: float valves, expansion valves (thermostatic or electronic), and variable orifices.

2-stage chiller
Economizer

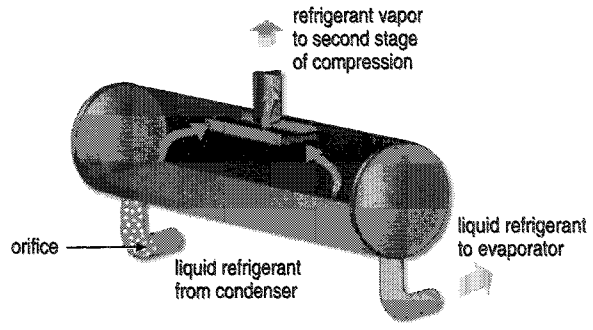

Figure 15

Economizer

An **economizer** can be used in conjunction with multiple expansion devices to improve the efficiency of a multistage chiller. In a chiller with a 2-stage compressor, the expansion process can be separated into 2 steps with an economizer chamber between.

period one
Components

notes

Liquid refrigerant from the condenser enters the first expansion device, which reduces the pressure of the refrigerant to that of the second-stage impeller inlet. This pressure drop causes a portion of the liquid refrigerant to evaporate, or flash, and the resulting mixture of liquid and vapor enters the economizer chamber. Here, the vapor is separated from the mixture and is routed directly to the inlet of the second stage impeller. The remaining liquid travels on to the second expansion device and evaporator.

Just before entering the evaporator, the liquid refrigerant flows through a second expansion device that reduces its pressure and temperature to evaporator conditions.

Flashing a portion of the refrigerant prior to the economizer reduces the amount of compressor power required, since the refrigerant vapor generated in the economizer only needs to be compressed by the second-stage impeller.

The benefit of the economizer will be discussed in greater detail in Period 2.

3-stage chiller
Economizer

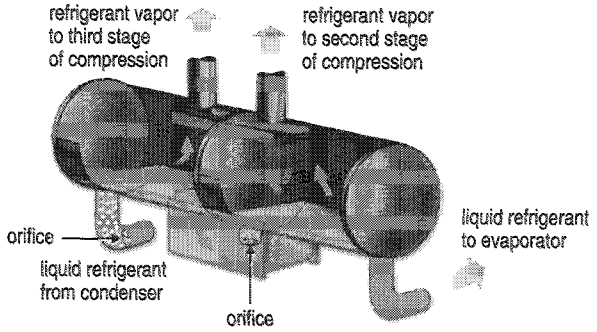

Figure 16

In a chiller with a 3-stage compressor, the expansion process can be separated into 3 steps with separate economizer chambers between the steps.

Liquid refrigerant from the condenser enters the first orifice (expansion device), which reduces the pressure of the refrigerant to that of the third-stage impeller inlet. This pressure drop causes a portion of the liquid refrigerant to flash, and the resulting mixture of liquid and vapor enters the high-pressure chamber of the economizer. Here, the vapor is separated from the mixture and is then routed directly to the inlet of the third-stage impeller. The remaining liquid travels on to the second expansion device.

The second expansion device further reduces the pressure of the refrigerant to that of the second-stage impeller inlet. This pressure drop causes a portion of the liquid refrigerant to flash, and the resulting mixture of liquid and vapor enters the low-pressure chamber of the economizer. Here, the vapor is separated from the mixture and routed directly to the inlet of the second-stage impeller. The remaining liquid travels on to the third expansion device and evaporator.

notes

Again, the final expansion device reduces the pressure and temperature of the refrigerant to evaporator conditions.

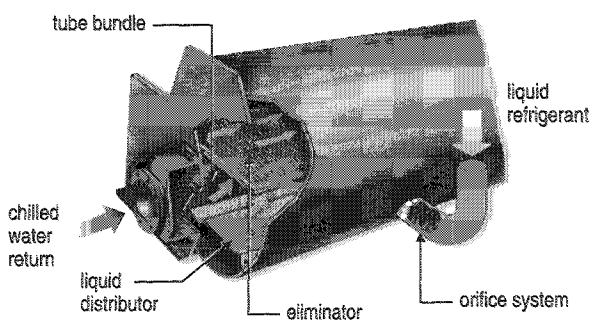

Figure 17

Evaporator

In the **flooded shell-and-tube evaporator** shown, the low-pressure mixture of liquid refrigerant and refrigerant vapor enters the distribution system that runs the entire length of the shell. Small openings and baffles in the passage of the liquid distributor provide an even spray of refrigerant over the surfaces of the tubes inside the evaporator shell, where the refrigerant absorbs heat from relatively warm water flowing through the tube bundle. This transfer of heat boils the liquid refrigerant on the tube surfaces. The resulting vapor passes through an eliminator that prevents liquid from being drawn upward. The vapor collects in a large chamber at the top of the shell and is drawn back to the compressor. The now-cool water can be used in a variety of comfort or process applications.

Some chiller designs may make use of a **direct expansion (DX) shell-and-tube evaporator**. In this type of evaporator, liquid refrigerant flows through the tubes and water fills the surrounding shell. As heat is transferred from the water to the refrigerant, the refrigerant boils inside the tubes and the resulting vapor is drawn to the compressor.

notes

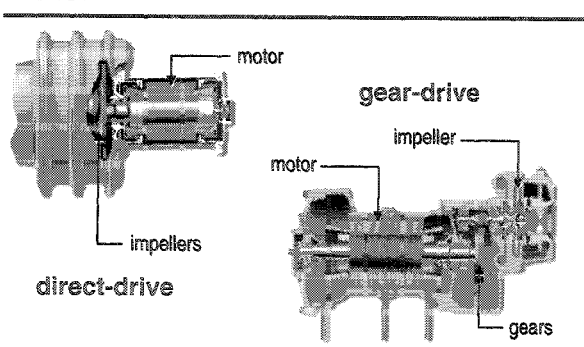

Figure 18

Motor

A motor is used to rotate the impeller(s). A **direct-drive motor** is connected directly to the impeller shaft and the impeller rotates at the same speed as the motor. A **gear-drive motor** transfers its energy to the impeller shaft using a set of gears. This allows the impeller to rotate at a higher speed than the motor.

The direct-drive motor requires fewer bearings and does not incur gear losses. Additionally, since the compressor rotates at a lower speed, it can be much quieter.

Direct-drive compressors are, however, only practical in centrifugal chillers that use low-pressure refrigerants.

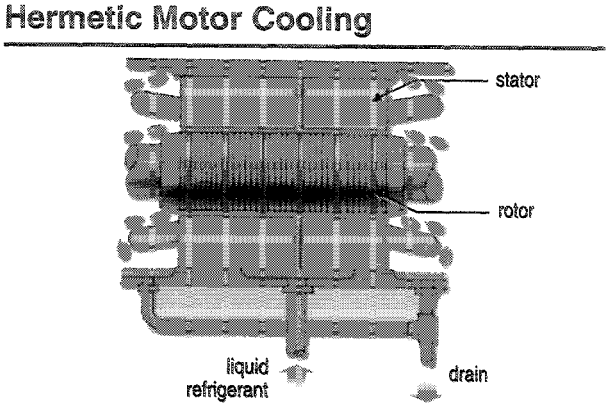

Figure 19

Another important difference in compressor motors is the issue of hermetic versus open. A **hermetic motor** is totally enclosed within the chiller's refrigeration system. An **open motor** is mounted externally—outside of the

notes

chiller's refrigeration system—and uses a coupling to connect the motor and compressor shafts.

The heat generated by the hermetic motor is absorbed by liquid refrigerant that flows around, through, and over the motor. The heat must be rejected by the chiller's condenser.

The heat generated by the open motor is rejected to the air drawn in from the equipment room. This heat must still be rejected from the equipment room, either by mechanical ventilation or, if the room is conditioned, the building's cooling system. In some designs, this air is simply drawn into the motor housing by the rotating motor shaft. The vent passages tend to get dirty and clog, resulting in higher operating temperatures and hot spots that adversely affect motor efficiency and reliability. Other designs, such as totally-enclosed fan-cooled (TEFC) and totally-enclosed air-over (TEAO), use a separate fan with a protective housing to cool the motor.

Hermetic compressor motors eliminate the need for the shaft couplings and external shaft seals that are associated with open motors. The coupling needs precise alignment, and these seals are a prime source of oil and refrigerant leaks. On the other hand, if a motor burns out, a hermetic chiller will require thorough cleaning, while a chiller with an open motor will not.

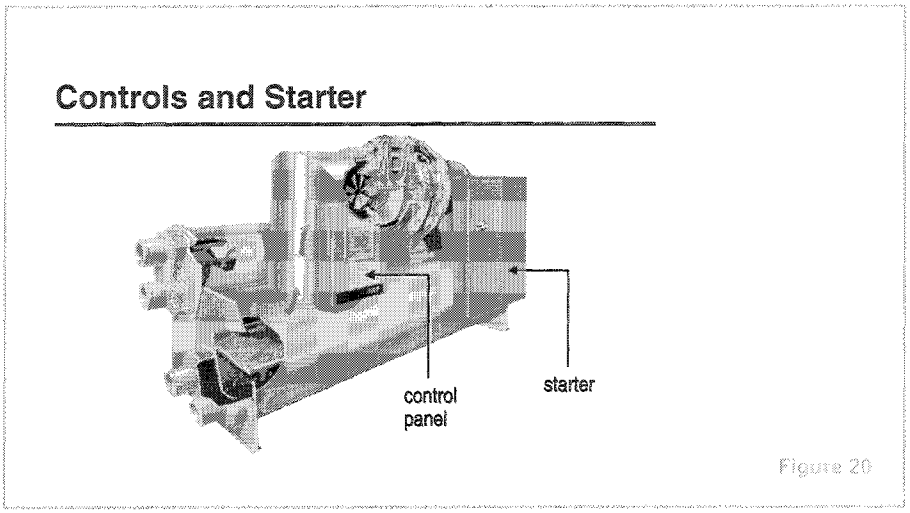

Figure 20

Controls and Starter

A microprocessor-based **control panel** is provided on the chiller to provide accurate chilled-water control as well as monitoring, protection, and adaptive limit functions. These controls monitor chiller operation and prevent the chiller from operating outside its limits. They can compensate for unusual operating conditions, keeping the chiller running by modulating system components rather than simply shutting it down when a safety setting is violated. When serious problems occur, diagnostic messages aid troubleshooting.

Modern control systems not only provide accurate, optimized control and protection for the chiller, but can also interface with a building automation system for integrated system control. In a chilled water system, optimal

notes

performance is a system-wide issue, not just a matter of chiller design and control.

A **starter** links the chiller motor and the electrical distribution system. Its primary function is to connect (start) and disconnect (stop) the chiller from line power—similar to what a switch does for a light bulb. The starter, however, handles much more current and must have the appropriate interlocks to work with the chiller control panel and oil pump.

Every electrically driven chiller requires a starter. It must be compatible with the characteristics of both the compressor motor and the electrical circuitry of the chiller. There are many types of starters, including star-delta, across-the-line, auto-transformer, primary reactor, and solid state. A variable-speed drive, which is used to modulate the speed of the motor during normal operation, also serves as a starter. Important characteristics to consider when selecting a starter include first cost, reliability, line voltage, and available current.

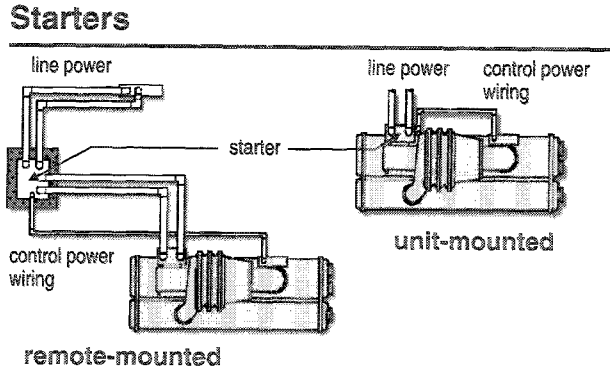

Figure 27

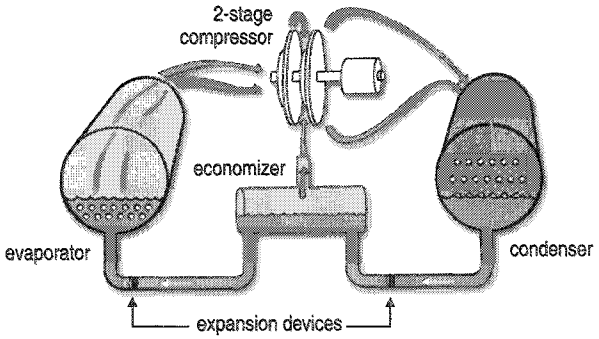
The starter may be mounted on, or remotely from, the chiller. Use of a unit-mounted starter reduces electrical installation costs. It may also improve reliability and save system design time, since all of the components are pre-engineered and factory mounted.

Depending on the type of starter selected, there are several options that can simplify installation. Disconnects allow the starter to be isolated from the electrical distribution system, and short-circuit protection can be provided using fuses or a circuit breaker.



notes

Centrifugal Water Chillers

period two
Refrigeration Cycle

A pressure–enthalpy (*p-h*) chart illustrates the refrigeration cycle of the centrifugal water chiller.

2-stage centrifugal chiller
Refrigeration Cycle

First, let's review the components of a 2-stage centrifugal chiller in the context of the refrigeration cycle.

Refrigerant vapor leaves the evaporator and flows to the compressor, where it is compressed to a higher pressure and temperature. High-pressure refrigerant vapor then travels to the condenser where it rejects heat to water, and then leaves as a saturated liquid. The pressure drop created by the first expansion device causes part of the liquid refrigerant to evaporate and the resulting mixture of liquid and vapor enters the economizer. Here, the vapor is separated from the mixture and routed directly to the inlet of the second-stage impeller. The remaining saturated liquid refrigerant enters the second expansion device.

period two
Refrigeration Cycle

notes

The pressure drop created by the second expansion device lowers the pressure and temperature of the refrigerant to evaporator conditions, causing a portion of the liquid refrigerant to evaporate. The resulting mixture of liquid and vapor enters the evaporator. In the evaporator, the liquid refrigerant boils as it absorbs heat from water and the resulting vapor is drawn back to the compressor to repeat the cycle.

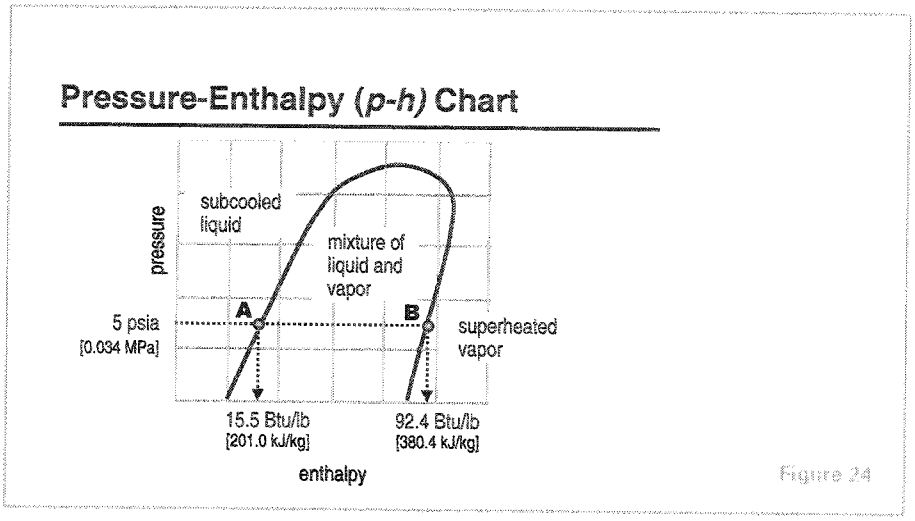


Figure 24

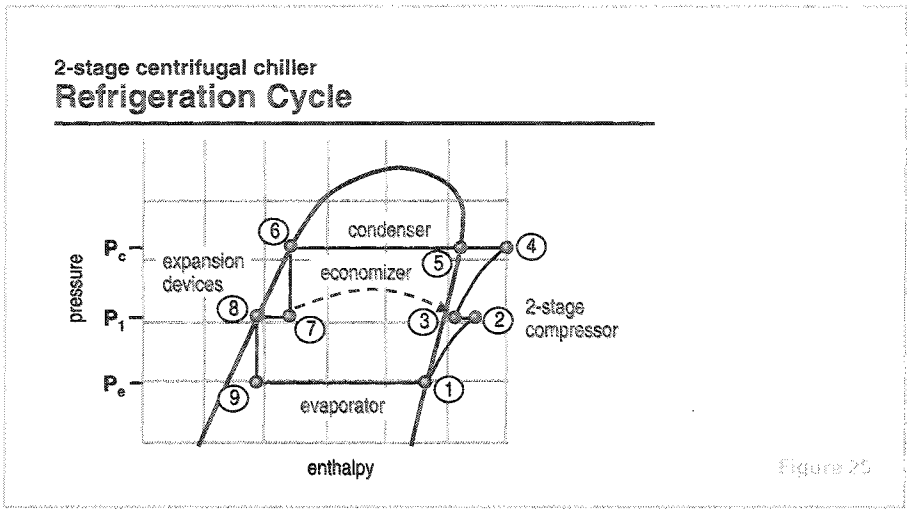
The **pressure-enthalpy chart** plots the properties of a refrigerant—refrigerant pressure (vertical axis) versus enthalpy (horizontal axis). **Enthalpy** is a measure of the heat content, both sensible and latent, per pound [kg] of refrigerant.



For example, **A** represents the heat content of saturated *liquid* HCFC-123 refrigerant at 5 psia [0.034 MPa] and 34°F [1.1°C]. **B** represents the heat content of saturated *vapor* HCFC-123 refrigerant at the same pressure and temperature. The difference in heat content, or enthalpy, between **A** and **B**—that is, 76.9 Btu/pound [179.4 kJ/kg]—is the amount of heat required to transform 1 pound of saturated liquid refrigerant to saturated refrigerant vapor at the same pressure and temperature.

If the heat content of the refrigerant at any pressure falls to the right of the curve, the vapor is superheated. Similarly, if the heat content of the refrigerant falls to the left of the curve, the liquid is subcooled. Finally, when the heat content of the refrigerant falls inside the curve, the refrigerant exists as a mixture of liquid and vapor.

Let's plot the theoretical vapor-compression refrigeration cycle for a 2-stage centrifugal water chiller on a pressure-enthalpy chart.

period two
Refrigeration Cycle

notes

Refrigerant leaves the evaporator as saturated vapor ① and flows to the first-stage impeller of the compressor. There, the refrigerant vapor is compressed to a higher pressure **(P_1)** and temperature ②. Cooler refrigerant vapor that flashed within the economizer is mixed with the refrigerant discharged from the first-stage impeller, reducing the heat content of the mixture ③. The second stage of compression further elevates the pressure **(P_c)** and temperature of the refrigerant ④.

Energy provided to the compressor is imparted to the refrigerant as an increase in pressure and superheat. Superheated refrigerant vapor leaves the compressor and enters the condenser.

Water flowing through the condenser absorbs heat from the hot, high-pressure refrigerant vapor, causing it to desuperheat ⑤ and condense into saturated liquid ⑥ before leaving the condenser to travel to the first expansion device.

The first expansion device reduces the pressure (⑥ to ⑦) of the refrigerant to the second-stage impeller inlet pressure **(P_1)**. This pressure drop causes a portion of the liquid refrigerant to evaporate, or flash. The evaporating refrigerant absorbs heat from the remaining liquid refrigerant, reducing its enthalpy from ⑦ to ⑧. The resulting mixture of liquid and vapor enters the economizer ⑦. Here, the vapor is separated from the mixture and routed directly to the second-stage impeller inlet ③ and the remaining liquid travels on to the second expansion device ⑧.

Just before it enters the evaporator, the liquid refrigerant flows through a second expansion device that reduces its pressure **(P_e)** and temperature to evaporator conditions ⑨. The cool, low-pressure mixture of liquid and vapor enters the distribution system in the evaporator shell and absorbs heat from water that flows through the tubes. This transfer of heat boils the liquid refrigerant, and the resulting saturated refrigerant vapor is drawn back to the compressor ① to repeat the cycle.

period two
Refrigeration Cycle

notes

2-stage centrifugal chiller
Refrigeration Cycle

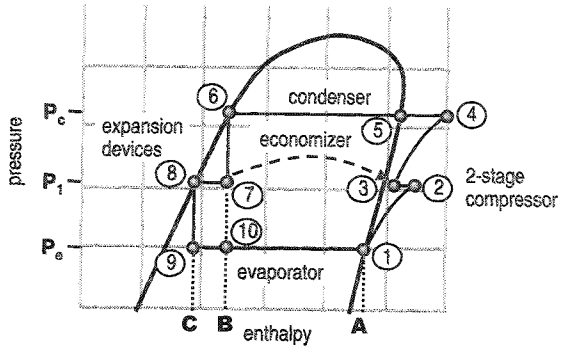


Figure 26

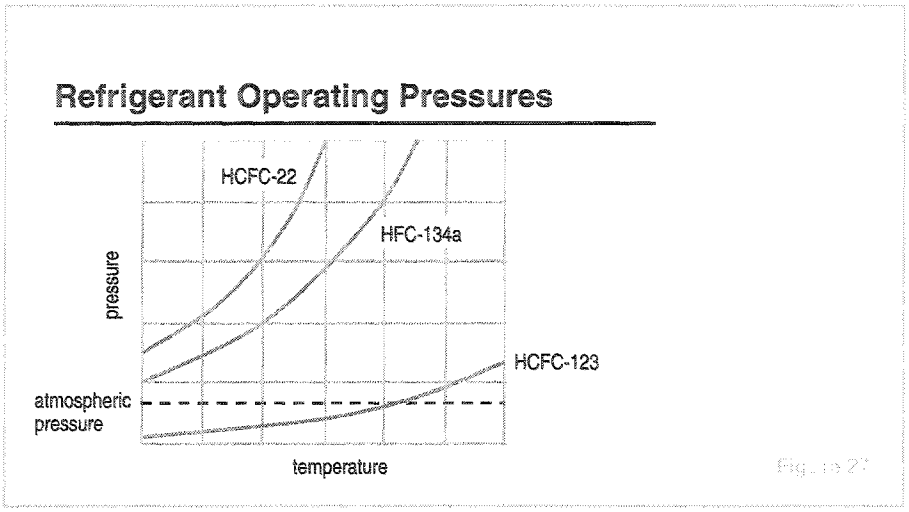
The change in enthalpy from **C** to **A** that occurs during the refrigeration cycle is called the **refrigeration effect**. This is the amount of heat that each pound [kg] of liquid refrigerant will absorb when it evaporates.



The benefit of the economizer can be demonstrated by comparing the refrigeration cycles with and without an economizer.

Without an economizer, refrigerant from the condenser ⑥ expands directly to evaporator conditions ⑩, producing a smaller refrigeration effect (**B** to **A**). Some chiller designs may subcool the liquid refrigerant in the condenser (⑥ moves to the left) to increase this refrigeration effect.

Also, in a chiller without an economizer, all of the refrigerant vapor must go through both stages of compression to return to condensing conditions. In a chiller with an economizer, refrigerant vapor that flashes in the economizer bypasses the first stage of compression, resulting in an overall energy savings of 3 to 4 percent.

period two
Refrigeration Cycle

notes

Refrigerants

When selecting which refrigerant to use in a centrifugal water-chiller, the manufacturer considers efficiency, operating pressures, compatibility with materials, heat transfer properties, stability, toxicity, flammability, cost, availability, and environmental impact.

Refrigerants commonly used in centrifugal chillers can be classified as low, medium, or high pressure based on the normal operating pressures in the refrigeration cycle.

Chillers using a high-pressure refrigerant like HCFC-22, or a medium-pressure refrigerant like HFC-134a, operate at pressures that are well above atmospheric pressure. As we are about to see, some sections of chillers that use a low-pressure refrigerant such as HCFC-123 operate at below-atmospheric pressure.

period two
Refrigeration Cycle

notes

Low-Pressure Chillers

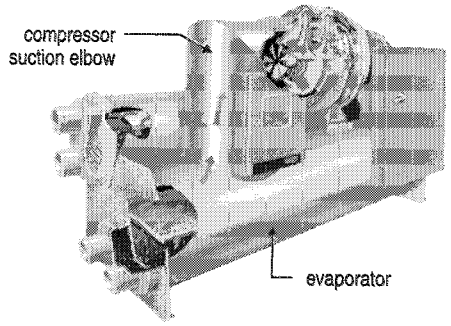


Figure 28

In chillers designed to use a low-pressure refrigerant, the evaporator and the piping leading to the suction side of the compressor operate at pressures that are lower than atmospheric pressure. Therefore, if small leaks exist in either of these sections, air will leak into the chiller instead of refrigerant leaking out.

Air inside a chiller reduces the surface area available for heat transfer. It also increases the refrigerant pressure in the condenser, which increases the pressure difference required across the compressor and causes more power to be consumed. In extreme cases, air can cause the compressor to surge, limiting the chiller's ability to produce cold water. Finally, infiltration of moist air can cause corrosion and other harmful chemical reactions inside the chiller.

Purge System

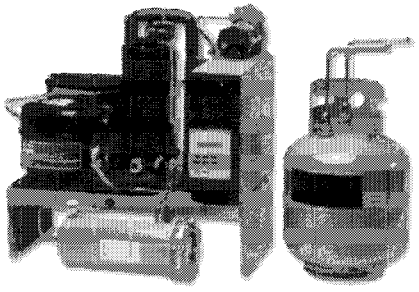

Figure 29

Purge System

Low-pressure chillers typically include a **purge system** to remove air and moisture that may leak in, while minimizing the emission of refrigerant.

Refrigeration Cycle

notes

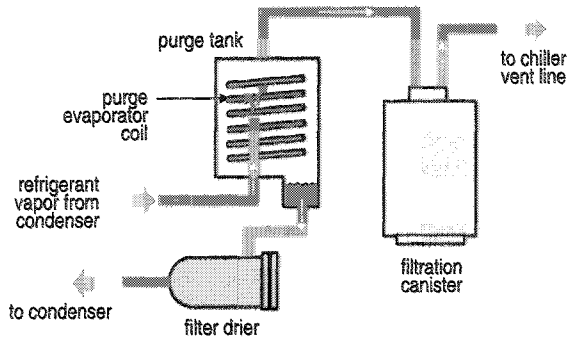

Figure 30

The purge consists of a small refrigeration system, a pump-out system, controls, and a filter drier. The purge's refrigeration system includes a small compressor, a finned-tube air-cooled condensing coil, an expansion valve, and an evaporator coil inside of the purge tank.

The tank with the evaporator coil separates condensable refrigerant from noncondensable air. Because the purge evaporator operates at a lower temperature and pressure than the chiller condenser, a mixture of refrigerant vapor and air is drawn from the chiller condenser, just above the level of the liquid refrigerant. (This is where air typically concentrates in a low-pressure chiller.) The mixture enters the purge tank, and the refrigerant condenses on the cold evaporator tubes and returns to the chiller condenser as liquid. The air does not condense but instead accumulates in the top of the tank. Eventually, enough air accumulates to cover a large portion of the coil. The air insulates the coil, reducing the amount of heat transferred and the temperature of the refrigerant leaving the purge evaporator coil. This temperature is called the purge suction temperature. The drop in purge suction temperature signals the need for a pump-out sequence.

When the purge suction temperature drops below the set point, a controller turns on the pump-out compressor and opens the isolation valves. Since the air contains a very small amount of refrigerant, it is pumped from the purge tank into a filtration canister. This canister adsorbs nearly all of the remaining refrigerant, and the air is then piped to the chiller vent line. When the purge suction temperature rises again, the controls close the valves and turn off the pump-out compressor.

A filter drier is located in the refrigerant drain line, between the purge tank and the chiller condenser. The filter drier removes moisture, acid, and dirt from the liquid refrigerant before it returns to the condenser.

The purge controls can also be used to track and record how often pump-out occurs. Leaks can be detected early by comparing pump-out activity over the last 24 hours to the 30-day average.

notes

Centrifugal Water Chillers

period three
Compressor Capacity Control

Figure 31

The capacity of most centrifugal compressors is controlled by vanes at the inlet of the compressor impeller.

While a survey of other centrifugal compressor designs shows that there are various methods of capacity control, many of them function in a manner similar to the inlet vanes presented in this period.

Inlet Vanes

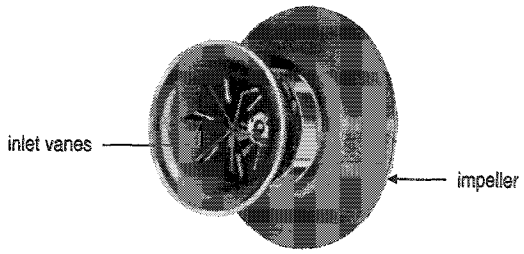

Figure 32

Inlet vanes, installed ahead of the impeller, are a common method of modulating the capacity of the compressor over a wide range of load conditions (refrigerant flow rates). These vanes "preswirl" the refrigerant before it enters the impeller. By changing the refrigerant's angle of entry, inlet vanes lessen the ability of the impeller to take in the refrigerant. As a result, each inlet vane position creates a new compressor performance characteristic without changing the rotational speed of the impeller.

period three
Compressor Capacity Control

notes

Multistage Compressor

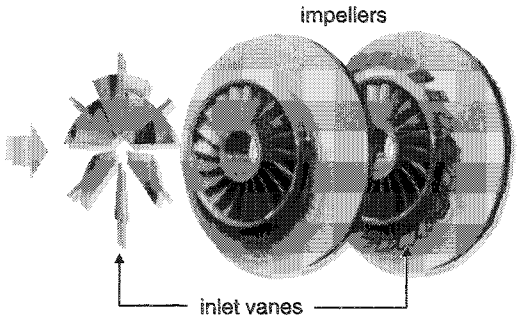

Figure 33

In a **multistage centrifugal compressor**, the operating characteristics of each impeller are modulated by the impeller's own set of inlet vanes.

This example shows 2 impellers in series. These impellers share the task of compressing the refrigerant. Centrifugal water chillers are generally available with 1, 2, or 3 impellers.

Impeller

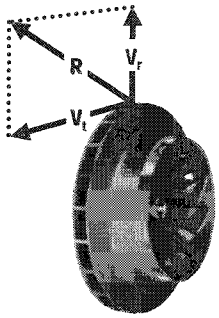

Figure 34

The forces that act on the refrigerant vapor within the centrifugal compressor impeller can be broken down into 2 components. One component acts to move the refrigerant away from the impeller in a radial direction. This component is called **radial velocity (V_r)**.

The second component acts to move the refrigerant in the direction of impeller rotation. This component is called **tangential velocity (V_t)**.

Together, these components generate the **resultant velocity vector (R)**, the length of which is proportional to the amount of kinetic energy in the

Compressor Capacity Control

notes

refrigerant. Recall that kinetic energy is converted to static energy, or static pressure.

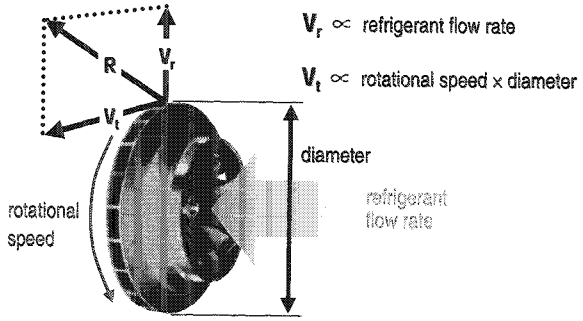

Figure 35

The radial velocity **(V_r)** for a given compressor is directly proportional ($\propto$) to the flow rate of refrigerant vapor through the compressor.

The tangential velocity **(V_t)** is proportional to the product of impeller rotational speed and impeller diameter.

Therefore, the static-pressure-producing capacity of a compressor can be adjusted by changing the flow rate of refrigerant, the impeller speed, or the diameter of the impeller.

Compressor Capacity Control

notes

Compressor Unloading

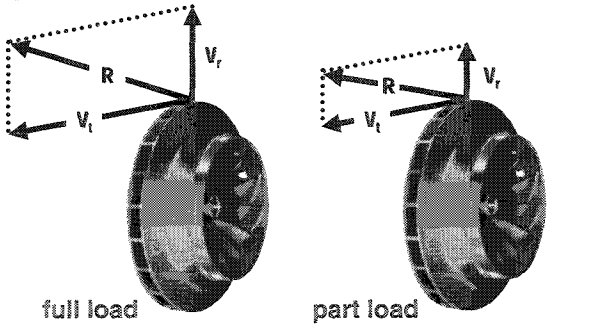

Figure 36

Consider a given-diameter compressor impeller that rotates at a constant speed. As the load on the chiller decreases, the inlet vanes partially close and the flow rate of refrigerant through the compressor drops. Radial velocity **(V_r)**, which is proportional to refrigerant flow, decreases as well.

Even though the speed of rotation and diameter of the impeller are constant, the tangential velocity **(V_t)** (which is proportional to the product of impeller rotational speed and impeller diameter) drops because of the pre-swirling of the refrigerant caused by the inlet vanes.

The result is a shorter resultant velocity vector **(R)**, which means that less static pressure is generated.

period three
Compressor Capacity Control

notes

Surge

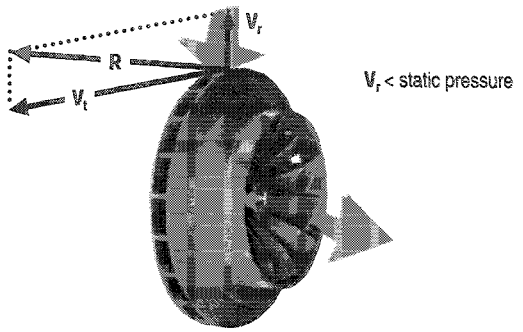

Figure 37

As the load and the corresponding refrigerant flow rate continue to fall, the radial velocity (force) drops, too. At some point, the radial force becomes smaller than the generated static pressure, letting the pressurized refrigerant vapor flow backward from the diffuser passages into the impeller. This instantaneously reduces the pressure within the passages below the radial force and the compressor is able to re-establish the proper direction of refrigerant flow.

This condition is known as **surge**. So long as this unstable load condition exists, the refrigerant alternately flows backward and forward through the compressor impeller, generating noise and vibration.

Compressor Map

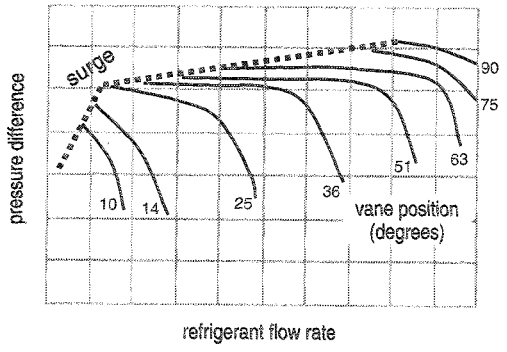

Figure 38

These curves represent the performance of a typical 2-stage compressor over a range of inlet vane positions. The pressure difference between the compressor inlet (evaporator) and outlet (condenser) is on the vertical axis and the refrigerant flow rate is on the horizontal axis. The dashed line represents the

notes

conditions that cause the compressor to surge. Any operating point that falls to the right of this line is satisfactory for stable operation.

Operating Point

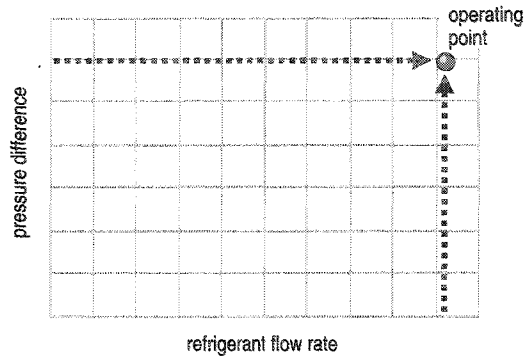

Figure 39

To balance the load on the chiller, the compressor must pump a certain quantity of refrigerant vapor at evaporator pressure and elevate it to the pressure dictated by the condensing conditions.

The intersection of the refrigerant flow rate and the pressure difference between the inlet and outlet of the compressor identifies the compressor **operating point.**

compressor map for a
2-Stage Compressor

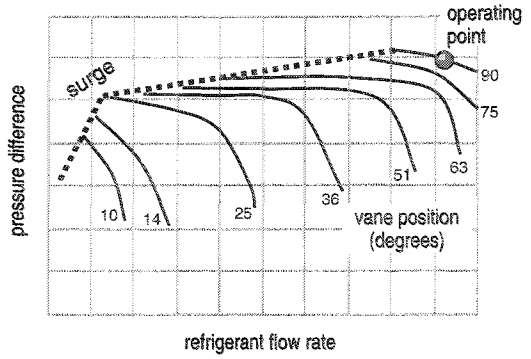

Figure 40

Superimposing the operating point on the previous compressor performance curves establishes the point at which the compressor will balance the load. In this example, the compressor will balance the load with its inlet vanes open 90°.

Compressor Capacity Control

notes

compressor map for a
2-Stage Compressor

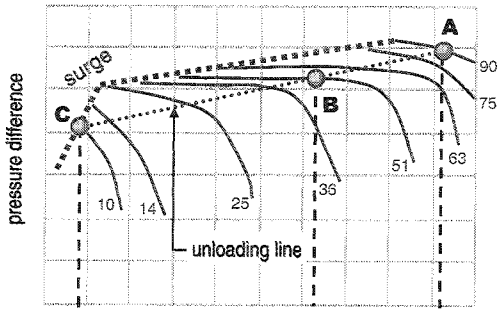

Figure 41

The starting point **(A)** is the full-load operating point. As the load on the chiller decreases, the inlet vanes partially close, reducing the flow rate of refrigerant vapor through the compressor and balancing the chiller capacity with the new load **(B)**.

Less refrigerant, and therefore less heat, is transferred to the condenser. Since the heat rejection capacity of the condenser is now greater than required, the refrigerant condenses at a lower temperature and pressure. This reduces the pressure difference between the evaporator and the condenser.

Continuing along the unloading line, the compressor remains within its stable operating range until it reaches the surge region at **C**.

Compressor Capacity Control

notes

Adjustable-Frequency Drives

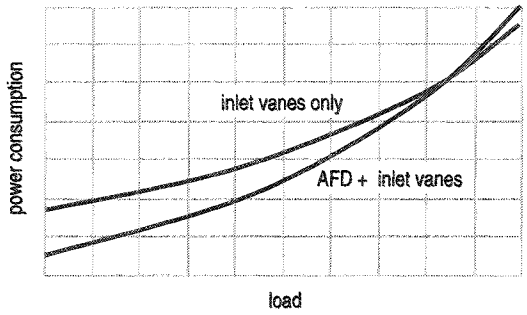

Figure 42

An **adjustable-frequency drive (AFD)**, or variable-speed drive, is another device used to vary the capacity of a centrifugal compressor. AFDs are widely used with fans and pumps, and with the advancement of microprocessor-based controls for chillers, they are now being applied to centrifugal water chillers.

Using an AFD with a centrifugal chiller can degrade the chiller's full-load efficiency. It will, however, offer energy savings by reducing motor speed at low-load conditions when cooler condenser water is available. An AFD also controls the inrush current at start-up, reducing stress on the compressor motor.

Certain system characteristics favor the application of an adjustable frequency drive, including:

- A substantial number of part-load operating hours
- The availability of cooler condenser water
- Chilled-water reset control
- High electrical charges

Performing a comprehensive energy analysis is the best method of determining if an adjustable-frequency drive is desirable. Depending on the application, it may make sense to take the additional money needed to purchase an AFD and use it to purchase a more efficient chiller instead.

period four
Maintenance Considerations

notes

Centrifugal Water Chillers

period four
Maintenance Considerations

Figure 43

This period discusses general maintenance requirements of centrifugal water chillers. Although some of the information applies specifically to the design presented in this clinic, requirements for other centrifugal chiller designs are also included.

Maintenance Considerations

- **Operating log**
- **Mechanical components**
- **Heat-transfer surfaces**
- **Fluid analysis**

Figure 44

Once a centrifugal chiller is installed and put into operation, it usually continues to function without a full-time attendant. In many cases, the machine starts and stops on a schedule controlled by a building automation system or a simple time clock. The only daily maintenance requirement is to complete and review the operating log.

Water chillers are designed for maximum reliability with a minimum amount of maintenance. Like all large mechanical systems, however, certain routine maintenance procedures are either required or recommended.

notes

operating log
ASHRAE Guideline 3

- Chilled water inlet and outlet temperatures and pressures
- Chilled water flow
- Evaporator refrigerant temperature and pressures
- Evaporator approach temperature
- Condenser water inlet and outlet temperatures and pressures
- Condenser water flow
- Condenser refrigerant temperature and pressures
- Condenser approach temperature
- Oil pressures, temperature, and levels
- Addition of refrigerant
- Addition of oil
- Vibration levels

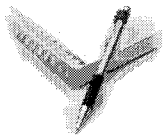

Figure 45

Guideline 3, "*Reducing Emission of Halogenated Refrigerants in Refrigeration and Air Conditioning Equipment and Systems,*" is one of several advisory documents published by the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE). This guideline includes a list of recommended data points to be logged daily for each chiller. Much of this data may be available from the display on the chiller control panel.

Special attention should be given to:

- Reviewing the operating log and trends
- Observing the oil pressure drop to determine if the oil filter needs to be replaced
- Monitoring evaporator and condenser approach temperatures
- Observing and recording the oil level
- Monitoring purge pump-out operation

period four
Maintenance Considerations

notes

maintenance considerations
Mechanical Components

- **Required maintenance**
  - Compressor and motor: no maintenance required
  - Controls: no maintenance or calibration required
- **Recommended maintenance**
  - Visually inspect overall unit
  - Inspect safety controls and electrical components
  - Tighten electrical connections
  - Check for leaks

Figure 46

The compressor/motor assembly in direct-drive, hermetic compressor designs requires little periodic maintenance. The hermetic motor eliminates the need for external shaft seals associated with open motors. (These seals are a prime source of oil and refrigerant leaks and should be inspected on a regular basis.) Hermetic motor designs also eliminate the annual coupling and seal inspections, alignment, and shaft seal replacement associated with open motors.

With the advent of microprocessor-based controls, the control panel and auxiliary controllers require no recalibration or maintenance. Remotely-mounted electronic sensors send information to the unit controller, which can be connected to a building automation system to communicate information and allow system-level optimization. These systems can notify the operator with an alarm or diagnostic message when a problem occurs.

As for any mechanical equipment, a daily visual inspection of the chiller is recommended to look for oil leaks, condensation, loosened electrical or control wiring, or signs of corrosion. Special attention should be given to safety controls and electrical components.

A qualified service technician should check the chiller annually for leaks. The United States Environmental Protection Agency (EPA) mandates refrigerant recovery whenever a refrigeration circuit is opened during the normal service of any air conditioning system.

period four
Maintenance Considerations

notes

maintenance considerations
Mechanical Components

▲ **Other design-specific requirements**

- Change oil when oil analysis dictates
- Replace oil filter periodically
- Replace filter drier periodically
- Clean oil strainers annually
- Check shaft alignment annually
- Check coupling annually
- Replace shaft seal every 2 to 4 years
- Compressor teardown inspection every 5 to 10 years

Figure 47

Some centrifugal compressor designs do require periodic maintenance of mechanical system components. This includes oil and refrigerant filter changes, oil strainer changes, and a compressor inspection.

Open-motor compressor designs require shaft alignment, coupling inspection, bearing lubrication, and cleaning of the motor windings on a quarterly or annual basis.

In all cases, strictly follow the maintenance requirements and recommendations published by the manufacturer.

maintenance considerations
Heat Transfer Surfaces

▲ **Recommended maintenance**

- Use a qualified water treatment specialist
- Clean condenser tubes as needed
- Clean water-side strainers
- Test tubes every 3 years

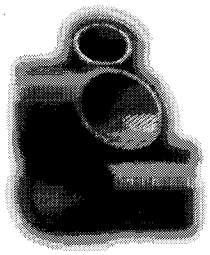

Figure 48

To ensure optimum heat transfer performance, the heat transfer surfaces must be kept free of scale and sludge. Even a thin deposit of scale can substantially reduce heat transfer capacity. Engage the services of a qualified water treatment specialist to determine the level of water treatment required to remove contaminants from the cooling tower water.

period four
Maintenance Considerations

notes

Scale deposits are best removed by chemical means. During this process, the water-cooled condenser is commonly isolated from the rest of the cooling-tower-water circuit by valves, while a pump circulates cleaning solution through the condenser tubes.

Sludge is removed mechanically. This typically involves removing the water boxes from the condenser and loosening the deposits with a stiff-bristled brush. The loosened material is then flushed from the tubes with clear water. As part of this procedure, the strainers in both the chilled-water and cooling-tower-water circuits should be cleaned every year.

Every 3 years (more frequently in process or critical applications), a qualified service organization should perform nondestructive inspections of the evaporator and condenser tubes. The eddy-current tube test is a common method.

Rarely, problems may arise that cause refrigerant or water leaks. These must be repaired immediately.

Fluid Analysis

- **Oil analysis**
  - Conduct annual analysis to verify system integrity
  - Measure oil pressure drop to determine if filter needs changing
  - Measure charge
- **Refrigerant charge**
  - Conduct analysis of refrigerant
  - Inspect purge system

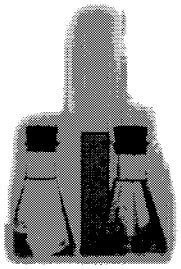

Figure 49

Oil analysis is an important annual maintenance task required for centrifugal water chillers. It may be conducted more frequently for chillers that run continuously or more often than normal. This test, performed by a qualified laboratory, verifies the integrity of the refrigeration system by testing the concentrations of moisture, acidity, and metal. This analysis can determine where problems exist or could potentially develop. By taking oil samples on a regular basis, normal operating trends for the compressor and bearing metals can be analyzed. Instead of adopting a "change the oil once a year whether it needs it or not" approach, regular oil analyses can be used to determine proper oil change intervals and predict major problems before they occur.

Refrigerant analysis measures contamination levels and determines suitability for continued use. It can also determine if recycled refrigerant is suitable for reuse. Refrigerant analysis helps extend the life of the existing charge and ensures that the chiller is operating at peak efficiency.

period four
Maintenance Considerations

notes

Regularly logging oil and refrigerant charges, and examining the trends of this data, can help identify potential problems before they occur.

Oil Analysis

▲ **Why perform regular oil analysis?**

- Helps reduce maintenance costs
- Detects problems without compressor disassembly
- Extends service life of oil charge
- Reduces environmental problems related to oil disposal
- Helps maintain compressor efficiency and reliability
- Helps lower refrigerant emissions

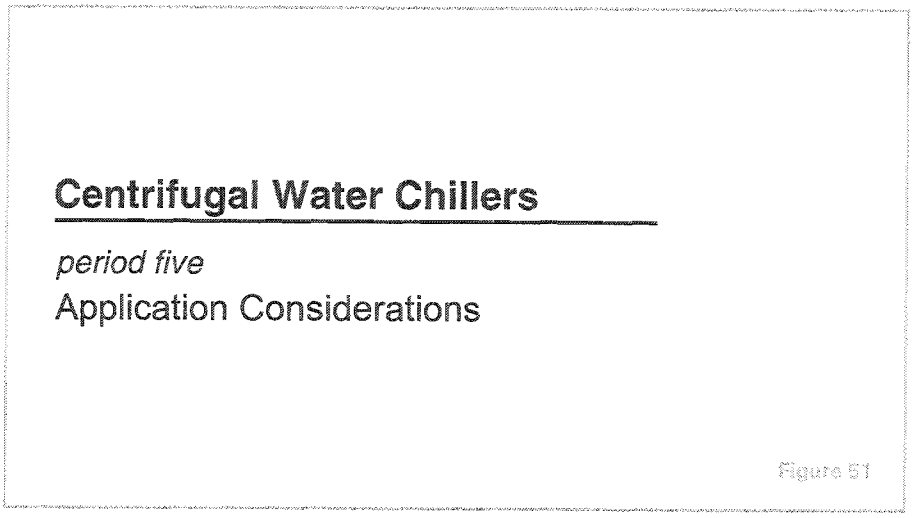

Figure 50

An oil analysis is a key preventive maintenance measure and should be conducted at least annually. It will help the compressor last longer while maintaining chiller efficiency and reducing refrigerant emissions.

A certified chemical laboratory can be contracted to perform the analysis for all types of compressors. Often the chiller manufacturer can provide this service.

notes

Several considerations must be addressed when applying centrifugal water chillers, including:

- Condensing temperature control
- Constant or variable evaporator-water flow
- Short evaporator-water loops
- Heat recovery
- Free cooling
- Equipment certification standards

While not all-inclusive, this list of considerations does represent some of the key issues.

notes

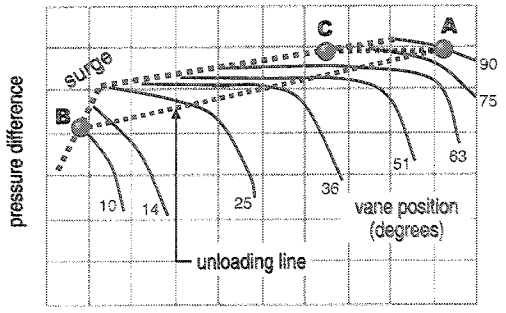

Figure 52

Condensing Temperature Control

To achieve stable compressor unloading over a wide range of conditions, a reduction in condensing pressure (condenser relief) must accompany a reduction in load.

The starting point **(A)** is the full-load operating point. As the chiller load decreases, the flow rate of refrigerant vapor through the compressor also decreases. In turn, the pressure difference between the evaporator and the condenser moves the operating point downward toward **B**.

If the condenser pressure had been controlled to a constant value instead, the compressor would have unloaded along a nearly constant pressure line toward **C**. This would result in a greatly reduced range of operation.

Condenser relief is, however, only beneficial to a certain point. ALL chillers require a minimum pressure difference between the evaporator and condenser to ensure proper management of oil and refrigerant. This minimum pressure difference depends on the chiller's design and controls. The most common method of maintaining this pressure difference at various load conditions is to control the condensing temperature by varying the temperature or flow rate of water through the condenser. By controlling condensing temperature, most centrifugal water chillers can start and operate over a wide range of conditions.

Controlling condensing temperature: (1) maintains chiller efficiency, (2) maintains the required pressure differential between the evaporator and condenser for controlled flow through the refrigerant metering system, and (3) prevents the pressure imbalance that could cause oil loss problems.

notes

condensing temperature control

Cooling Tower Bypass

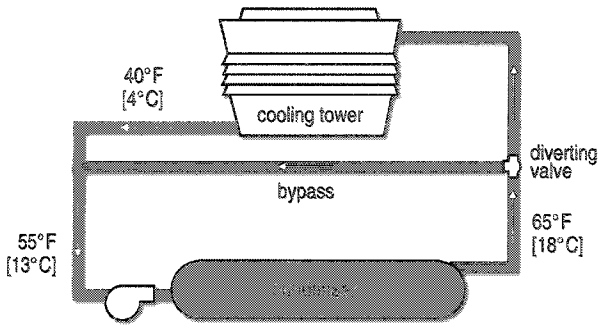

Figure 53

Controlling the refrigerant pressure difference between the evaporator and condenser of a water-cooled chiller is accomplished by varying the temperature or flow rate of the water flowing through the condenser. The following are 5 common methods used to control condensing temperature:

1) Cycling or varying the speed of the cooling tower fans to control the temperature of the water leaving the cooling tower

2) Using a cooling tower bypass pipe to mix warmer leaving-condenser water with the colder tower water and control the temperature entering the condenser as illustrated here

3) Modulating a throttling valve to restrict the flow of water through the condenser

4) Using a chiller bypass pipe to vary the flow rate of water through the condenser

5) Using a variable-speed drive on the condenser water pump to vary the water flow rate through the condenser

Each of these strategies has its advantages and disadvantages. Selecting the appropriate condensing temperature control scheme will depend on the specific requirements of the application.

The water flow rate through the chiller condenser must stay between the minimum and maximum condenser bundle flow rates specified by the chiller manufacturer.

notes

evaporator water flow
Constant or Variable Flow

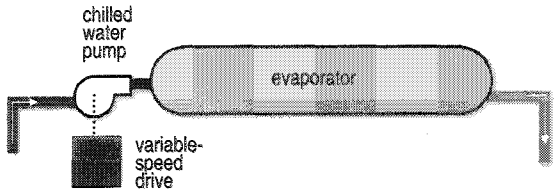

Figure 54

Constant or Variable Evaporator Water Flow

Previous chiller designs required that a constant flow rate of water be maintained through the evaporator. This requirement has changed due to advances in chiller controls. Increased sensing and control capabilities now allow chiller manufacturers to design controls that monitor, and respond faster to, fluctuating conditions.

While the chiller may be able to handle variable water flow through the evaporator, the specific application of the chilled water system may not warrant variable flow. As always, each application should be analyzed to determine if variable evaporator water flow is warranted.

variable evaporator water flow
Limitations

- **Maintain minimum and maximum water flow rates through the chiller evaporator**
- **Rate at which the evaporator water flow changes must be kept below the corresponding limit to:**
  - Maintain the chilled water set point control
  - Keep the chiller on line
  - Protect the chiller from damage

Figure 55

The controls on many current chiller designs can properly control the chiller in response to varying evaporator flow rates, with the following limitations:

notes

1) The water flow rate through the chiller evaporator must stay between the minimum and maximum flow rates for the evaporator bundle, as specified by the chiller manufacturer. These limits depend on the specific design variables of the actual evaporator bundle such as the number of tubes, number of passes, and geometry. Implementation of a method for sensing evaporator water flow through each chiller is the only way to make sure that the water flow rate stays within these limits.

2) The rate of change for the evaporator water flow rate must not exceed a specified level, depending on the level of protection desired. For example, the maximum rate of change to maintain the chilled water set point is more stringent than the maximum rate of change to keep the chiller on line. There are 3 common levels of protection desired: maintaining chilled water set point control, keeping the chiller on line, and protecting the chiller from damage.

The limits for these different levels of protection should be obtained from the chiller manufacturer.

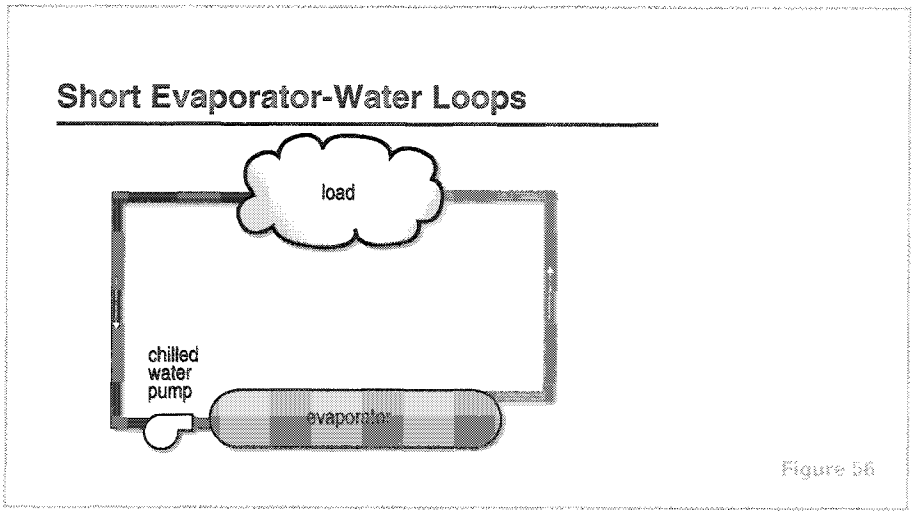

Figure 56

Short Evaporator-Water Loops

Proper chilled water temperature control requires that the temperature of the chilled water returning to the evaporator not change any faster than the chiller controls can respond. The volume of water in the evaporator loop acts as a buffer, ensuring that the return water temperature changes slowly and, therefore, providing stable temperature control. If there is not a sufficient volume of water in the loop to provide an adequate buffer, temperature control can be lost, resulting in erratic system operation.

The chiller manufacturer should be consulted for volume requirements of the evaporator-water loop.

notes

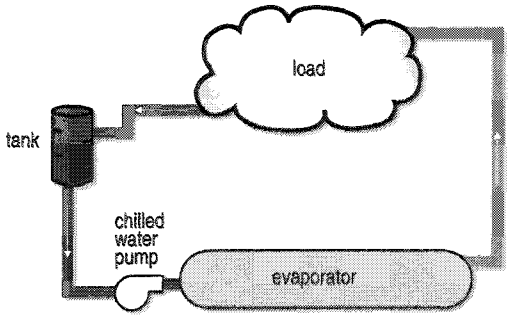

Figure 57

Short water loops may be unavoidable in close-coupled or very small applications, particularly in systems where the load consists of only a few air handlers or processes.

To prevent the effect of a short water loop, a storage tank or large header pipe can be added to the system to increase the volume of water in the loop and ensure a slowly changing return water temperature.

A second solution is to reduce the water flow rate in the chilled water loop while using the same size pipes. This also increases the loop time—the time it takes a particle of water to travel through the chilled water loop—and ensures that the return water temperature changes slowly. This solution has the added benefit of reduced pumping energy requirements.

period five
Application Considerations

notes

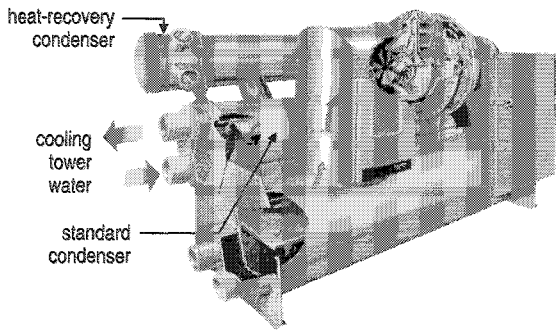

Figure 58

Heat Recovery

Salvaging usable heat from the refrigeration cycle—heat that would normally be rejected to the atmosphere—can significantly reduce the operating costs of many buildings.

Heat recovery is most commonly accomplished using 2 condensers and the fact that hot refrigerant vapor migrates to the area with the lowest temperature. Raising the refrigerant condensing temperature in the standard condenser prompts the refrigerant to flow instead to the second condenser, where it rejects its heat to the water flowing through the tubes. The condensing temperature in the standard condenser is controlled by varying the temperature or the flow rate of the cooling tower water.

Typical uses for the hot water from the second condenser include: heat for spaces around the perimeter of the building, reheat coils in air conditioning systems, and bathroom, laundry, or kitchen requirements. Any building with a simultaneous heating and cooling load is a potential candidate for heat recovery.

notes

Heat-Recovery Chiller Options

heat-recovery (dual) condenser	auxiliary condenser	heat pump
◆ Second, full-size condenser	◆ Second, smaller size condenser	◆ No extra condenser
◆ Large heating loads	◆ Preheating loads	◆ Large base heating loads or continuous operation
◆ High hot water temperatures	◆ Moderate hot water temperatures	◆ High hot water temperatures
◆ Controlled	◆ Uncontrolled	◆ Controlled
◆ Degrades chiller efficiency	◆ Improves chiller efficiency	◆ Chiller efficiency preserved

Figure 59

Three types of heat-recovery chillers are commonly available:

The **dual-condenser**, or **double-bundle**, heat-recovery chiller contains a second, full-size condenser that serves a separate hot water loop. It is capable of more heat rejection and higher leaving-water temperatures. This type of chiller allows the amount of heat being rejected to be controlled, although chiller efficiency is sacrificed for higher hot water temperatures.

Similarly, an **auxiliary-condenser** heat-recovery chiller makes use of a second, smaller condenser bundle. It is not capable of rejecting as much heat as the dual-condenser chiller. Since its leaving-water temperatures are also lower, it is typically used to preheat returning hot water before it goes to the primary heating equipment or to preheat incoming water prior to entering a traditional water heater. It requires no additional controls and actually improves chiller efficiency.

A **heat-pump** chiller is a standard chiller (no extra shells are required) applied where the useful heat transfer occurs in the condenser, not the evaporator. The evaporator is connected to the chilled water loop, typically upstream of other chillers, but it only removes enough heat from the chilled water loop to handle the heating load served by the condenser water loop. This application is useful in a multiple-chiller installation, where there is a base or year-round comfort or process load, or where the quantity of heat required is significantly less than the cooling load. Chiller efficiency is not compromised.

notes

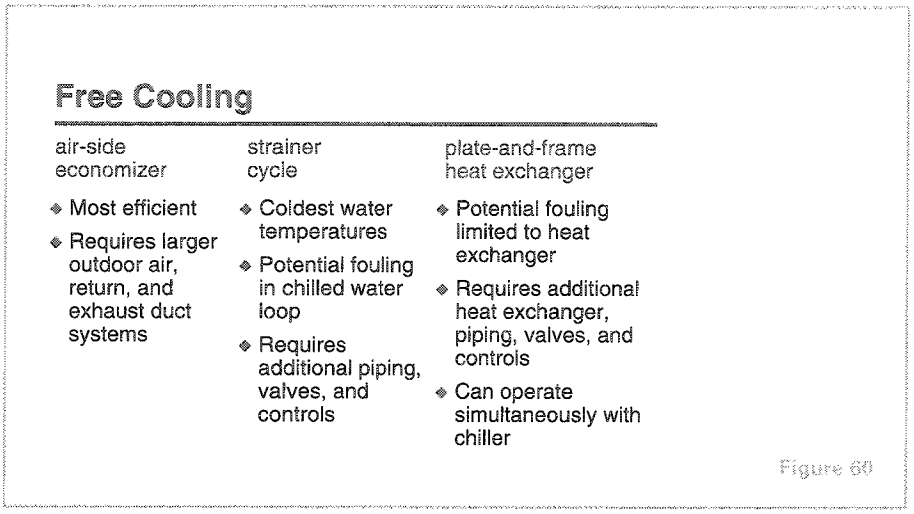

Figure 60

Free Cooling

Many buildings require some form of year-round cooling to handle interior spaces or other loads. When the outdoor air temperature falls below the indoor dew point temperature, it is possible to use an **air-side economizer** to satisfy these cooling requirements. This method of "free cooling" involves using outdoor air for cooling instead of recirculating warmer indoor air. It is the most efficient method of free cooling because it allows all of the chilled water and/or refrigeration system components to be turned off. This method, however, requires larger duct systems to deliver the outdoor air to the air handler and to return and exhaust this larger amount of air.

A second method of applying free cooling is to pump water from the cooling tower loop directly into the chilled water loop when its temperature is low enough to satisfy the cooling load. This is commonly called the **strainer cycle** because a strainer or filter is needed to prevent debris and contaminants carried by the cooling tower water from entering the chilled water loop. Although this method is very efficient, the contamination common in open cooling tower systems causes concern about "fouling" (deposits of scale or sludge) inside the chilled water coils. Ongoing treatment of the chilled water loop is required.

Another method of providing free cooling is similar to the strainer cycle but involves the use of a **plate-and-frame heat exchanger**, or **water-side economizer**, to isolate the chilled water loop from the cooling tower loop. This is a popular method of free cooling because it is efficient and eliminates potential contamination of the chilled water loop. In addition, the heat exchanger can be operated simultaneously with the chiller.

notes

free cooling
Refrigerant Migration

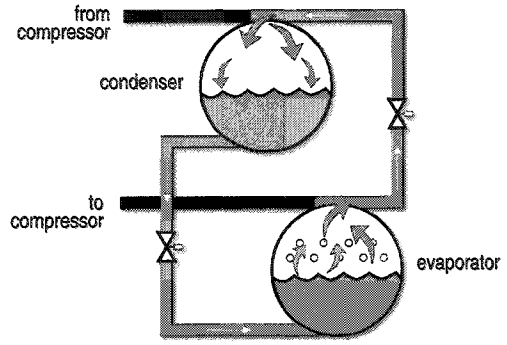

Figure 61

This leads to the discussion of a free cooling principle called **refrigerant migration**. It involves adapting a water chiller so that it functions as a simple heat exchanger.

When the available condenser water is cooler than the desired chilled water temperature, the compressor is turned off and bypass valves in the chiller refrigerant circuit are opened to let the refrigerant circulate without help from the compressor. Because refrigerant migrates to the area with the lowest temperature, refrigerant boils in the evaporator and the vapor flows to the cooler condenser bundle. After the refrigerant condenses, it flows (by gravity) back to the evaporator.

The advantages of refrigerant migration are these: no extra components are required in the system, control is performed by the chiller itself, and there are no additional fouling concerns. It is possible for the free cooling chiller to satisfy many cooling load requirements without operating the compressor, especially when the system can accommodate warmer chilled water temperatures at part-load conditions.

notes

equipment certification standards
ARI Standard 550/590

- **Purpose**
  - Establish definitions, testing, and rating requirements
- **Scope**
  - Factory designed and prefabricated water chillers
  - Vapor-compression refrigeration
  - Air-cooled and water-cooled condensing

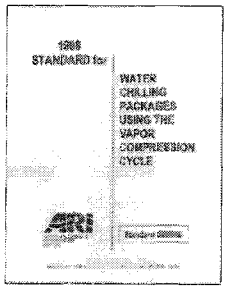

Figure 62

Equipment Certification Standards

The Air Conditioning & Refrigeration Institute (ARI) establishes rating standards for packaged HVAC equipment. ARI also certifies and labels equipment through programs that involve random testing of a manufacturer's equipment to verify published performance.

The overall objective of ARI Standard 550/590–1998 is to promote consistent rating and testing methods for all types and sizes of water chillers, with an accurate representation of actual performance. It covers factory-designed, prefabricated water chillers, both air-cooled and water-cooled, using vapor-compression refrigeration. This generally includes chillers with centrifugal, helical-rotary (screw), reciprocating, or scroll compressors.

equipment certification standards
ARI Standard 550/590

- **Standard rating conditions**
  - Common system conditions for published ratings
  - Fouling factor
- **Integrated Part Load Value (IPLV)**
  - Part-load efficiency rating
  - Based on an "average" single-chiller installation
  - Standard operating conditions

Figure 63

The standard rating conditions used for ARI certification represent typical design temperatures and flow rates for which water-cooled and air-cooled systems are designed. They are not suggestions for good design practice for a

notes

given system—they simply define a common rating point to aid comparisons. Trends toward improved humidity control and energy efficiency have changed some of the actual conditions selected for specific applications.

Impurities in the chilled- and condenser-water systems eventually deposit on evaporator and condenser tube surfaces, impeding heat transfer. Catalogued performance data includes a fouling factor that accounts for this effect to more closely predict actual chiller performance.

ARI's part-load efficiency rating system establishes a single, blended estimate of stand-alone chiller performance. The Integrated Part Load Value (IPLV) predicts chiller efficiency at the ARI standard rating conditions using weighted averages representing a broad range of geographic locations, building types, and operating-hour scenarios, both with and without an air-side economizer. While the weighted averages place greater emphasis on the part-load operation of an average, single-chiller installation, they will not—by definition—represent any particular installation.

Additionally, ARI notes that more than 80 percent of all chillers are installed in multiple-chiller plants. Chillers in these plants exhibit different unloading characteristics than the IPLV weighted formula indicates. Appendix D of the Standard explains this further:

> *...The [IPLV] equation was derived to provide a representation of the average part-load efficiency for a single chiller only. However, it is best to use a comprehensive analysis that reflects actual weather data, building load characteristics, operational hours, economizer capabilities, and energy drawn by auxiliaries such as pumps and cooling towers, when calculating the chiller and system efficiency. This becomes increasingly important with multiple chiller systems because individual chillers operating within multiple chiller systems are more heavily loaded than single chillers within single chiller systems.*

Remember that the ARI rating is a standardized representation. Many chillers do not run at standard rating conditions and few are applied in single-chiller installations. Performing a comprehensive energy analysis is the best method of comparing the system operating cost difference between 2 chillers.

Quiz

Questions for Period 1

1) A centrifugal compressor converts _____ energy to _____ energy.

2) Does the refrigerant velocity increase in the impeller, diffuser passages, or volute of the compressor?

3) What is the benefit of using an economizer cycle with a multistage centrifugal compressor?

4) What is the difference between a hermetic and an open motor?

Questions for Period 2

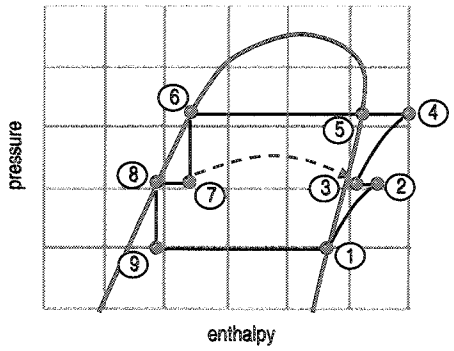

Figure 71

5) Using the pressure-enthalpy diagram in Figure 71, identify the following process of the 2-stage centrifugal chiller's refrigeration cycle:

a) ① to ②

b) ⑦ to ③

c) ⑨ to ①

6) Air, moisture, and other noncondensable gases are removed from a _____-pressure chiller by what component?

Questions for Period 3

7) What velocity component is directly proportional to the refrigerant flow rate through the compressor?

Quiz

8) What velocity component is directly proportional to the impeller's rotational speed times its diameter?

9) What are the 2 most common devices used to vary the capacity of a centrifugal compressor?

Questions for Period 4

10) Explain why proper water treatment is important.

Questions for Period 5

11) The refrigerant migration method of free cooling works because refrigerant migrates from the area of _____ temperature to the area of _____ temperature.

12) What is the purpose of a fouling factor?

Answers

1) kinetic energy to static energy

2) impeller

3) By flashing a portion of the refrigerant prior to entering the evaporator, the economizer reduces the compressor power required since the refrigerant vapor generated in the economizer only needs to be compressed by the higher-stage impeller.

4) A hermetic motor is totally enclosed within the chiller's refrigeration system and the heat it generates is absorbed by liquid refrigerant. An open motor is mounted externally—outside of the chiller's refrigeration system—and uses a coupling to connect the motor and compressor shafts. The heat generated by the open motor is rejected to the air drawn in from the equipment room.

5) **a)** first stage of compression or first-stage impeller

b) economizer

c) evaporator

6) low-pressure chiller; purge system

7) radial velocity (V_r)

8) tangential velocity (V_t)

9) inlet vanes and adjustable-frequency (or variable-speed) drive

10) The heat transfer (tube) surfaces inside the chiller must be kept free of scale and sludge to ensure optimum performance. Even a thin deposit of scale can substantially reduce heat transfer capacity.

11) higher; lower

12) It is used to more closely predict actual chiller performance by accounting for the effect of impurities in the chilled- and condenser-water systems. These impurities will eventually deposit on evaporator and condenser tube surfaces, impeding (fouling) heat transfer.

Glossary

adjustable-frequency drive (AFD) A device used to vary the capacity of a centrifugal compressor by varying the speed of the motor that rotates the impeller(s).

air-side economizer A method of free cooling that involves using cooler outdoor air for cooling instead of recirculating warmer indoor air.

ARI Air Conditioning & Refrigeration Institute

ARI Standard 550/590 A publication titled *"Standard for Water Chilling Packages Using the Vapor-Compression Cycle,"* used to promote consistent rating and testing methods for all types and sizes of water chillers. It covers factory-designed, prefabricated water chillers, both air-cooled and water-cooled, using the vapor-compression refrigeration cycle.

ASHRAE American Society of Heating, Refrigerating and Air Conditioning Engineers

ASHRAE Guideline 3 A publication titled *"Reducing Emission of Halogenated Refrigerants in Refrigeration and Air Conditioning Equipment and Systems,"* that includes a recommended list of data points to be logged daily for each water chiller.

compressor The mechanical device used by the chiller to increase the pressure and temperature of the refrigerant vapor.

condenser The region of the chiller where refrigerant vapor is converted to liquid as it rejects heat to water or air.

control panel The microprocessor-based panel that monitors the chiller's operation, protects it from damage, provides the operator with data and diagnostic messages, and permits interfacing with a building automation system.

diffuser passages Passages inside the centrifugal compressor that start out small and become larger as the refrigerant travels through them. As the size of the diffuser passages increases, the velocity, and therefore the kinetic energy, of the refrigerant decreases. This kinetic energy is converted to static energy or static pressure.

direct-drive motor A type of motor that is connected directly to the compressor shaft, in which the impeller rotates at the same speed as the motor.

direct expansion (DX) shell-and-tube evaporator A type of evaporator where refrigerant flows through the tubes and water fills the surrounding shell.

dynamic compression A method of compression that involves converting energy from one form to another to increase the pressure and temperature of the refrigerant vapor.

Glossary

economizer The component of a multistage centrifugal chiller used to remove vapor from the refrigerant mixture after it passes through an expansion device. This reduces the compressor power required since the refrigerant vapor generated in the economizer only needs to be compressed by the higher-stage impeller(s).

enthalpy The property of a refrigerant indicating its heat content, both sensible and latent.

evaporator The region of the chiller where the system chilled water is continuously cooled by boiling the refrigerant as it picks up heat from the returning system water.

expansion device The component of the chiller used to reduce the pressure and temperature of the refrigerant.

flash The process of liquid refrigerant being vaporized by a sudden reduction of pressure.

flooded shell-and-tube evaporator A type of evaporator where water flows through the tubes and refrigerant fills the surrounding shell.

gear-drive motor A type of motor that transfers its energy to the impeller shaft using a set of gears, allowing the impeller to rotate at a higher speed than the motor.

hermetic motor A type of motor that is totally enclosed within the chiller's refrigeration system and rejects its heat to the liquid refrigerant.

impeller The rotating component of a centrifugal compressor that draws refrigerant vapor into its internal passages and accelerates the refrigerant as it rotates, increasing its velocity and kinetic energy.

inlet vanes A device used to vary the capacity of a centrifugal compressor by "pre-swirling" the refrigerant in the direction of rotation before it enters the impeller, lessening its ability to take in the refrigerant vapor.

loop time The amount of time it takes a particle of water to travel through the chilled water loop.

multistage centrifugal compressor A centrifugal compressor that uses more than 1 impeller to share the task of compressing the refrigerant.

open motor A type of motor that is mounted externally—outside of the chiller's refrigeration system—and uses a coupling to connect the motor and compressor shafts. It rejects its heat to air drawn in from the equipment room.

orifice plate A type of expansion device that uses a fixed plate with holes drilled in it to reduce the pressure and temperature of the refrigerant to the conditions of the evaporator.

Glossary

notes

pressure-enthalpy chart A graphical representation of the saturated properties of a refrigerant, plotting refrigerant pressure versus enthalpy.

purge A device used to remove air, moisture, and other noncondensable gases that may leak into a low-pressure chiller.

refrigerant migration A method of free cooling that allows the chiller to be used as a heat exchanger, without operation of the compressor. It is possible, when the condensing temperature of the refrigerant is low enough, for refrigerant to migrate from the evaporator to the condenser.

refrigeration effect The amount of heat that each pound [kg] of liquid refrigerant will absorb when it evaporates.

starter A device used to connect and disconnect the chiller motor and the electrical distribution system.

surge A condition of unstable compressor operation where the refrigerant alternately flows backward and forward through the compressor impeller, generating noise and vibration.

variable-speed drive See adjustable-frequency drive.

volute A large space around the perimeter of a centrifugal compressor that collects refrigerant vapor after compression.

water-cooled condenser A type of condenser that rejects the heat of the refrigerant to water flowing through it.

Multiple-Chiller-System Design and Control

SYS-APM001-EN (October 2000)

TRANE®

Multiple-Chiller-System Design and Control

Mick Schwedler, applications engineer
Ann Yates, information designer

Preface

This manual examines chilled-water-system components, configurations, options, and control strategies. The goal is to provide system designers with options they can use to satisfy the building owners' desires, but this manual is not intended to be a complete chiller-system design manual.

System designers may get the most use from this manual by familiarizing themselves with chilled-water-system basics and understanding the benefits of various options. Thereafter, when a specific job will benefit from these advantages, consult appropriate sections of the manual in detail.

The *Engineers Newsletters* that are referenced in this manual are available at: www.trane.com/commercial/library/newsletters.asp

The Trane Company, in proposing these system design and application concepts, assumes no responsibility for the performance or desirability of any resulting system design. System design is the prerogative and responsibility of the system designer.

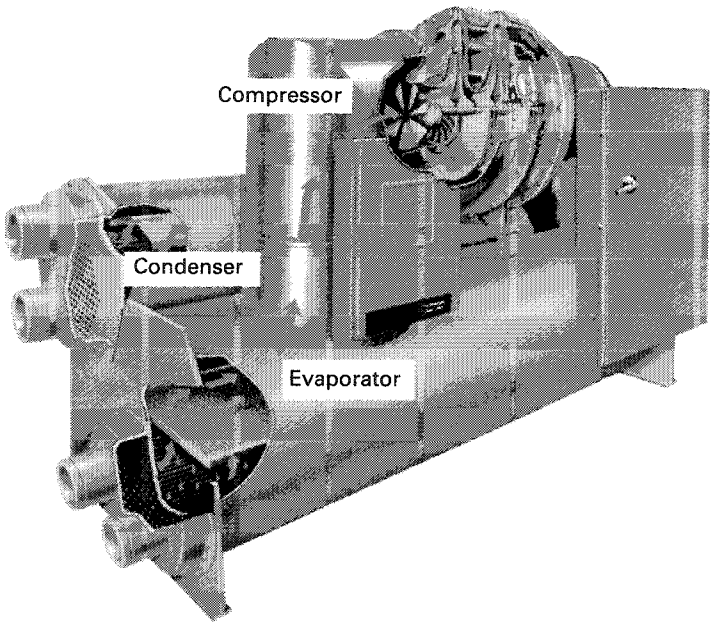
Introduction

Many building owners continually search for solutions that allow their businesses to offer higher quality, and to be more competitive and profitable. HVAC systems designers often use chilled-water systems to provide high-quality, cost-effective air conditioning for building owners. With the advent of more flexible chillers, system-level controls, and software analysis tools, the number of chilled-water-systems options has exploded.

Chilled-Water-Plant Basics



Chilled-water plants consist of these functional parts:

- Chillers that produce chilled water
- Loads, often satisfied by coils, that transfer heat from air to water
- Chilled-water distribution pumps and pipes that send chilled water to the previously mentioned loads
- Condenser-water pumps, pipes, and cooling towers that reject heat (for water-cooled chillers)
- Controls that coordinate the operation of the mechanical components together as a system

Chiller

There are a variety of water chiller types. Most commonly, they are absorption, centrifugal, helical rotary, and scroll. Some reciprocating chillers are also available. Chillers can be either air- or water-cooled. Major vapor-compression chiller components include an evaporator, a compressor(s), a condenser, and an expansion device(s). This manual discusses the chiller's evaporator and condenser and their relationship to the chilled-water plant.

Figure 1 Typical vapor-compression chiller

Chilled-Water-Plant Basics

Evaporator

The evaporator section of a water chiller is a shell-and-tube, refrigerant-to-water heat exchanger. Depending on the chiller's design, either the refrigerant or the water is contained within the tubes.

- In a flooded shell-and-tube evaporator, cool, liquid refrigerant at low-pressure enters the distribution system inside the shell and moves uniformly over the tubes, absorbing heat from warmer water that flows through the tubes.
- In a direct-expansion (DX) shell-and-tube evaporator, warmer water fills the shell while the cool, lower-pressure liquid refrigerant flows through the tubes.

In either design, there is an approach temperature, which is the temperature difference between the refrigerant and exit water stream. The approach temperature is a measure of the heat transfer efficiency of the evaporator.

Effect of chilled-water temperature

For a given chiller, as the leaving chilled-water temperature drops, the refrigerant temperature and pressure must also drop. Conversely, as the leaving chilled-water temperature rises, so do the refrigerant temperature and pressure. When the leaving chilled-water temperature changes, the work a compressor must do also changes. The effect of leaving chilled-water temperature change on power consumption can be 1.0 percent to 2.2 percent per degree fahrenheit [1.8 percent to 4.0 percent per degree celsius]. Always consider the energy consumption of the entire system — not only the chiller. It is important to remember that although reducing leaving chilled-water temperature penalizes the chiller, it may benefit the pumps because less water is pumped through the system. System interactions are covered in more detail in the next section *Chilled-Water-System Options.*

Effect of chilled-water flow rate

Since the evaporator is a heat exchanger, it is sensitive to water flow rate. Excessive flow may result in high water velocity, erosion, vibration, or noise. Insufficient flow reduces heat transfer efficiency and causes poor chiller performance. Some designers have concerns over low flow rates causing fouling. Generally, as Webb and Li[3] noted, these concerns are unwarranted since the chilled-water loop is a closed system, thus reducing the chances of materials entering the system and causing fouling. Chilled-water flow through the chiller must be kept within specific minimum and maximum limits. Contact the manufacturer for these limits.

Chilled-Water-Plant Basics

Some chiller controls can accommodate very little flow variation during machine operation.[2] Other, more sophisticated, chiller controls allow some flow variation. Some chillers can tolerate flow rate variations of as much as 30 percent per minute or greater, while others can only tolerate up to 2 percent per minute. It is important that chiller capabilities are matched to system requirements. Contact the chiller manufacturer to determine allowable rate of flow variation before varying the flow through the evaporator in a chiller. Flow variation is discussed in detail in the section *Variable-Primary-Flow Systems*, page 40.

Water-cooled condenser

To cool a building or process, the transferred heat must ultimately be rejected. The total amount of heat rejected includes the sum total of the evaporator load, the compressor work, and the motor inefficiency. In a hermetic chiller, where the motor and compressor are in the same housing, these loads are all rejected through the condenser. In an open chiller, where the motor is separate from the compressor and connected by a shaft, the motor heat is rejected directly to the surrounding air. The evaporator load and the compressor work are rejected through the condenser and the motor heat must be taken care of by the air-conditioning system.

Effect of condenser-water temperature

For a given chiller, as the leaving condenser-water temperature rises, refrigerant temperature and pressure also rise. Conversely, as leaving condenser-water temperature drops, so do refrigerant temperature and pressure. As the refrigerant pressure and temperature changes, the work a compressor must do also changes. The effect of leaving condenser-water temperature change on power consumption can be 1.0 percent to 2.2 percent per degree fahrenheit [1.8 percent to 4.0 per degree celsius]. Always consider the energy consumption of the entire system — not just the chiller. It is important to remember that although raising the leaving condenser-water temperature penalizes the chiller, it may benefit the pumps and cooling tower through the use of reduced flow rates and higher thermal driving-forces on the tower. System interactions are covered in more detail in the section *Condenser-System Variations*, page 69.

Effect of condenser-water flow rate

Since the condenser is a heat exchanger, it is sensitive to water flow rate. For example, excessive flow may result in high water velocity, erosion, vibration, or noise, while insufficient flow reduces heat transfer efficiency and causes poor chiller performance. Therefore, condenser-water flow through the chiller should be kept within a specific range of limits, except during transient startup

conditions. Contact the manufacturer for these limits. Some chillers may allow extended operation below the selected flow rates.

If water velocity through the condenser tubes is too low for significant periods of time and the water is extremely hard, long-term fouling of the tubes may also occur. Webb and Li[3] tested a number of internally-enhanced condenser tubes at low velocity (3.51 ft/s [1.07 m/s]) and high water hardness. While they found that some of the internally-enhanced tubes fouled, in the long term they concluded:

> Because of the high hardness and low water velocity used in these tests, we do not believe that the fouling experienced is typical of that expected in commercial installations. With use of good maintenance practices and water quality control, all of the tubes tested are probably suitable for long-term fouling applications.

It is important to remember that a chiller selected for low flow (as discussed in the next section *Chilled-Water-System Options*) does not necessarily have low velocity through its tubes. If tube fouling is a major concern, consider the use of smooth rather than internally-enhanced tubes in the condenser for ease of cleaning.

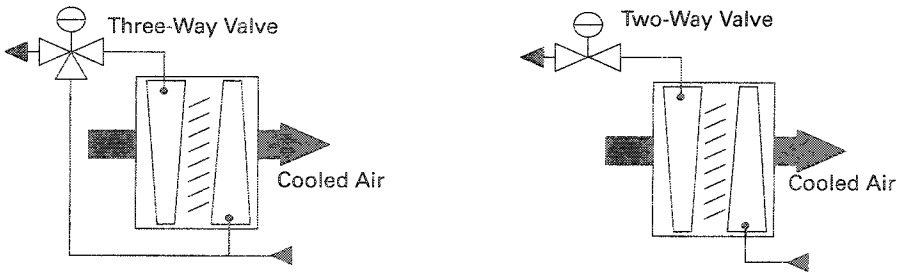
Air-cooled condenser

Obviously, air-cooled chillers do not use condenser-water since they reject their heat by having ambient air passed across refrigerant-to-air heat exchangers. In packaged air-cooled chillers, the manufacturers attempt to provide optimal performance by staging fans in response to chiller load and ambient, dry-bulb temperature.

Loads

In comfort cooling applications, loads are usually satisfied by air handlers equipped with coils to transfer heat from conditioned space air to circulating chilled-water. Air is thus cooled and dehumidified as it passes through the finned surface of the cooling coils. Since the psychrometric process of conditioning air takes place at the coils, selection of the optimum coil size and type from the wide variety available is important for proper system performance.

Chilled-Water-Plant Basics



Some specialized process loads do not involve cooling air. Instead, they may involve heat transfer directly within a piece of process equipment, such as the cooling jacket of an injection molding machine. Heat transferred from the loads can be controlled in a number of ways:

- Three-way valve
- Two-way valve
- Variable-speed pump
- Uncontrolled coils

Three-way valve load control

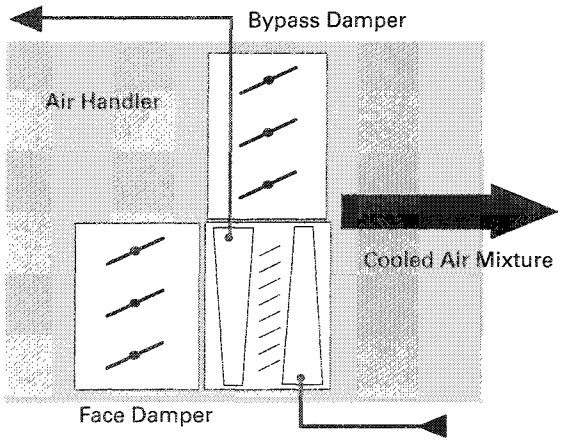
A three-way control valve regulates the amount of water passing through a coil in response to loads. The valve bypasses unused water around the coil and requires a constant flow of water in the system, regardless of load. A drawback of this bypass is that the temperature of the water leaving the three-way valve is reduced at part-load conditions. This can be a major cause of so-called "low Δ T syndrome" discussed on page 63 in the section *Chilled-Water-System Issues*. Three-way valves are used in many existing systems.

Figure 2 Valve-controlled loads

Two-way valve load control

A two-way, water modulating valve at the coil performs the same water throttling function as the three-way valve. The coil sees no difference between these two methods. The chilled-water system, however, sees a great difference. In the case of the two-way valve, *all* flow in the coil circuit is throttled. No water is bypassed. Consequently, a system using two-way valves is a variable-flow chilled-water system. The temperature of the water leaving the coil is not diluted by bypass water so at part-load conditions, the system return-water temperature is higher than with three-way valve control.

Chilled-Water-Plant Basics



Variable-speed pumping load control

By using a pump for each coil, the flow may be controlled by varying the pump speed. In such systems, there may be no control valves at the coil. This can reduce both the valve and the valve installation costs.

Uncontrolled coils

Figure 3 shows a control variation using an uncontrolled or "wild"coil. In this system, control of the conditioned air supply is executed by face-and-bypass dampers that permit a portion of the air to bypass the coil surface. Advantages of the strategy are the elimination of control valves and improved part-load dehumidification. A disadvantage is that all the water is pumped all the time; however, in systems with very small water pressure drops, this system arrangement may work economically.

Figure 3 Uncontrolled coil

Chilled-water distribution system

Chilled water is circulated through fixed piping — most commonly steel, copper, or plastic — that connects the chiller with various load terminals. Piping is sized to meet a project's pressure loss, water velocity, and construction cost parameters. Pressure drop is overcome by the use of a chilled-water pump.

Chilled-Water-Plant Basics

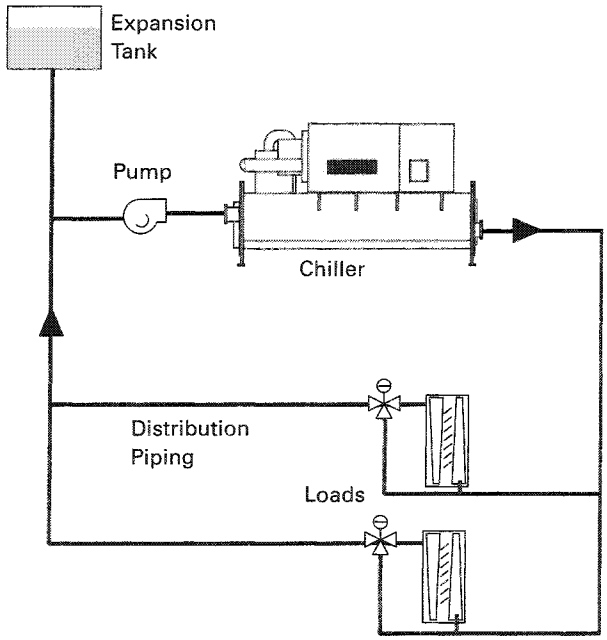
Chilled-water pump

The purpose of the chilled-water pump is to circulate chilled water within the loop. Generally, the pump must overcome the frictional pressure losses caused by the piping, coils, and chiller and the pressure differential across open control valves in the system. The pump, while working at the system static pressure, does not need to overcome this static pressure. For example, in a forty-story building the pump need not overcome the static pressure due to those forty stories.

The pump is typically located upstream of the chiller, however it may be anywhere in the system, provided that the pump:

- meets the minimum pump net positive suction head requirements. That is, the system pressure at the pump inlet must be both positive and high enough to allow the pump to operate properly;
- maintains the minimum dynamic pressure head at critical system components (usually the chiller). If the dynamic pressure head is not high enough at these components, proper flow will not be established through them;
- accommodates the total pressure (static head plus dynamic head) on system components such as the chiller's evaporator, valves, etc.

Note that the pump heat is added to the water and must be absorbed by the chiller. Generally, this represents a very small temperature increase.



Multiple pumps are often used for redundancy. Depending on the terminal control devices and system configurations, the chilled-water pumps may be either constant or variable-flow.

Chilled-Water-Plant Basics

Distribution piping

By itself, the distribution system is easy to understand. Figure 4 shows a simplified distribution system consisting of multiple cooling coils, each controlled by a thermostat that regulates the flow in its respective coil. The valves may be either three-way or two-way. As previously discussed, three-way valves require constant water flow, while two-way valves allow the water flow in the system to vary. As flow varies, the pump may simply ride its curve or use a method of flow control such as a variable speed drive. See the section *System Configurations*, on page 27, for a detailed discussion of distribution system options.

Figure 4 Simplified distribution system

2000 ASHRAE HVAC Systems and Equipment Handbook, Chapter 12, Hydronic Heating and Cooling System Design[1] contains additional reference information on the components of a chilled water distribution system.

The distribution system may contain other components, such as an expansion tank, control valves, balancing valves, check valves, and an air separator, to name a few. The density, and therefore the volume of the water in a "closed" chilled-water distribution system, varies as it undergoes changes in temperature. The expansion tank allows for this expansion and contraction of water volume.

Chilled-Water-Plant Basics

Condenser-water system

As in chilled-water distribution systems, condenser-water system piping — most commonly steel, copper, or plastic — is sized to meet a project's operating pressure, pressure loss, water velocity, and construction cost parameters. Pressure drop through piping and the chiller's condenser, plus the cooling-tower static lift, is overcome by use of a condenser-water pump.

Cooling tower

To reject heat, water is passed through a cooling tower where a portion of it evaporates, thus cooling the remaining water. A particular cooling tower's effectiveness at transferring heat depends on water flow rate, water temperature, and ambient wet bulb. The temperature difference between the water entering and leaving the cooling tower is the range. The temperature difference between the leaving water temperature and the entering wet-bulb temperature is the approach.

Effect of load

As the building load — or heat rejection — decreases, range and approach also decrease. This means that when the building is at part load, the cooling tower can provide colder water at the same ambient wet bulb.

Effect of ambient conditions

As ambient wet-bulb temperature drops, the approach — at a constant load — increases. This must be considered when cooling-tower-control strategies are developed. Detailed descriptions of these conditions appear in the subsection, *Chiller-tower energy balance,* page 72. For additional information, refer to *2000 ASHRAE HVAC Systems and Equipment Handbook,* Chapter 36, "Cooling Towers."[1]

Chilled-Water-Plant Basics

Controls

The chilled-water supply temperature is usually controlled at the chiller. Most commonly, supply water temperature is used as the sensed variable to permit control of chiller capacity to meet system load demand. Supply-temperature control strategies may be used on either constant- or variable-flow systems. As previously discussed, flow control is executed at the load terminals using three-way or two-way valves, or separate pumps for each coil.

Control capabilities run the gamut from slow-acting pneumatic controls, to electromechanical controls, to sophisticated digital controls that use algorithms tuned to give superior performance.

Chiller control

Today's chiller controls are capable of doing more than simply turning the chiller on and off. At a minimum, these controls should monitor:

- Safety points such as bearing temperatures and electrical points that, when out of range, may cause motor failure.
- Data points that may cause operational problems if corrective action is not taken. An example is low chilled-water or refrigerant temperature, which may result in freezing in or around the evaporator tubes.
- General points that should be logged daily to ensure proper chiller performance.

Table 1 lists the ASHRAE-recommended monitoring points.

Table 1 Recommended chiller-monitoring points per ASHRAE Guideline 3-1996

Chilled Water	Flow	Condenser Water	Flow
	Inlet Pressure		Inlet Pressure
	Inlet Temperature		Inlet Temperature
	Outlet Pressure		Outlet Pressure
	Outlet Temperature		Outlet Temperature
Evaporator	Approach Temperature	Condenser	Approach Temperature
	Refrigerant Pressure		Refrigerant Pressure
	Refrigerant Temperature		Refrigerant Temperature
Oil	Level	Refrigerant	Level
	Pressure		Compressor Discharge Temperature
	Temperature		Additional Required
	Additional Required	Vibration Levels	

Chilled-Water-Plant Basics

In addition to monitoring data, it is vital that the chiller controls alert operators to possible problems. Diagnostic messages are necessary for the operator to respond to safety issues and data points that are outside normal operating ranges.

While communicating these diagnostic messages is a requirement, some chiller controls include factory-installed programming that responds to the diagnostic messages. For example, when the chilled-water temperature nears freezing, the chiller sends a diagnostic message and *adapts* its operation by reducing the compressor capacity, raising the chilled-water temperature to a safer condition.

Finally, the chiller controls should communicate with a system-level controller. There are many system aspects that are outside the chiller's direct control, such as condenser-water temperature and the amount of fluid flowing through the evaporator and condenser. To minimize the system energy costs, the system controls must coordinate chiller, pump, cooling-tower, and terminal-unit controls. This can only be done if adequate information is communicated from each system component to the system-level controls.

Pump control

In so-called constant flow systems, the pumps are either on or off, providing relatively constant flow when in the *on* position. In practice, some flow variation will occur as system pressure drop changes. In a variable-flow system, pump control is most often performed by maintaining a pressure differential at a selected point in the system. For example, a variable-speed drive will increase its speed if the sensed pressure differential is too low, or slow down if the pressure differential is too high. The control point is selected to minimize over-pressuring the system and to assure adequate flow at all critical loads. Optimal pumping control strategies are addressed in *Critical valve reset*, page 47.

Chilled-Water-System Options

There are many chilled-water-system design options; however, in a basic sense, each option is a function of flow, temperature, system configuration, and control. This section discusses the effect of flow rate and temperature decisions.

It is important to remember that temperatures and flow rates are variables. By judicious selection of these variables, chilled-water plants can be designed to both satisfy chilled-water requirements and operate cost effectively.

Refer to ARI Standard 550/590–1998, *Standard for Water Chilling Packages Using the Vapor Compression Cycle* and the ARI Standard 560–1992, *Standard for Absorption Water Chiller and Water Heating Package*, for additional information. Both are published by the Air-Conditioning & Refrigeration Institute. (www.ari.org)

Chilled-water systems are often designed using flow rates and temperatures applied in testing standards developed by the Air-Conditioning and Refrigeration Institute (ARI), ARI 550/590–1998[1] for vapor compression chillers and ARI 560–1992[2] for absorption chillers. These benchmarks provide requirements for testing and rating chillers under multiple rating conditions. They are *not* intended to prescribe the proper or optimal flow rates or temperature differentials for any particular system. In fact, as component efficiency and customer requirements change, these standard rating conditions are seldom the optimal conditions for a real system. There is great latitude in selecting flow rates, temperatures, and temperature differences.

Chilled- and condenser-water temperatures

Leaving chilled-water and entering condenser-water temperature selection can be considered independently of their respective flow rates. However, temperatures and flow rates should be selected together to design an efficient and flexible chilled-water-system.

Standard rating temperatures

Currently, the standard-rating-condition temperatures in ARI 550/590[1] and ARI 560[2] are:

- Evaporator leaving water temperature: 44°F [6.7°C]
- Water-cooled-condenser, entering-water temperature: 85°F [29.4°C]
- Air-cooled-condenser, entering-air dry bulb: 95°F [35.0°C]

For years, these temperature definitions were the benchmarks in system designs. Today, designers apply a variety of different temperatures. ARI 550/590 reflects this trend by allowing the chilled-water and condenser-water temperatures to be selected at non-standard points and the chiller to be tested as specified by the standard.

Chilled-Water-System Options

Chilled-water temperatures

Chilled water (without antifreeze) at 34°F (1.1°C) is possible with some chillers that use sophisticated evaporator-design and chiller-control methods.

Currently, comfort cooling systems are designed with chilled-water-supply temperatures that range from 44°F [6.7°C] to 38°F [3.3°C], and, in some cases, as low as 34°F [1.1°C]. Reasons to decrease the chilled-water temperature include these:

- The system design more readily accommodates wider temperature *differences* (lower flow rates) than the standard rating conditions (see the subsection *Selecting flow rates*, page 16).
- Lower water temperature allows lower air temperatures (and flows) to be selected resulting in reduced airside installed and operating costs.
- Colder water in the same chilled-water coil may provide better dehumidification.
- Colder water can be used to increase the capacity of an existing chilled-water distribution system. In some instances, this can save significant capital expenditures to add capacity to large central plants that have reached their flow limits.

Some system designers hesitate to use lower chilled-water temperatures, concerned that:

- the chiller will become less efficient. As discussed earlier, lower chilled-water temperature makes the chiller work harder. However, while the lower water temperature increases chiller energy consumption, reducing the chilled-water flow rate reduces pump energy. This combination often lowers system energy consumption.
- lower chilled-water temperatures may require more insulation on piping to prevent condensation ("sweating"). Assure that pipes are properly insulated at all water temperatures. Lower temperature water will not always require more insulation.

Condenser-water temperatures

Today's chillers can run at various entering condenser-water temperatures, varying from design temperature to the lowest allowable temperature for that particular chiller design. However, many existing older chillers are limited in their allowable condenser-water temperatures. Contact the chiller manufacturer for these limits. Optimal condenser-water-temperature control is discussed in the section, *Condenser-System Variations*, page 69.

Chilled-Water-System Options

Chilled- and condenser-water flow rates

The selection of chilled-water and condenser-water flow rates is a powerful tool that designers have at their disposal. Kelly and Chan[5], and Schwedler and Nordeen[6], found that reducing flow rates can reduce the costs of chilled-water-system installation and/or operation.

Standard-rating flow rates

Presently, the standard-rating-condition flow rates in ARI 550/590 are:

- 2.4 gpm/ton [0.043 lps/kW] for evaporator
- 3.0 gpm/ton [0.054 lps/kW] for condenser

This evaporator flow rate corresponds to a 10°F [5.6°C] temperature difference. Depending on the compressor efficiency, the corresponding condenser temperature difference is 9.1°F to 10°F [5.1°C to 5.6°C].

Absorption chillers are rated using ARI Standard 560–1992, *Standard for Absorption Water Chiller and Water Heating Package*[2]. The evaporator flow rates are the same as those used in ARI 550/590; however, condenser (often called cooling water) flow rates differ depending on the absorption chiller design. Table 2 shows the standard rating conditions for various absorption chillers.

Table 2 Standard rating conditions for absorption chillers

Absorption Chiller Type		Condenser Flow Rate gpm/ton	Condenser Flow Rate lps/kW
Single Effect		3.60	0.065
Double Effect	Steam or hot water	4.00	0.072
	Direct fired	4.50	0.081

Chilled-Water-System Options

Selecting flow rates

Designers may use the standard *rating* conditions to compare manufacturers' performances at exactly the same conditions. However, these standards allow any flow rates to be used and certified comparisons to be made at those conditions. For a given load, as flow rate decreases, the temperature differential increases. Table 3 reflects a 450-ton [1,580-kW refrigeration] chilled-water system, both as a base case and with low flow.

Table 3 Standard rating conditions for chilled-water systems

Chilled Water System		Base Case	Low Flow
Evaporator flow rate, gpm [lps]		1,080 [68.1]	675 [42.6]
Chilled water temperature °F [°C]	Entering	54.0 [12.2]	57.0 [13.9]
	Leaving	44.0 [6.7]	41.0 [5.0]
Condenser flow rate, gpm [lps]		1,350 [85.2]	900 [56.8]
Condenser water temperature °F [°C]	Entering	85.0 [29.4]	85.0 [29.4]
	Leaving	94.3 [34.6]	99.1 [37.3]
Chiller power, kW		256.0	292.0

In this example, notice that the leaving-chilled-water temperature decreases and the leaving-condenser-water temperature increases. This means that the chiller's compressor must provide more lift and use more power. How does this impact system energy consumption? Using the following assumptions, we can calculate system energy usage:

- 80 feet of water [239 kPa] pressure drop through chilled-water piping
- 30 feet of water [89.7 kPa] pressure drop through condenser-water piping
- 78°F [25.6°C] design wet bulb
- 93-percent motor efficiency for pumps and tower
- 75-percent pump efficiency
- Identical pipe size in chilled- and condenser-water loops (either a design decision, or indicating changing flows in an existing system)

The pressure drop through the chiller will change. When using the same size pipe, the pressure drop changes with nearly the square of the flow. While this is true for straight piping, the pressure drop does not follow this exact relationship for control valves or branches serving loads of varying diversity.

Chilled-Water-System Options

Be sure to calculate the actual pressure drop throughout the system. Hazen–Williams and Darcy–Weisbach calculate the change is to the 1.85 and 1.90 power, respectively. The examples here use the more conservative 1.85 power:

$$DP2/DP1 = (Flow2)/(Flow1)^{1.85}$$

Table 4 Low-flow conditions for chilled-water pump

	Base Case	Low Flow
Flow rate, gpm [lps]	1,080 [68.1]	675 [42.6]
System pressure drop, ft water [kPa]	80.0 [239]	33.5 [100]
Evaporator-bundle pressure drop, ft water [kPa]	29.7 [88.8]	12.6 [37.7]
Pump power output, hp [kW]	39.9 [29.8]	10.5 [7.80]
Pump electrical power input, kW	32.0	8.4

Given different flow rates and entering water temperatures, a different cooling tower can be selected for the low-flow condition:

Table 5 Low-flow conditions for cooling tower

	Base Case	Low Flow
Flow rate, gpm [lps]	1,350 [85.2]	900 [56.8]
Static head, ft water [kPa]	19.1 [57.1]	12.6 [37.7]
Tower fan power output, hp [kW]	30.0 [22.4]	20.0 [14.9]
Tower fan electrical power input, kW	24.1	16.0

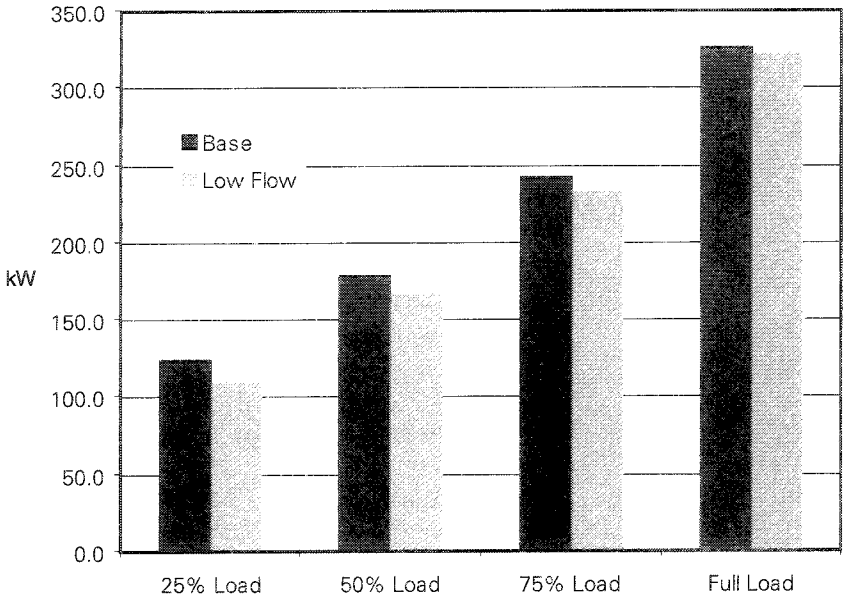
Table 6 Low-flow conditions for condenser-water pump

	Base Case	Low Flow
Flow rate, gpm [lps]	1,350 [85.2]	900 [56.8]
System pressure drop, ft water [kPa]	30 [89.7]	14.2 [42.5]
Condenser-bundle pressure drop, ft water [kPa]	19.9 [59.5]	9.6 [28.7]
Tower static lift, ft water [kPa]	19.1 [57.1]	12.6 [37.7]
Pump power output, hp [kW]	31.4 [23.4]	11.0 [8.2]
Pump electrical input, kW	25.2	8.8

Chilled-Water-System Options

The total system power is now as follows:

Table 7 Total system power



Component Power (kW)	Base Case	Low Flow
Chiller	256.0	292.0
Chilled-water pump	32.0	8.4
Condenser-water pump	25.2	8.8
Cooling tower	24.1	16.0
Total power for chilled-water system	337.3	325.2

It becomes clear that flow rates can affect full-load system power. Even though the chiller requires more power in the low-flow system, the power reductions experienced by the pumps and cooling tower result in an overall savings for the system. What happens at part-load conditions? Figure 5 shows the part-load performance based on the following assumptions:

- The chilled-water pump includes a variable frequency drive
- The condenser-water pump remains at constant power
- The cooling tower is controlled to produce water temperatures lower than design

Chilled-Water-System Options

Figure 5 Chilled-water-system performance at part load

While the magnitude of the benefit of low-flow changes depends on the chiller type used (centrifugal, absorption, helical-rotary, scroll), all chilled-water systems can benefit from judicious use of reduced flow rates.

Coil response to decreased entering water temperature

A coil is a simple heat exchanger. If we want it to deliver the same sensible and latent capacity while we supply it with cooler water, the coil's controls respond by reducing the amount of water passing through it. As the amount of water decreases while the amount of heat exchanged remains constant, the leaving water temperature increases. Therefore, by producing cooler water, a low-flow system can be applied to an existing building. In a retrofit application it is wise to reselect the coil, using the manufacturer's selection program, at a new chilled-water temperature to ensure its performance will meet requirements.

When coil performance data is not available from the original manufacturer, some designers use this approximation. For each 1°F –1.5°F [0.6°C–1.1°C] the water temperature entering the coil decreases, the water returns 1°F [0.6°C] warmer and gives about the same sensible and total capacities.

For example, consider a coil operating at 44°F [6.7°C] entering temperature and 54°F [12.2°C] leaving temperature. By changing the entering-water temperature to 41°F [5.0°C] the coil-leaving temperature will be approximately 56°F –57°F [13.3°C–13.9°C]. Let's look at this example in a table.

Chilled-Water-System Options

Table 8 Effect of decreased water temperature

		Original Selection °F [°C]	Chilled-water reduction for each 1° return water increase °F [°C]			
Coil water temperature	Entering	44 [6.7]	1°	41 [5.0]	1.5°	41 [5.0]
	Leaving	54 [12.2]		57 [13.9]		56 [13.3]

One possible concern of low-supply water temperatures is the ability of the valve to control flow properly at low load conditions. A properly sized valve with good range can work well in low- flow systems. In existing systems, valves may need to be replaced if they cannot operate with the new range of flows, but the coils do not need to be replaced.

Cooling-tower options with low flow

Smaller tower

Like coils, cooling towers are heat exchangers — although often misunderstood heat exchangers. The tower exchanges heat between the entering (warmest) water temperature and the ambient wet bulb. Therefore, in a new system or when a cooling tower is replaced, a low-flow system design allows a smaller, more efficient cooling tower to be selected. How is this possible?

Since the amount of heat rejection is approximately the same in standard-rating-condition and low-flow systems, we can estimate the heat exchange area necessary to reject the heat:

$Q = U A_1 \Delta T_1$, where A = area, U = coefficient of heat transfer, and
ΔT = temperature difference

$= U A_2 \Delta T_2$ or $A_1 \Delta T_1 = A_2 \Delta T_2$

Using standard rating conditions, the temperature difference between tower entering temperature and ambient wet bulb for ΔT_1 is:

$\Delta T_1 = 94.2 - 78 = 16.2°F\ [34.6 - 25.6 = 9.0°C]$

while at typical low-flow conditions for ΔT_2 it is:

$\Delta T_2 = 99.1 - 78 = 21.1°F\ [37.3 - 25.6 = 11.7°C]$

Therefore:

$A_1 \times 16.2 = A2 \times 21.1$ or $A_2 = 0.77\ A_1$

Chilled-Water-System Options

In a cooling tower, the heat exchange capacity can be changed by either surface area or airflow, or some combination of the two. A cooling-tower manufacturer's selection program can give the exact size and power requirements. In the example on pages 16–18, both the cooling-tower size and airflow (hence, required fan power) were reduced.

Same tower, smaller approach

Another option is to use the same cooling tower at a lower flow rate. In a new system, this is a design decision, but in an existing system, it is often a constraint. Given the same heat rejection load, the low flow system allows the cooling tower to return colder water; that is, the tower's approach to the ambient wet bulb decreases. In the previous example of 450 tons [1580 kW], the same cooling tower would have resulted in an entering condenser-water temperature of 83.5°F [28.6°C] instead of the 85°F [29.4°C] with the smaller cooling tower. It is important to realize that the entering temperature for the tower would be approximately 97.6°F [36.4°C]. Therefore, the effect of reduced flow rate on chiller energy consumption is partially offset by the lower entering-condenser water temperature.

Same tower, larger chiller

One retrofit option that benefits many building owners is installing a new, larger chiller and using the existing cooling tower, condenser-water pump, and condenser-water pipes. In many cases, this allows the building owner to increase the chilled-water-system capacity for an expansion, with a limited budget. Table 9 shows the conditions for an existing 450-ton [1,580-kW] chiller replaced by a 675-ton [2,370-kW] chiller. This is a capacity increase of 50 percent. A more extensive discussion of this example is contained in the next section, *System Configurations.* It is important to select the new chiller based on the new conditions.

Table 9 Retrofit capacity changes

		Present	Expansion retrofit
Capacity, tons [kW refrigeration]		450 [1,580]	675 [2,370]
Cooling tower	Flow rate, gpm [l/s]	1350 [85.2]	1,350 [85.2]
	Entering temperature, °F [°C]	94.3 [34.6]	103 [39.4]
	Leaving temperature, °F [°C]	85 [29.4]	88 [31.1]
Ambient wet bulb, °F [°C]		78 [25.6]	78 [25.6]

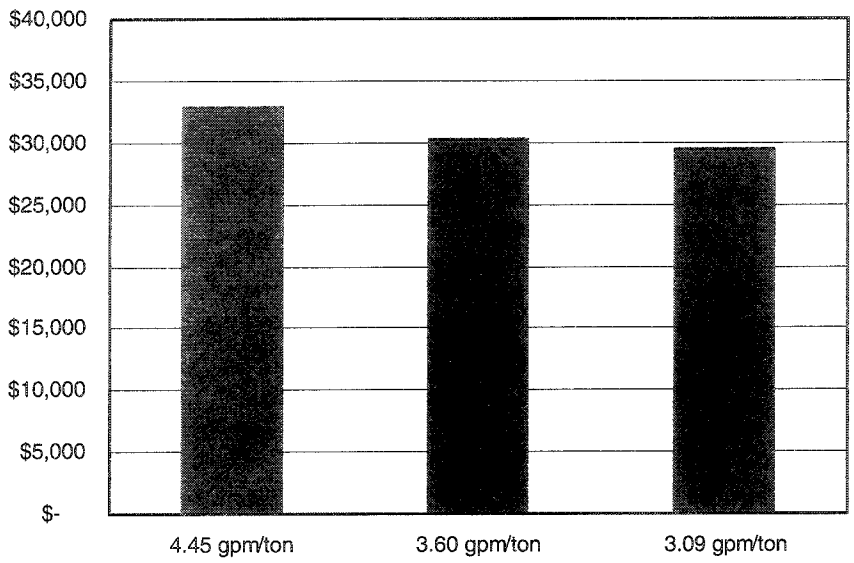
Chilled-Water-System Options

Cost implications

Several considerations should be kept in mind when determining sizes for new systems. As pipe size is decreased, so are valve and specialty sizes and costs. Remember that reducing pipe size increases pressure drop. Keep a balance between first cost and operating costs. This can significantly reduce the system retrofit costs since existing pipes may be used.

By reducing either chilled- or condenser-water flow rates alone, the following installed-cost reductions are possible:

- Reduced pump size, valves, strainers, fittings, electrical connections
- In new systems, reduced pipe sizes
- In existing systems, more capacity from existing, chilled-water piping systems
- Reduced cooling-tower size, footprint, and fan power



Alternatively, a physically smaller cooling tower may be selected using low flow. A reduced footprint can benefit building owners in a number of ways:

- Reduced real estate requirements (often more important than realized)
- Reduced structural requirement, since the amount of tower water is reduced
- Reduced excavation and material costs in the case of a large, built-up tower with a concrete sump
- Improved aesthetics because of the reduced tower height

In addition to reducing installation costs, operating cost reductions for the whole system are also available. Due to a smaller pump and/or tower, the pump and tower operating costs can be reduced substantially with less adverse impact on the chiller operating cost. Analysis programs such as DOE 2.1, TRACE®, or System Analyzer™ software can be used to determine annual operating costs. Nordeen and Schwedler[6] showed that operating costs for chilled-water systems using absorption chillers can benefit greatly from reduced condenser-water flow. Figure 6 shows operating costs as generated with System Analyzer™ analysis software.

Chilled-Water-System Options

Figure 6 Annual system operating costs

Kelly and Chan[5] compare the operational costs of chilled-water-system designs in site locations. Their summary states:

> In conclusion, there are times you can "have your cake and eat it too." In most cases, larger ΔT's and the associated lower flow rates will not only save installation cost but will usually save energy over the course of the year. This is especially true if a portion of the first cost savings is reinvested in more efficient chillers. With the same cost chillers, at worst, the annual operating cost with the lower flows will be about equal to "standard" flows but still at a lower first cost.

Chilled-Water-System Options

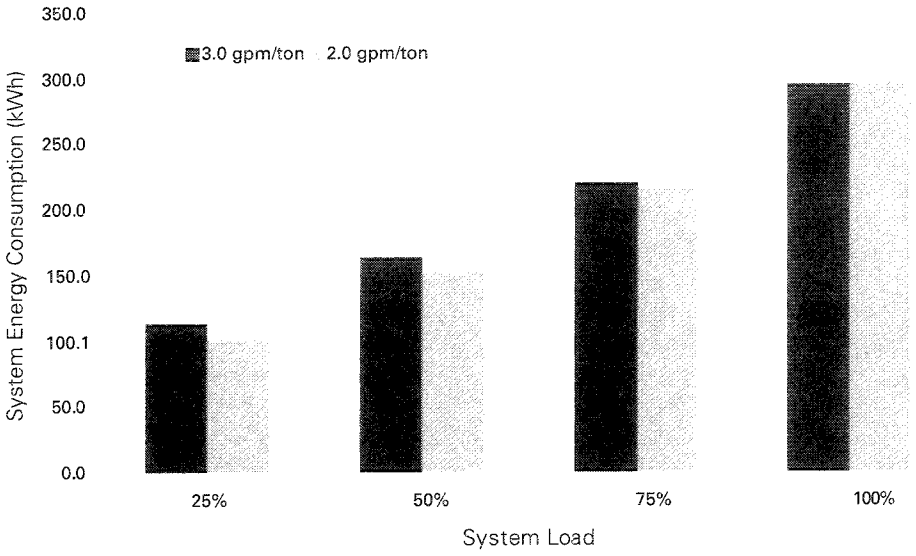
Misconceptions about low-flow rates

Some common misconceptions about low-flow systems include:

1. Low flow is only good for long piping runs
2. Low flow only works well for specific manufacturers' chillers
3. Low flow can only be applied to new chilled-water systems

Let's discuss each of these three misconceptions.

Misconception 1 — Low flow is only good for long piping runs.



One way to examine this claim is to use our previous example, but to concentrate on the condenser-water side. We'll start with the example covered on pages 16–18. Using the same chiller, but a smaller cooling tower and a more conservative zero condenser-water-pipe pressure drop, we can examine the effect of reducing flow rates.

Table 10 Reduced flow-rate effect

Condenser Water Pump	Base Case	Low Flow
Flow rate, gpm [lps]	1350 [85.2]	900 [56.8]
System pressure drop, ft water [kPa]	0	0
Condenser bundle pressure drop, ft water [kPa]	19.9 [59.5]	9.6 [28.7]
Tower static lift, ft water [kPa]	19.1 [57.1]	12.6 [37.7]
Pump power output, hp [kW]	17.7 [13.2]	6.7 [5.0]
Pump fan electrical input, kW	14.2	5.4

Chilled-Water-System Options

Figure 7 System energy comparison (no pipe)

Energy consumption for the chiller plus condenser-water pump plus cooling-tower fans is shown in Figure 7. Note that only at full load does the total power of the chilled-water *plant* increase. Recall that this is with absolutely **no** pressure drop through the condenser-water piping, valves, or fittings. It is interesting to note that the break-even point at full load is approximately 8 feet of head (water) [23.9 kPa]. Also note that at all part-load conditions, the total power of the low-flow system is less than that of the base system. It is easy to see that even for short piping runs, reducing flow rates can improve plant energy consumption.

Misconception 2 — Low flow only works for specific manufacturers' chillers.

Demirchian, et al.[3], Eley[4], and Schwedler and Nordeen[6] independently showed that system energy consumption can be reduced by reducing flow rates. It is interesting to note that in the systems studied, three different chiller manufacturer's chillers were examined, yet the energy savings only varied from 2.0 to 6.5 percent. In all cases, regardless of which manufacturer's chillers were used, the system energy consumption was reduced. In addition, Demirchian, et al.[2], and Schwedler and Nordeen[6] also noted reduced first costs.

Chilled-Water-System Options

Misconception 3 — Low flow can only be applied to new chilled-water systems.

As previously discussed in the manual in the sub-sections *Coil response to decreased entering water temperature* and *Cooling tower options with low flow*, there are distinct opportunities to use existing infrastructure (pumps, pipes, coils, and cooling towers) to either expand available cooling capacity and/or reduce system energy costs by using lower flow rates.

Upon examination, it is clear that low-flow systems allow savings even on short piping runs, work with all manufacturers' chillers, and can be used in retrofit applications. As a designer, remember to review the benefits to the building owner. Often, reducing flow rates can provide significant value.

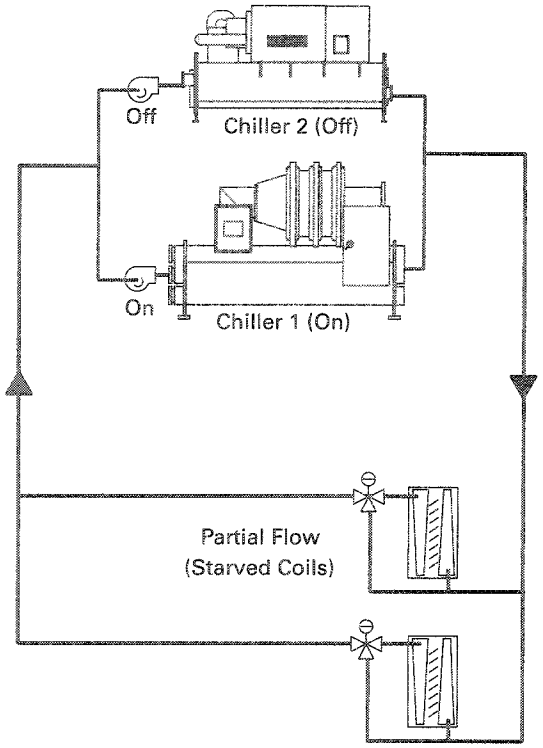
System Configurations

Multiple-chiller systems are more common than single-chiller systems for the same reason that most commercial airplanes have more than one engine, the balance of reliability and cost. The most typical system configuration, by far, has two chillers. Since system loads can vary throughout a wide spectrum, multiple-chiller systems can often operate with one chiller. During these periods, if the system is designed properly, the energy required to operate a second chiller and its auxiliaries can be conserved.

Parallel chillers

Figure 8 shows a system with two chillers piped in parallel, using a single, chilled-water pump.

Figure 8 Parallel chillers with single, common chiller pump

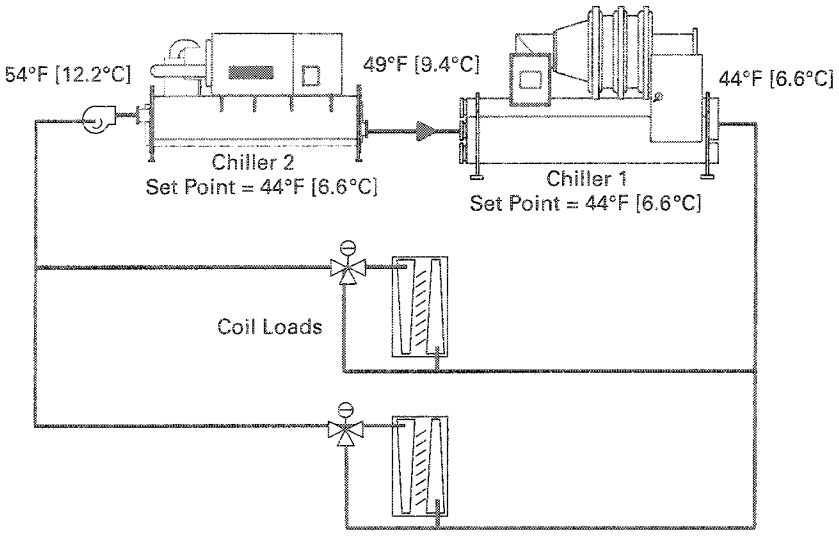


With constant flow loads, water flows in both chillers continually, whether the chiller is operating or not. Clearly, this can disrupt supply chilled-water temperature when only one chiller is operating. The temperatures indicated in Figure 8 show how the supply water temperature rises when one chiller is cycled off in response to a part-load condition. This may result in inadequate dehumidification capabilities or the inability to satisfy specific loads.

Alternatively, the running chiller can be reset to produce a lower supply temperature at this condition. In this way, the mixed system-supply-water temperature may be maintained at a more acceptable temperature. This complicates the control system and presents the possibility of increasing chiller energy consumption due to the requirement for lower temperature water. There will also be a low limit to this water temperature, dependent on the chiller's low pressure cut out control, low-evaporator-refrigerant-temperature limits, or low leaving-chilled-water limits.

System Configurations

Figure 9 Parallel chillers with separate, dedicated chiller pumps



If separate, dedicated chiller pumps are used (Figure 9), a chiller–pump pair can be cycled together. This solves the flow mixing problem described above, but presents a new problem. With only one pump operating, total system water flow will decrease significantly, according to the pump–system curve relationship. All the load terminals in the system will receive less water, regardless of their need. Consequently, it is possible to starve some loads that are still high, perhaps those serving internal spaces with constant loads, or to starve the loads farthest from the pump.

System Configurations

Series chillers

If chillers are piped in series, as in Figure 10, the mixing problem disappears and the starving coils problem when one of the pumps is not running is resolved. Series flow presents a new set of temperature and flow control challenges.

Figure 10 Series chillers

The flow rate through each chiller is the entire system flow, that is, double the individual flow rate of the parallel chillers (two chillers). This means that the chiller evaporator must accommodate the doubled water quantity. All things being equal, this results in fewer water passes and decreased chiller efficiency. However, this efficiency loss is more than offset by increased chiller efficiency since the upstream chiller operates at warmer temperatures. Also, pressure losses are additive when the chillers are piped in series. This may increase total system pressure loss significantly. On the other hand, series chillers may work very well in low-flow systems, where the system temperature difference is greater than 16°F [9°C], resulting in less pressure loss. Low-flow systems are discussed in detail beginning on page 16.

System Configurations

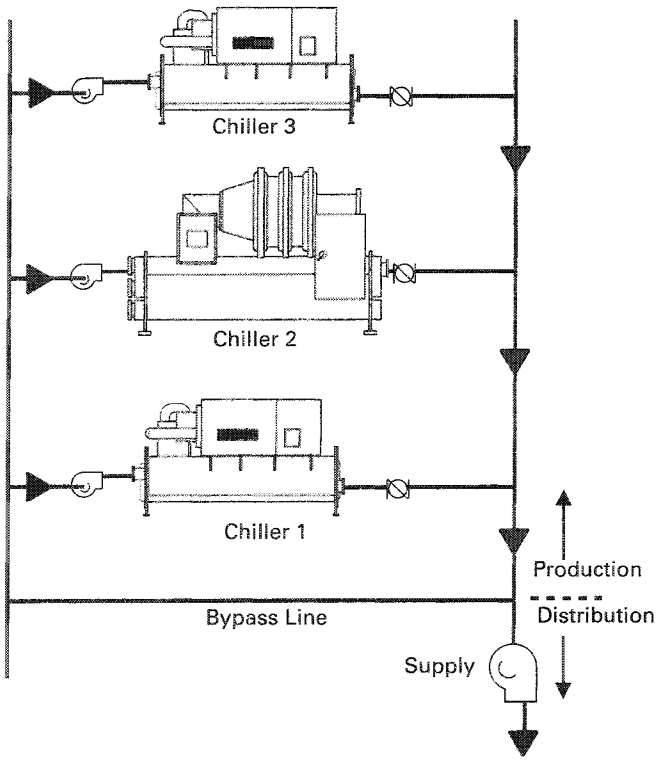
Temperature control can be executed in several ways. Figure 10 shows a strategy where the controller on each chiller is set at the system design set point. Either chiller can be used to meet the system demand for up to 50 percent of the system load. At system loads greater than 50 percent, the upstream chiller is preferentially loaded because it will attempt to produce the design leaving chilled-water temperature. Any portion of the load that remains is directed to the downstream chiller.

If chiller set points are staggered (upstream at 49°F [9.4°C] and downstream at 44°F [6.7°C]), the downstream chiller is loaded first. The upstream machine then meets any portion of the system load that the downstream chiller cannot meet. This control strategy offers several benefits. The first is that the upstream chiller is always operating at an elevated temperature. This allows it to operate at a higher efficiency. Also, placing an absorption chiller in the upstream position increases its capacity. As an example, an absorption chiller that can produce 500-tons [1,760-kW] at a leaving chilled-water temperature of 44°F [6.7°C] may produce 600-tons [2,110-kW] at 50°F [10°C]. Centrifugal, helical-rotary, reciprocating, and scroll chillers experience capacity and efficiency changes to a lesser degree. By judicious use of the series configuration, these benefits can provide reduced installed cost and fuel flexibility to the building owner.

Equal loading of the two chillers may be accomplished by using a chiller plant management system to reset the upstream chiller's set point in response to changes in system load.

System Configurations

Primary–secondary (decoupled) systems



The root cause of essentially all of the difficulties with parallel chiller control is the fixed relationship between chiller and system flow rates. If, instead, we can hydraulically decouple the production (chiller) piping from the distribution (load) piping, it is possible to control them separately. The fixed relationships are then broken apart.

System basics

Hydraulic decoupling

Figure 11 shows the basic decoupled system. This strategy is also referred to as a primary–secondary pumping arrangement. Separate pumps are dedicated to production and distribution. While the same water is pumped twice (by different pumps), there is no duplication of pumping energy. This is because the production pumps overcome only the chiller and production-side pressure drop while the distribution pumps overcome only the distribution system pressure drops.

Figure 11 Decoupled arrangement

System Configurations

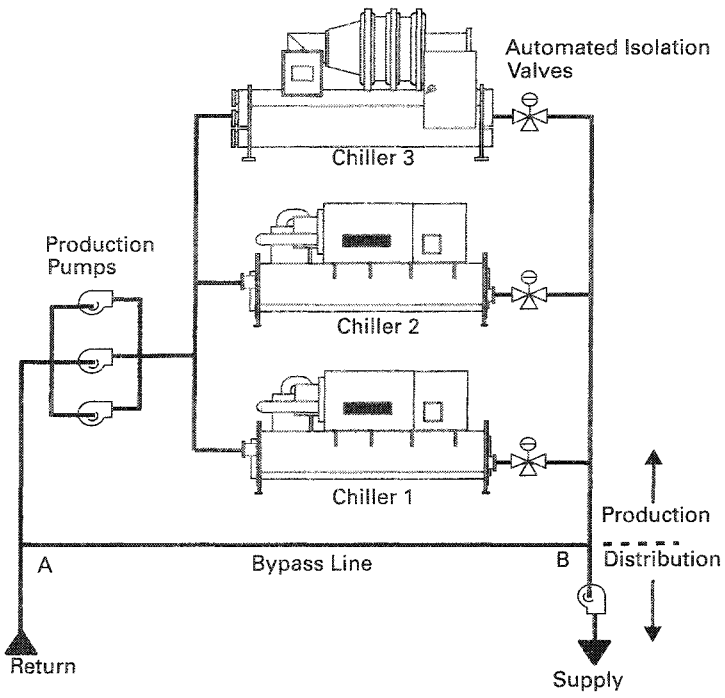
The unrestricted bypass line hydraulically decouples the production and distribution pumps so that they cannot operate in a series coupled pumping arrangement.

Although the two pumping systems are independent, they have three things in common:

- bypass piping,
- no-flow static head (from the building water column), and
- water.

Changes in flows or pressures, due to variations in dynamic head or the number of chillers operating, cannot cross the bypass line.

The extent of decoupling depends solely on the restriction (or lack of restriction) in the bypass pipe. Total decoupling is accomplished only if the bypass piping has zero pressure loss at any flow. Since this is not possible, some insignificant pump coupling will exist. The important issue is to keep the bypass piping free of unnecessary restrictions such as check valves. See *Check valve in the bypass line*, page 63, for further discussion.



Production

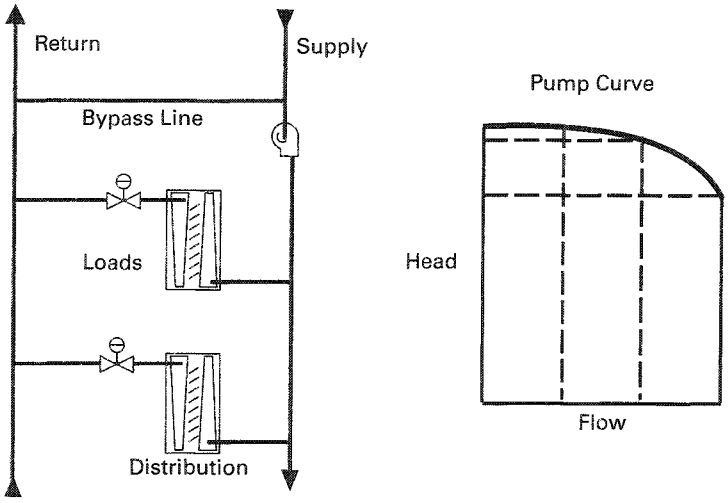
An individual production (chiller) pump need only pump water from the return bypass tee (point A in Figure 12), through its chiller, and into the tee at the supply-end of the bypass line (point B in Figure 12). This represents a relatively small pressure differential and a low pumping-power requirement. In addition, each individual pump operates only when its corresponding chiller runs.

Production loops are independent, one from another, as well as from the distribution loop. They may consist of pump–chiller pairs that act as independent chillers. Or, manifolded and stepped pumps can be teamed with automatic, two-position chiller valves to operate in the same way as pump–chiller pairs. Figure 12 shows the latter arrangement. Temperature control is also independent. The conventional, chilled-water temperature controller, furnished with the chiller, serves this function.

System Configurations

Figure 12 Production loop

Chillers may be of any type, age, size, or manufacturer. System operation is simplest, however, if all of the chillers are designed to operate with the same leaving chilled-water temperature and through the same system temperature rise (temperature difference) across the chiller.



It is interesting to note that if the chillers in a decoupled system make the same chilled-water temperature, then all the operating chillers are loaded to equal *percentages*. There may be times when preferentially loading a chiller is desired. This is discussed in the section *Chilled-Water-System Variations*, page 54.

System Configurations

Distribution

Distribution pumps take water from the supply water tee (point B in Figure 12), push it through all the distribution piping and load terminals, and then on to the return water tee (point A in Figure 12). This pump can (and should) allow variable flow.

Figure 13 Distribution loop

By itself, the distribution system is easy to understand. Figure 13 shows a simplified distribution system consisting of multiple cooling coils, each controlled by a valve that regulates the flow in its respective coil. In this case, the flow control valves should not be three-way because a constant flow is not desired. Instead, two-way modulating valves are used. As the aggregate loads change system flow, a constant speed pump would "ride" its flow-rate-versus-head-pressure. This means that in response to the change of flow required, the pump will find a new equilibrium point along its operating curve. An example pump curve is shown in Figure 13.

Alternatively, multiple pumps or variable-speed pumps can be used to limit the dynamic pumping head, similar to VAV fan control. Properly designed, part-load pumping power can approach the theoretical cubic relationship to flow, thus reducing energy consumption significantly. Today, most decoupled systems use a variable-speed drive on the distribution pump.

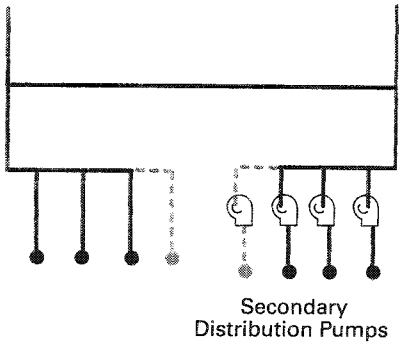
Distribution basics The distribution system benefits from the ability to accommodate load diversity, the fact that system flow is variable, and (in a properly operating system) the fact that return water is maintained at temperatures near design. The last assumption is further discussed in the subsection *Low ΔT syndrome*, page 63.

System Configurations

Load diversity Not all chilled-water loads peak simultaneously. Therefore, the quantity of water that flows at any one time is reduced from the "sum of the peaks" load that would be required in a constant-flow-distribution loop. This presents the possibility of reducing chiller, pump, and pipe sizes significantly.

Variable flow Only the water that the loads actually use is pumped. Most of the time, this means a significantly reduced flow rate, accompanied by an even more significant reduction in pumping energy.

Elevated return-water temperatures Because unused chilled-water does not bypass the cooling coils, all water that is returned accomplishes some cooling. Theoretically, the return-water temperature will always be at least as high as it is at full load. From a practical standpoint, this is not always possible, but it is closely approached in a properly operating system. In fact, at most part-load conditions, water returns from properly functioning air-conditioning coils at higher-than-design temperatures. In systems that use counterflow cooling coils, this occurs because the water leaving the coil tries to approach the temperature of the entering air stream.



Warm return water provides advantages in system design. It permits "preferential" loading of chillers, for example. Warmer return water is useful with all systems, but particularly so with heat recovery and free cooling applications. The section *Chilled-Water System Variations*, page 54 has further information.

Pumping Arrangements

Common

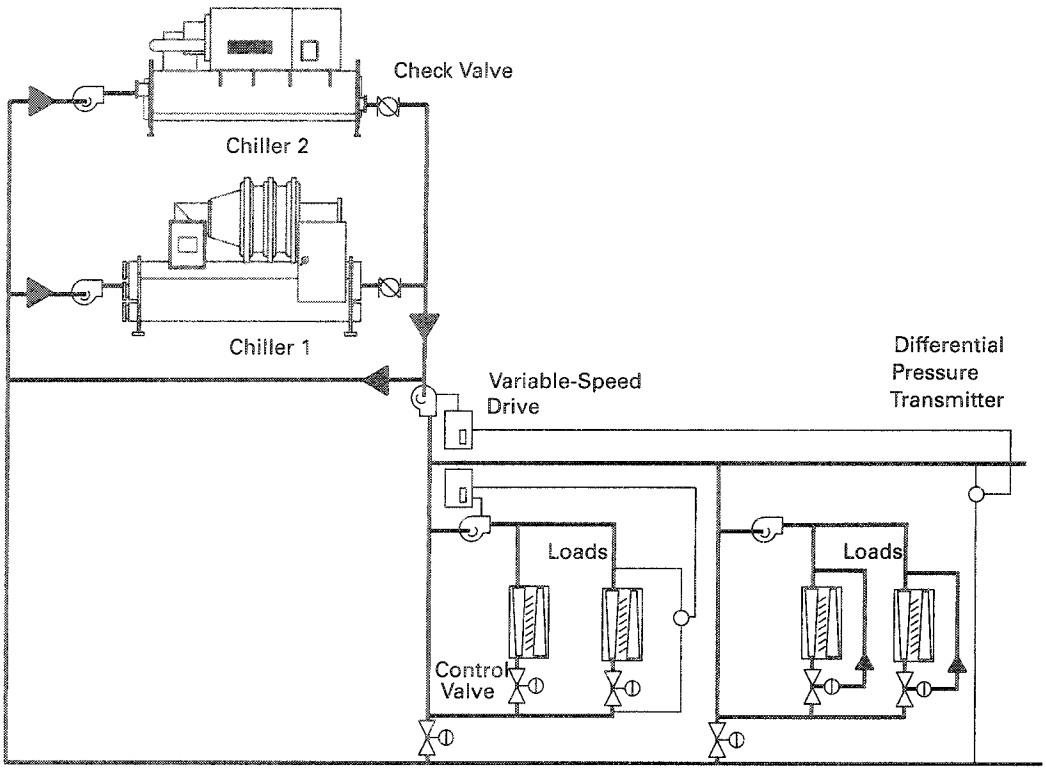
A variety of distribution system arrangements is possible. A single, large pumping station, as shown in Figure 12, can be used. The station may consist of single or multiplexed pumps sequenced.

Figure 14 Campus pumping arrangement

Campus

Alternatively, each of several secondary distribution systems can be piped in parallel. For example, Figure 14 shows separate distribution systems for each of three loads. Clearly, this arrangement lends itself to the possibility of plant expansion, by simply adding secondary distribution pumps to the existing plant.

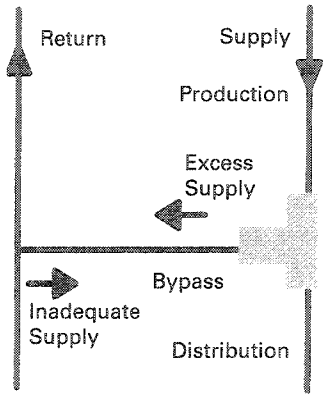
Tertiary or distributed



Tertiary pumping is an extension of primary–secondary pumping when the distribution or secondary pump must overcome diverse and severe pumping requirements.

System loads can also be decoupled from the secondary distribution system. This is frequently done with very large systems. Figure 15 shows one method of providing "tertiary pumping" at the loads. A "load" may be something as large as an entire building, or as small as an individual cooling coil. When one or more loads have extreme head requirements the degree of rangability of the distribution pump is severely curtailed. Tertiary pumping allows the excess pumping requirements to be placed on a third pumping system thus shielding the distribution pump from divergent pressure requirements.

Most importantly, the loads must be controlled so that only the water needed to perform cooling is taken from the distribution loop. Water must not be allowed to flow into the return piping until it has sustained a specific temperature rise. Tertiary pumps can be either constant flow or variable flow, to best meet the terminal load requirements.



Pumping Arrangements

Figure 15 Tertiary pumping arrangement

Decoupled system–principle of operation

Figure 16 Decoupled system supply tee

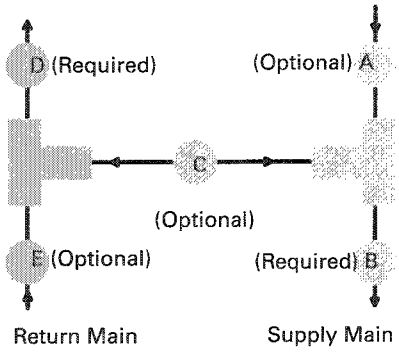
At the tee connecting the supply and bypass lines, a supply–demand relationship exists, as shown in Figure 16. Think of the total flow rate from all operating pump–chiller pairs as supply. Demand is the distribution system flow required to meet loads. Whenever supply and demand flows are unequal, water will flow into, or out of, the bypass line. Flow can be sensed directly or inferred from the bypass-water temperature.

Inadequate supply to meet demand causes return water to flow out of the bypass leg of the tee into the distribution system. The mixture of chiller supply and warm system return water, then, flows into the distribution loop. Supply-water temperature control is compromised when this happens. If the bypass line flow into the supply tee (Figure 16) can be sensed, its presence can be used to energize another pump–chiller pair. The increase in supply water flow from the additional pump changes the supply–demand relationship at the tee, eliminating return-water mixing. As long as return-water mixing does not occur at the supply tee, no additional chiller capacity is required. When mixing does occur, an additional chiller may be needed, depending on the amount of mixing that can be tolerated.

Pumping Arrangements

Much of the time supply exceeds demand, and the surplus flows to the return tee. If a chiller pump is stopped prematurely, the bypass line flow will again show a deficit and the pump will be cycled on again. The amount of surplus flow necessary depends on the size of the chiller to be shut off. The surplus flow must exceed a certain quantity before shutting off a chiller–pump pair. This is discussed in *Chiller sequencing*, page 39. If all chillers are equal in size, the surplus flow signal can be constant.

Control of the number of chillers is accomplished by simply noting the direction of flow in the bypass line. Thus, the system operates as a flow-based demand system, not a temperature-based demand system.



Flow-based control

To properly operate a primary–secondary system, an indication of direction of flow and the flow rate through the bypass line is necessary. This may be done either directly or indirectly. When bypass flow is from supply to return, it is called *surplus*. Bypass flow moving from return to supply is termed *deficit*.

Flow-sensing

Direct flow-sensing in the bypass line can be accomplished in several ways. A number of flow-metering technologies have been used successfully. These include Pitot tube, Venturi, orifice plate, differential pressure, turbine, impeller, vortex, magnetic, and ultrasonic transit-time. The accuracy, ease of installation, maintainability, and cost of meter technologies vary widely. To give accurate results a flow meter must be calibrated periodically, with some flow meters requiring more frequent calibration than others. When using flow-sensing devices, it is important to understand the range of flows a device can properly measure and its calibration requirements. The readings will only be as good as the instrumentation. Also note that many flow-measurement devices require several diameters of straight pipe for accurate readings.

Figure 17 Temperature-sensing

Temperature-sensing

Mixed water streams at the outlets of the supply and return water tees, Figure 17, can be used to indirectly determine the supply–demand relationship. Standard temperature-mixing equations can be used to determine the exact amount of surplus or deficit flow in the bypass line.

The five temperatures sensed — at points A, B, C, D, and E — are received by a programmable controller. (Some control systems use only two sensors, at points B and D, in conjunction with "pre-programmed" algebraic mixing equations.) Processing software applies the classic mixing equations and determines the resulting action to properly control the chilled-water system.

Pumping Arrangements

Note that sensor D needs to be very accurate, especially if there are many chillers, since small temperature changes may warrant chiller sequencing. Either temperature sensing strategy has a cost and flexibility advantage if a building or chiller-plant management system already exists, or is planned.

Chiller sequencing

Given the amount and direction of flow in the bypass line, chillers can be added or subtracted.

Adding a chiller

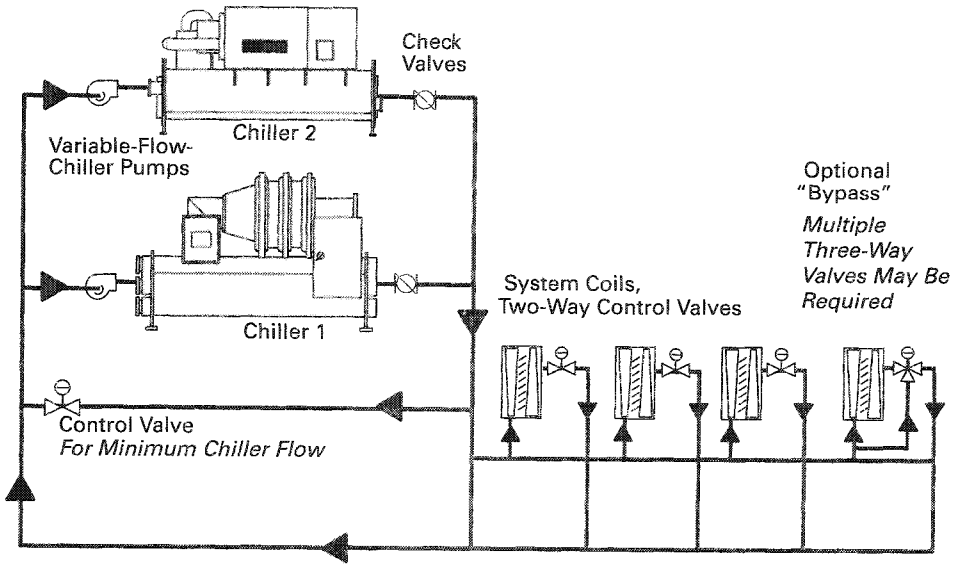
When there is deficit flow in the bypass line, the system is receiving water at a temperature above the system design temperature. (Also see the *Low ΔT syndrome* discussion, page 63.) At this point in time, a chiller and pump may be added. Many operators sense deficit flow for a particular amount of time (for example, 15 minutes) to ensure that the deficit flow is not a result of system transients. This reduces the chances of cycling a chiller; that is, turning on a chiller and then turning it off after a short time.

Subtracting a chiller

A chiller may be turned off when enough surplus water is flowing through the bypass line. How much is enough? Enough so that the chiller does not cycle on again in a short time period. Many system operators compare the amount of surplus flow with the flow rate of the chiller they are considering turning off. If this ratio is 110 to 115 percent, they turn the chiller off. Let's look at an example:

Chiller 1 can make 960 gpm [60.6 L/s] of 40°F [4.4°C] chilled-water, while Chiller 2 can make 1,440 gpm [90.8 L/s]. At present, there is 1,100 gpm [69.4 L/s] of surplus flow in the bypass line.

- The surplus bypass flow is presently 115 percent of Chiller 1's flow. If we turn Chiller 1 off, we will have 140 gpm [8.8 L/s] of surplus flow left.
- Note that the surplus bypass flow is presently only 76 percent of Chiller 2's flow. If we turn Chiller 2 off, we will have 340 gpm [21.5 L/s] of *deficit* flow. It is clear that we would have to cycle that chiller back on soon.



In this case, we could turn Chiller 1 off, but leave Chiller 2 on for the most efficient use of the chillers.

Variable-Primary-Flow Systems

Another method for balancing the production and distribution flows is to make them equal. Variable-flow systems require chillers that can operate properly when evaporator flow varies.

Conceptually, the variable-primary-flow (VPF) system resembles the familiar constant primary–variable secondary design more commonly known as the decoupled" system.[1] For example, both require a bypass. The bypass line for a VPF system is required to ensure that minimum flow through chillers can be maintained. Each chiller in the arrangement shown has a dedicated pump whose operation coincides with the chiller it serves.

Figure 18 Variable-primary-flow system

In a VPF system, **water flow varies throughout the entire system** — through the evaporator of each operating chiller as well as through the cooling coils.

Two-way control valves on coils, check (or isolation) valves on chillers, and a bypass pipe with a control valve are required to implement a VPF system. However:

- variable-flow chiller pumps eliminate the need for a separate distribution pump.
- the bypass can be positioned either upstream or downstream of the cooling coils.
- a control valve in the bypass ensures that the amount of flow through the operating chiller(s) never falls below the minimum limit.

Variable-Primary-Flow Systems

Dispelling A Common Misconception
True or false: "Chillers operate more efficiently in a system with variable rather than constant primary flow because of the greater log mean temperature difference (LMTD)."

It is true that the return water temperature in a properly operating VPF system remains constant as the amount of flow changes. It is also true that the LMTD can be increased by changing the production (primary) side of the chilled-water loop from constant to variable flow. But there are other facts to consider.

In a system with constant primary flow:
- Entering-evaporator temperature and LMTD fall as the cooling load diminishes.
- The convective heat transfer coefficient, like the primary flow, remains constant despite reductions in load.

In a system with variable primary flow:
- The convective heat transfer coefficient in the chiller evaporator decreases with a reduction in flow.
- Reduced flow decreases the overall heat-transfer effectiveness of the chiller evaporator.

The net effect is that the power consumption for a given chiller is virtually the same whether the chiller's evaporator flow is variable or constant.

VPF advantages

VPF systems present building owners with several cost-saving benefits that are directly related to the pumps. The most obvious cost savings result from eliminating the secondary distribution pump, which in turn avoids the material and labor expenses incurred with the associated piping connections, electrical service, and variable-frequency drive. Although the number of pumps is reduced, the sizes of both the pumps and the variable-frequency drives increase since the pumps must be sized to overcome the entire system's pressure drop. This offsets some of the installed cost savings due to fewer pumps.

Building owners often cite pump-related energy savings as the reason that prompted them to install a VPF system. With the help of a software analysis tool such as System Analyzer™, TRACE® 600, or DOE 2.1, you can determine whether the anticipated energy savings justify the use of variable-primary flow in a particular application.

It may be easier to apply a variable-primary-flow system rather than a primary–secondary system to an existing chilled-water plant. Unlike the primary–secondary design, the bypass can be positioned almost anywhere in the chilled-water loop and an additional pump is unnecessary.

VPF caveats

Sequencing chillers requires a thorough understanding of system dynamics since flow rates will vary through every operating chiller. The control strategy needed to avoid cycling, or restarting the chiller too soon, becomes complicated as the number of chillers or the capacities of the different chillers increases. The system designer must thoroughly define the control sequence early in the design process and clearly communicate it to the controls provider. Better yet, on such a system, a partnership among owner, operator, designer, and chiller plant provider (including controls) can be formed.

Controlling the flow rate fluctuation is critical. Confirm the allowable flow fluctuations with the chiller manufacturer and design the system so that the rate of flow change is never exceeded. Operators must understand how VPF systems work, therefore training is mandatory. The success of a system design is directly related to the operator's ability to carry out the design intent.

An important consideration when investigating variable-primary-flow systems is the fact that VPF systems take more time and planning than other systems to design and commission properly. If this time and planning can't, or won't, be invested, you will probably have better results with the use of systems other than VPF.

Variable-Primary-Flow Systems

Limits

Evaporator flow rates change as system demand changes. However, there are limits to absolute flow rate and allowable rate of change. Exceeding those limits may cause chiller-control instability or catastrophic failure.

Absolute flow limits

Maintain the evaporator flow between the minimum and maximum limits. Today, the cataloged water velocity range for many chillers is 3–11 fps [0.9–3.4 m/s], although some manufacturers now allow selections in the 1.5–2.0 fps [0.46–0.61 m/s] range. Ask the chiller manufacturer for the actual flow-rate-limit values (gpm [lps]) for your machine. The upper limit is generally set to avoid tube erosion problems, while the lower limit maintains control stability.

Rate of change

If a chiller's control system can not respond properly, the chiller might actually respond to rapid flow-rate changes by turning off or locking out on a safety trip. To ensure that chillers stay on line, keep changes in evaporator flow rate within manufacturer-set limits. This may require the use of slow-acting, modulating control valves at each chiller to reduce flow variation as chillers are sequenced, especially if pumps are manifolded.

Application note
While flow through a chiller's evaporator is now allowed to change, chillers with advanced controls may react by temporarily unloading. This results in an elevated leaving chilled-water temperature — generally only for a short time. For applications that require strict chilled-water temperature control, check with the chiller manufacturer for recommendations concerning the use of variable-evaporator flow.

As of this manual's writing, the most advanced chiller controls can provide close temperature control if flow fluctuations are limited to less than 10 percent of design chiller flow per minute. For some advanced controls, relaxing this limit to 30 percent of design flow per minute is permissible in most comfort-cooling applications since the leaving-evaporator water temperature will not deviate from set point for more than a few minutes, if at all. Again, check with the chiller manufacturer for base limits

Bypass flow control

Just as in a primary–secondary system, VPF systems respond to load changes by modulating flow. As the system demand nears the minimum flow rate for a single chiller, water must be bypassed to keep the flow rate through the chiller evaporator above that minimum.

Methods

- **Bypass line with valve** As previously discussed, bypass may either be controlled at a central location or be assured through the use of three way valves. When a bypass line and valve are used, the valve must be slow acting and modulate open when the flow rate nears the minimum of any chiller on line. When the flow rate rises above the chiller's minimum by a preset limit, the valve may close.
- **Three-way valve** An alternative is to provide three-way valves in distant portions of the system. The pump must be controlled so these valves always keep the total of their flow above the chiller's minimum. One method to ensure this flow rate is to control the pump to maintain a pressure differential at this valve, thus ensuring nearly constant flow at this point in the system.

Variable-Primary-Flow Systems

Evaporator flow measurement

Measurements of evaporator flow are critical to VPF control. One common practice relies on direct measurement using flow meters. (Be aware that some flow meters require, but seldom receive, frequent calibration.) Another measures water pressure drop through the evaporator bundle and estimates evaporator flow based on manufacturer data.

Bypass locations

A bypass is required whether the primary flow is constant or variable. In a primary–secondary system the decoupler allows excess primary water to be bypassed. In the VPF system the bypass allows system control to maintain the flows to chillers' minimum flow requirements.

There are three common locations for the VPF bypass line:

- Place the smaller bypass required for a VPF system in the same position as the bypass in a "decoupled" system. A variable-speed drive on the pump located near the chillers reduces flow and allows substantial energy and operating cost savings. One drawback is that the valve must work against higher pressures — possibly causing wear and lack of controllability.
- Use three-way valves at some of the system coils. While this approach ensures minimum chiller flow, it reduces the pump operating cost-savings due to increased the system flow and decreased return water temperature.
- Locate a bypass line and valve near the end of the piping run. The bypass control valve sees a lower operating pressure and stable control. Some operating cost savings may be sacrificed to maintain the pump-operating pressure at a higher level with the bypass located away from the chillers. The line sizes must be large enough to allow the minimum flow rate.

Chiller sequencing

Variable-primary-flow systems have more complex chiller sequencing requirements than primary–secondary systems. In fact, it is the time and thought put into chiller sequencing that will ultimately allow a VPF system to work well — or cause it to fail. System designers must think through the process, communicate the sequence of operation to those providing system-level programming and make sure the system operator understands the system function for it to have any chance to work.

Variable-Primary-Flow Systems

Adding a chiller in a VPF system

When the chiller(s) already on-line can no longer increase their flow rate—due either to the pump capacity or the maximum allowable evaporator-flow rate—or when chillers cannot meet the system-chilled-water set point, a chiller may be added. In a properly operating system the supply-water temperature is monitored. When the temperature exceeds the design setpoint by a certain amount (for example, 1.5°F [0.8°C]) for a set time (for example, 15 minutes) an additional chiller starts.

As chillers are brought on-line, flow rates may fluctuate substantially. This is especially true in a system with two chillers. An example will help explain the challenges.

Table 11 Flow-rate-fluctuation examples

	Design flow rate gpm [L/s]	Minimum flow rate gpm [L/s]	Maximum flow rate gpm [L/s]
Chiller 1	960 [60.6]	576 [36.3]	2,110 [133.1]
Chiller 2	1,440 [90.8]	675 [42.6]	2,474 [156.1]

At a point in time, Chiller 1 is active and has 1,100 gpm [69.4 L/s] flowing through its evaporator. It can no longer satisfy the required system supply temperature. What happens if Chiller 2's valve is opened with no other action taken? If we assume that pressure drops are equal, 550 gpm [34.7 L/s] will flow through each chiller. This means Chiller 1's flow rate drops by 50 percent instantaneously (probably beyond what its controls can respond to) and we are below each chiller's minimum flow rate. Be aware that this could become an issue since chiller controls may protect the chiller by shutting it off. The result is that some combination of pump speed, bypass valve control, and slow-acting valves at the chillers must do two things:

- Keep change in flow rate within the equipment limitations
- Keep each chiller's flow rate above its minimum

The bottom line is that control of VPF systems MUST be considered during system design.

Variable-Primary-Flow Systems

Subtracting a chiller in a VPF system

Subtracting a chiller in a VPF system is not simple, either. As an example, suppose that both chillers are running near their minimum flow. Chiller 1 is at 650 gpm [41.0 L/s] and Chiller 2 is at 760 gpm [47.9 L/s], so the system total is 1,410 gpm [88.9 L/s].

Choice 1

Turn off Chiller 1: It is obvious that we should be able to turn Chiller 1 off and satisfy system load as long as the flow rate doesn't increase too rapidly. However, the system flow rate is close to the Chiller 2's design flow rate, and if the system flow increases, we may need restart Chiller 1.

Choice 2

Turn off Chiller 2: If Chiller 1 has a condenser water temperature lower than design, its capacity has increased. Could we turn off Chiller 2? Chiller 1's flow is certainly within the allowable limits, but it may or may not be able to supply the required capacity. In this case, the dilemma is to ensure that there is enough chilled water capacity after a chiller is turned off.

Obviously, control is an extremely important aspect of a VPF system. In many chilled-water systems with between two and five chillers, system designers elect to use a primary–secondary system design to minimize control complexity.

"Overpumping" a chiller in a VPF system

Some VPF practitioners use manifolded pumps, allowing them to "overpump" a chiller. As used here, overpump means to pump more water through a chiller than was specified in the original design. In the previous example, Chiller 1 would be "overpumped" any time its evaporator water flow exceeds 960 gpm [60.6 L/s]; however, the flow rate must still be less than the maximum allowable. Recall that pressure drop through the evaporator will increase roughly with the square of the flow. There are two reasons one might want to overpump a chiller.

As the condenser water temperature is allowed to fall, the chiller could produce more cooling — if allowed. The only way to actually get that increased capacity is to increase either the flow rate or the temperature difference. The return water temperature is set, so now the only choices are to decrease the leaving water temperature or increase the flow. Changing water temperature complicates the system operation, but increasing water flow may be fairly simple in a VPF system. By increasing the evaporator flow rate, the chiller can provide more cooling.

Variable-Primary-Flow Systems

Some system operators overpump a chiller as a "band-aid" for systems experiencing low ΔT syndrome (see page 61). An example of low ΔT syndrome is receiving a depressed (e.g. 49°F [9.4°C]) return-water temperature rather than the design (e.g. 56°F [13.3°C]) return-water temperature. Again, the only methods to load the chiller are to decrease the chilled-water temperature or to increase the flow. If the pumping power and speed allows, the operator may be able to increase the chiller's flow rate and capacity. Do not exceed the pump's operating envelope.

Critical VPF system requirements

While they do have benefits, variable-primary-flow systems[1] should not be used on all systems. Understanding and accounting for the following prerequisites are critical for a successful VPF system.

- Chiller controls must adequately regulate temperature as flows vary
- System level controls must adequately regulate both temperature and flow as system demand varies
- Adequate time must be budgeted to design and program the system control sequence
- The system operator must understand the intended operation
- The system must include a means of assuring all chiller minimum-flow requirements, normally one of the bypass methods previously discussed.

VPF complicates all aspects of system design and operation. Consequently, there are many steps that must be taken to allow a VPF system to work well.

Chilled-Water-Control Options

Chilled water reset — raising and lowering

Many chilled-water plants use chilled water reset, that is, changing the chiller's control setpoint, in an effort to reduce chiller energy consumption. As discussed in the first section *Chilled-Water Plant Basics*, page 3, raising chilled-water temperature reduces *chiller* energy consumption. In a constant-volume pumping system, this may reduce system energy consumption as long as humidity control is not lost. Humidity control may be lost if, as chilled-water temperature is increased, the air temperature leaving the coil increases to a point where it no longer performs adequate dehumidification.

In a variable-volume pumping system, however, raising the chilled-water temperature increases pump energy, often substantially, and typically increases total system energy. Before considering increased chilled-water temperature, the system operator should calculate the increased pumping energy and compare it with the chiller energy savings. It should be noted that ASHRAE/IESNA Standard 90.1–1999[1] requires chilled-water reset for constant-volume systems — with exceptions — but exempts variable-volume systems from this requirement for the reasons discussed.

An often overlooked method of decreasing *system* energy consumption is to *reduce* the chilled-water temperature, thereby decreasing pumping energy but increasing chiller energy. This strategy is possible with adequate chiller capacity and lift capability. Reducing chilled-water temperature may also improve dehumidification in the building. Another result of reducing the chilled-water temperature is increased chiller capacity during times when the condenser water temperature is cooler than design. This allows more time before another chiller and its ancillary equipment are started. This option is more fully discussed in *Low ΔT syndrome*, page 63.

Be aware that *any* change in chilled-water set point requires changes to be made to the system chiller-sequencing algorithms to ensure that system capacity is met. This added complication may not be warranted.

Chilled-Water-Control Options

Critical valve reset

Often, pumps are controlled to maintain a constant-pressure differential at a remote coil. Unless this coil serves the zone requiring the most cooling (the critical zone), the pump provides more pressure than necessary and consumes more power than necessary. Systems that have integrated air-side and chiller plant control systems and contain valves with direct digital controls present an opportunity for further pump operating-cost reduction. If a system is monitored to determine the critical valve at each point in time, the pump's operating pressure can be reset so that the critical zone's control valve is nearly open. Integrated control allows a system-level controller to determine the critical zone and reset the pump's set point dynamically, therefore reducing pump operating costs.

The controllers know the position of their individual valves, which modulate to maintain the required water flow through the coil. The building automation system continually monitors the valve controllers, looking for the most open valve. The controller resets the pump set point so that at least one valve, the one requiring the highest inlet pressure, is nearly wide open. The result is that the pump generates only enough pressure to get the required water flow through this "critical" valve, thus saving pumping energy.

Design Considerations

Chilled-water-pump configuration

Pumps may be either on the inlet or the outlet of the chiller, as long as the inlet of the pump experiences an adequate, positive suction pressure. In applications where there is a significant liquid column head (for example, a high-rise building), the pump is often located at the chiller's *outlet* so that the evaporator bundle is subject to the static head rather than the static-plus-dynamic (added by the pump) head. The need for high-pressure water boxes on the chiller can be eliminated.

An additional advantage of locating the pump upstream of the chiller is that if the pump motor rejects its heat to the water, the heat can be removed directly by the chiller. The chiller does not need to compensate for the pump heat by making colder water.

Pump per chiller

In either a primary–secondary or variable-primary-flow system, using one pump per chiller simplifies system hydraulics. The pump can be selected to produce the flow and pressure drop necessary for the specific chiller. Bringing additional pumps on changes system hydraulics, but only minimally. One drawback of such a system is a lack of redundancy, since the pump and chiller are dedicated to one another. This may be overcome by using a spare pump, pipes, and valves so that the spare pump could work with any chiller during emergency conditions.

Manifolded pumps

In an effort to resolve the redundancy consideration, some designers prefer to manifold pumps and provide $n+1$ pumps, where n is the number of chillers. Such an arrangement allows any pump to be used with any chiller. However, system hydraulics become more complicated. Unless all piping runs and evaporator pressure drops are equal, the amount of water flowing to each chiller will differ. As discussed with the variable-primary-flow system, manifolded pumps present a control challenge when chillers are sequenced.

Either pump configuration can be successful; one pump per chiller simplifies the hydraulics, while manifolded pumps allow redundancy.

Design Considerations

Bypass-line sizing

Bypass lines are required in both primary–secondary and variable-primary-flow systems. In a decoupled system, the bypass line should be sized for 110 to 115 percent of the largest chiller's design flow rate. In a VPF system, the bypass line should be sized for the largest chiller's minimum flow rate.

While minimal pressure loss is desirable, substantial water velocity can be accommodated without significant pressure loss in the relatively short length of bypass piping. The bypass line must be of sufficient length to prevent random mixing of the supply and return water streams; a minimum length of five to ten pipe diameters is recommended.

Amount of fluid in the loop

Two questions must be answered when determining how much fluid is necessary to maintain proper chilled-water-system control.

- How fast can the specific chiller respond to changing conditions?
- How fast can the system respond to changing conditions?

The amount of fluid the loop requires to operate properly is related to the larger of these two answers. Note that both answers describe an amount of time.

Required Volume = Flow Rate x Loop Time

Where:

- Required Volume = the amount of fluid in the coil, pipes, evaporator barrel, storage tank, etc., in gallons [liters]
- Flow Rate = the system flow rate, in gpm [lps]
- Loop Time = the time it takes for fluid to leave the chiller, move through the system and return to the chiller, *and allow for stable system operation*, in minutes [seconds]

Design Considerations

Chiller response to changing conditions

Follow the manufacturer's advice for the specific chiller being considered. This determines the absolute minimum amount of water the loop requires. However, this is the chiller minimum, not the system minimum, as discussed in the next section. Many of today's chillers have controls that respond quickly to changing conditions. Some chillers can react to a change in return water temperature in one minute; other chillers may require five or more minutes to react. The response varies, depending on chiller type and design.

System response to changing conditions

It is important to understand that even if a chiller can respond to rapidly changing conditions, the interaction between the chiller, system pumps, and control valves may define the minimum loop time. These components may "hunt" if the system conditions change too rapidly. Review these interactions to ensure that system control will be stable.

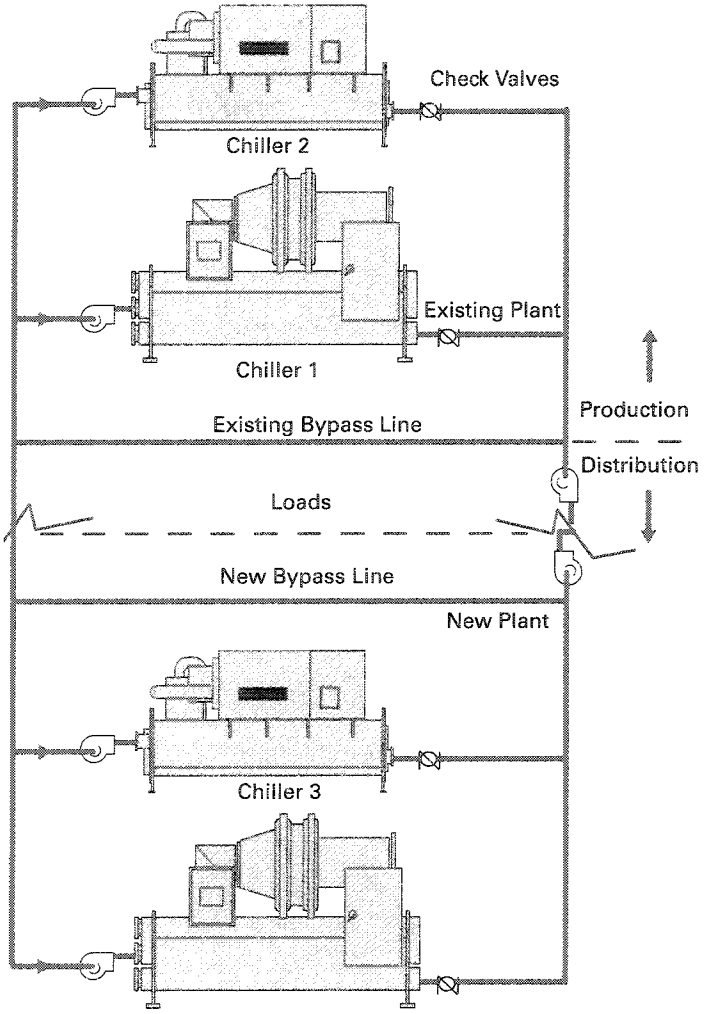
Example:
A specific chiller requires at least two minutes of water in the loop to operate properly. However, after considering the system interaction, it's decided that a five-minute loop time will work best. The system flow rate is 960 gpm [60.6 lps].

Required Volume (R.V.) = 960 gpm x 5 minutes = 4,800 gallons
[R.V. = 60 lps x 5 minutes x (60 seconds/1 minute) = 18,180 liters]

If the volume of fluid in the evaporator bundle, piping, and coils is less than the required volume, a tank should be added to increase loop volume. For optimal stability, the tank should be placed in the return water position and be designed to *mix* the returning-water stream with the water currently in the tank.

Plant expansion

Plant expansion can be performed easily in either a primary–secondary or variable-primary-flow system by adding another chiller and pump to the system. The two major considerations will be whether the chilled-water distribution pipes will be able to handle the flow and how to install the new chiller while other chillers are still providing cooling. When the new system flow rate complies with good piping practice and the pumps can deliver the water, the process works well. To maintain chilled-water flow during installation of a new chiller, some plants are constructed with piping stubs in place for the new chiller. In this way, the new chiller can be installed while the system is still operating, then the valves in the stubs can be opened.



Design Considerations

When decoupled systems are used on large campus-type systems, added loads are often located some distance away from the original loads. Yet, planners like the idea of somehow hooking the new loads to the existing system. The double-ended system shown in Figure 19 is one way of handling this requirement. A second production facility is placed at a convenient location in the new part of the campus. Its distribution plant is laid out as a mirror image of the original piping, and connects to it at the ends of each system.

This way, either production loop can feed into the now common distribution loop. The point of no-flow simply floats as the two production plants are loaded. If, at very low seasonal loads, the operators want to secure one entire production loop, it is not a problem if the on-line plant has adequate production and distribution capacity. With full-time plants, this tactic can be used to reduce operating expenses significantly for many weeks of the year. Further, it permits preferential loading of the newer, more efficient machinery.

Design Considerations

Figure 19 Double-ended decoupled system

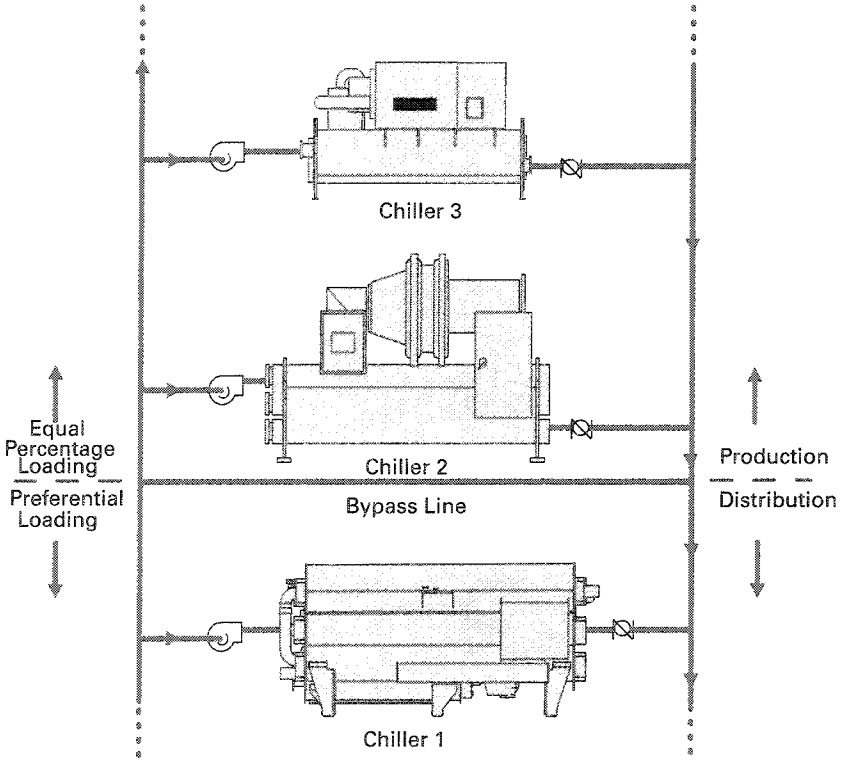
Chilled-Water System Variations

A number of chilled-water system variations can and should be used when appropriate. Each configuration offers specific advantages to solve problems and add value to the system.

Heat recovery

ASHRAE/IESNA Standard 90.1–1999[1] now requires heat recovery in specific applications. Indoor air quality concerns have spurred the use of systems that subcool supply air to dehumidify, then temper, the air to satisfy space conditions. ASHRAE/IESNA Standard 90.1–1999 also limits the amount of new reheat energy used in these applications. With these drivers, and energy costs, there has been a resurgence of heat recovery chillers. The example on page 58 describes a cost-effective recovered-heat scheme. This scheme is commonly used for service-water heating in resort hotels and for certain process loads.

Preferential loading



Preferential loading is desirable for systems that use heat recovery since the heat recovery chiller may remain more fully loaded, thus producing more heat that can be recovered for the desired process. Preferential loading may also be beneficial for use with either a high-efficiency chiller that should be fully loaded whenever possible, or a chiller using a fuel other than electricity, such as an absorption chiller using waste steam from a cogeneration plant or a chiller coupled with an engine that generates electricity. When used with the latter, the system is able to preferentially load the alternate fuel chiller when the cost of electricity is high.

Chilled-Water System Variations

Parallel arrangement

If a chiller, in a decoupled system, is moved to the distribution side of the bypass line, system hydraulics, and temperatures, the chiller is preferentially loaded when it is turned on. As shown in Figure 20, Chiller 1 always sees the warmest system water and is preferentially loaded. As previously discussed, chillers on the production side of the bypass line (Chillers 2 and 3) will be loaded to equal percentages.

Figure 20 Parallel preferential loading arrangement

One caveat when applying this arrangement is that chillers on the production side of the bypass line will run more often at low part-load conditions. Older chillers or newer chillers that have a high cycle point may not have this capability.

Chilled-Water System Variations

Sidestream arrangement

Figure 21 Sidestream preferential loading arrangement

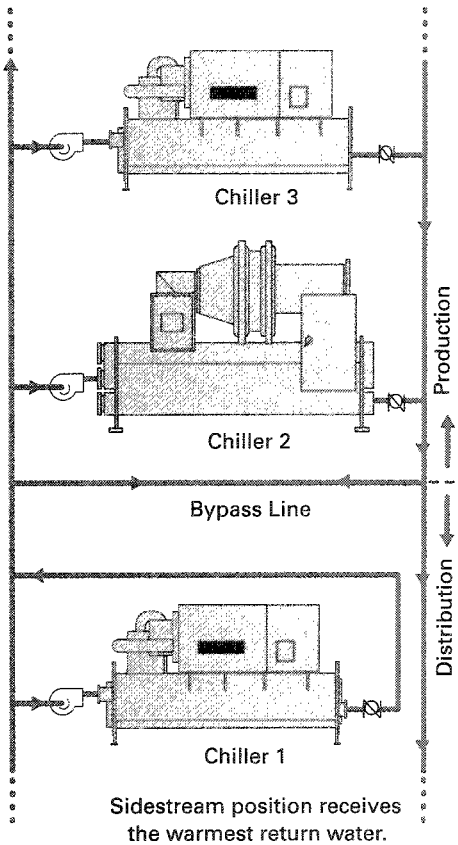


Figure 21 shows a simple modification to the traditional decoupled arrangement. The sidestream arrangement assures that the chiller piped in the sidestream position receives the warmest entering-water temperature and can fully load it whenever the chiller plant operates.

This arrangement is unique because it not only allows preferential loading, but it also permits the cooling device (chiller, heat exchanger, etc.) in the sidestream position to operate at any temperature change. This configuration precools the system-return water for the chillers downstream, reduces their loads and energy consumption, and decreases the overall operating cost of the chilled-water plant.

When cooling devices are located in the return piping of the distribution loop, they do not contribute to system demands for flow. They simply reduce the temperature of return water to the production loop. While this is counter-productive to the principle of striving for the highest possible return water temperature, it is often the best way to obtain free cooling, specialized heat recovery, or reducing the capital cost of ice storage equipment.

Sidestream, decoupled applications are usually most economical when the sidestream chiller is smaller than those on the production side of the bypass line. Since pumping requirements and energy consumption change with modifications to the system arrangement, it is best to use a computerized analysis tool to model the economic effects.

Following are three different system configurations that can benefit from the sidestream application.

Chilled-Water System Variations

Figure 22 Plate-and-frame heat exchanger

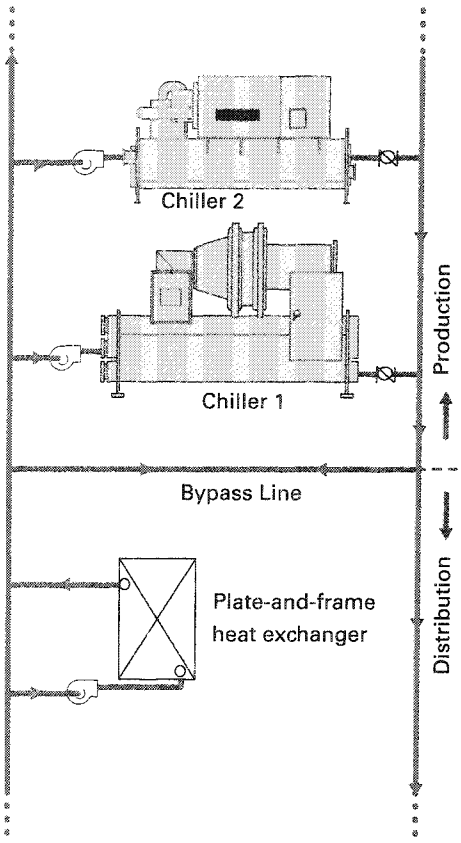

Plate-and-frame heat exchanger

A free-cooling heat exchanger[8] may be capable of chilling water to only 48°F [8.9°C] during some periods. Rather than overlook this portion of cooling capacity assistance, the heat exchanger does whatever it can to its portion of the total return stream. Chillers operating downstream can reduce chiller-water temperature further, allowing simultaneous free cooling and mechanical cooling. This configuration increases the hours that the heat exchanger may be used. Since this capacity is brought to bear on the warmest water in the system, it has the greatest impact.

Heat recovery

A similar situation occurs if a heat-recovery chiller is placed in this sidestream position[5] (see Figure 22). This chiller may be equipped with a heat recovery condenser or it could be a standard, single-condenser chiller operating as a heat pump. The chiller may not be capable of cooling water to the system supply temperature. That is unimportant with this configuration. Think of the machine as a heater instead of a chiller. Its primary function is heating, and cooling is a beneficial by-product. The passing return-chilled-water stream appears as an infinite heat source to the heat recovery chiller. The chiller only cools its evaporator water enough to satisfy the heating demand. This avoids the control predicament of deciding how to reject surplus condenser heat when the cooling and heating loads of a chiller do not strike a perfect heat balance.

Optional fuels

An absorption chiller may be applied in a sidestream location. This allows the chiller to be loaded whenever utility rates make it beneficial. It also ensures the absorption water chiller the warmest entering-water temperature, allowing it to operate more efficiently and produce more cooling.

System control

The flexibility of sidestream applications is increased by the fact that the devices are used to precool return water, not to produce the system chilled-water temperature. This means that they may be loaded by a different signal. In the case of a plate-and-frame heat exchanger, as long as return water is being cooled, there is an advantage to using it. A heat-recovery chiller can be loaded to produce just the amount of hot water necessary using the condenser-water leaving temperature as a signal. If preferential loading is used with an absorption chiller, it may be loaded simply by decreasing its leaving-water temperature.

Chilled-Water System Variations

Unequal chiller sizing

Many designers seem to default to using the same capacity chillers within a chilled-water plant.[2,3] There are benefits to sizing chillers to meet the system loads. One is that when a chiller is brought on line, so is its ancillary equipment, thus increasing *system* energy consumption. In general, the smaller the chiller, the smaller the ancillary equipment. Another is to ensure that chillers are efficiently loaded. Many times this can be accomplished by using chillers that do not have the same capacity. Examine the use of 60/40 splits (one chiller at 60 percentage system capacity, the other at 40 percent) or1/3–2/3 splits (one chiller at 1/3 of system capacity the other at 2/3). The benefit is that the system load can be more closely matched with the total chiller capacity, increasing total system efficiency.

Series–counterflow application

The series–counterflow configuration can work with all types of chillers. Duplex chillers are shown in Figure 23. A single large chiller may be built as a duplex machine. The evaporator and condenser water circuits are common to both *halves* of the duplex. Increased efficiency comes from the separation of the compressors and refrigerant circuits. Thus, each *half* is redundant for increased system reliability.

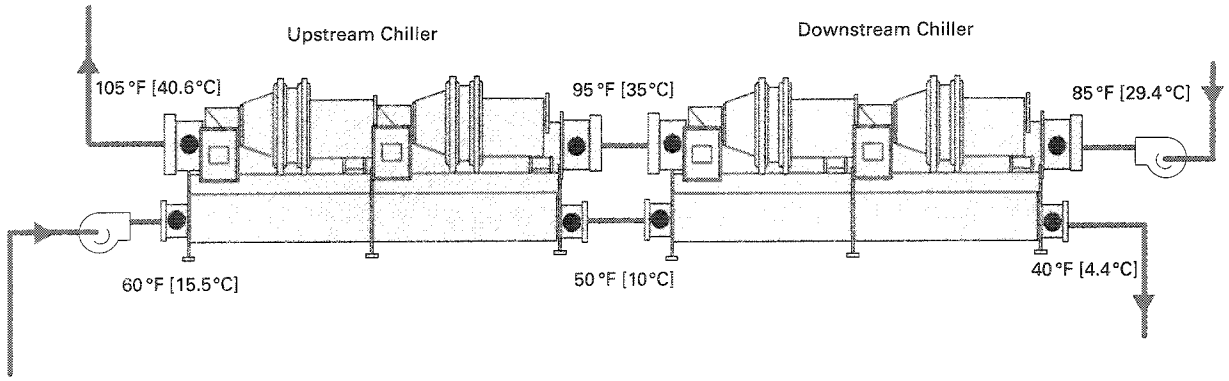
Another system configuration that can be very energy efficient incorporates the previously described series application, but does so for both the chilled water *and* condenser water. Figure 23 shows such a configuration.

Note that the downstream machine, in this case, produces 40°F [4.4°C] chilled water, while the upstream machine produces 50°F [10°C] chilled water. The downstream machine receives 85°F [29.4°C] condenser water, while the upstream machine receives 95°F [35°C] condenser water. Therefore, the pumping requirements are only 1.2 gpm/ton on the chilled water side and 1.5 gpm/ton on the condenser water side — greatly reducing pumping costs.

The configuration has the effect of equalizing each chiller's required lift, as shown in Figure 23a. The chilled- and condenser-water flow directions are opposite, or counter, to one another. Thus the name, series-counterflow.

Chilled-Water System Variations

Figure 23 Series–counterflow arrangement



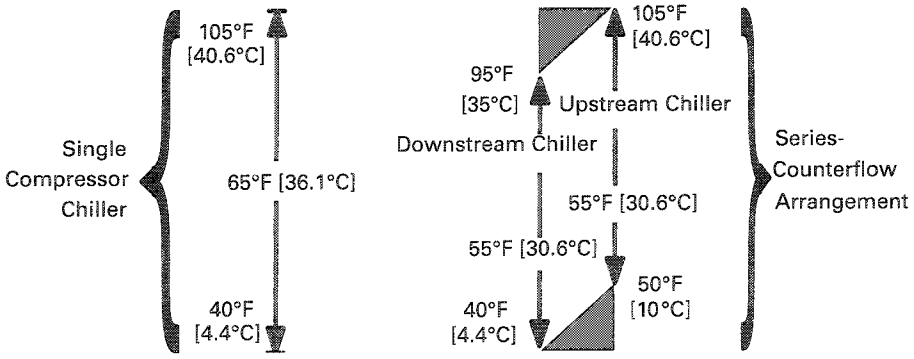


Figure 23a Equal lift concept

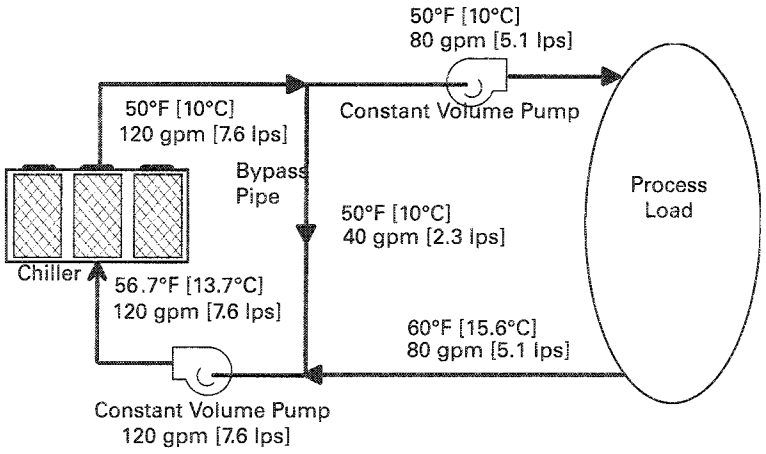
Chilled-Water System Variations



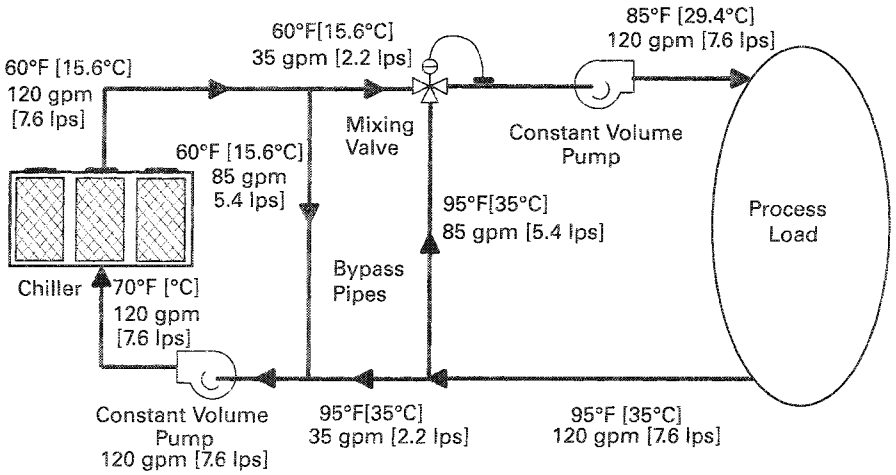
Applications outside the chiller's range

Designers may wish to use chillers to provide cooling for which the flow rate or temperature requirements are not within the ranges of a particular chiller, even though the chiller has adequate capacity. This often occurs with manufacturing processes. Let's look at two examples showing *system* designs that can satisfy the desired conditions.

Flow rate out of range

A plastic injection molding process requires 80 gpm [5.1 lps] of 50°F [10°C] water and returns that water at 60°F [15.6°C]. The selected chiller can operate at these temperatures, but has a minimum flow rate of 120 gpm [7.6 lps]. The following system in Figure 24 can satisfy the process. Decoupling the chiller from the process load allows the water flow to be different, ensuring that the flow through the chiller is within acceptable limits. With a single chiller system, one pump and a three-way valve gives the same results.

Figure 24 Flow rate out of range for equipment



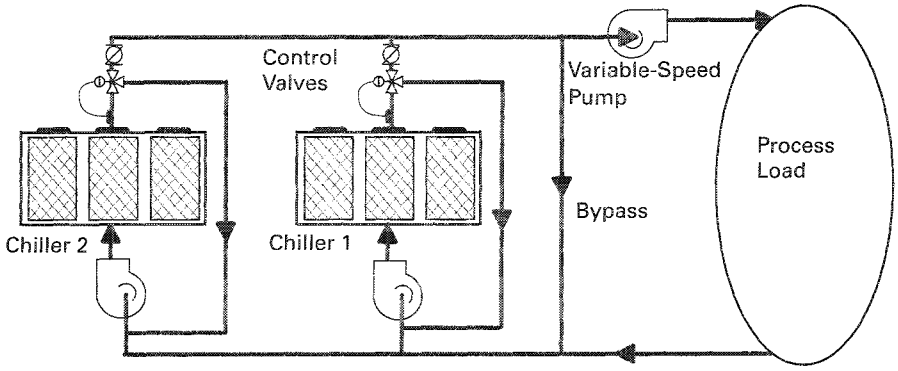
Chilled-Water System Variations

Temperatures out of range

A laboratory load requires 120 gpm [7.6 lps] of water entering the process at 85°F [29.4°C] and returning at 95°F [35°C]. The accuracy required is more precise than the cooling tower can provide. The selected chiller has adequate capacity, but a maximum leaving-chilled-water temperature of 60°F [15.6°C].

Using a pair of bypass pipes allows the mixing valve to supply the proper temperature to the process load and maintains acceptable water flow rates and temperatures through the chiller. In the example shown in Figure 25, the chiller and process flow rates are equal, although this is not a requirement. For example, if the chiller had a higher flow rate, more water would bypass and mix with the warm return water.

Figure 25 Temperatures out of range for equipment



An example of a process application layout where the required temperature control tolerance is more precise than the chiller controls allow is shown in the Figure 26.

For example, when Chiller 2 is turned on, it takes a certain amount of time to reach its supply-temperature setpoint. The dedicated control valve remains closed and water is bypassed until Chiller 2 reaches its setpoint, which keeps the water temperature supplied to the process within tolerance. When Chiller 2 reaches its setpoint, the control valve opens.

This design requires a different chiller-sequencing strategy than the standard decoupled system. Water must not be allowed to bypass from the return side to the supply side, since this will cause the temperature of the water supplied to the process to vary outside the tolerance. Set the system controls to turn on Chiller 2 before deficit flow occurs.

Chilled-Water System Variations

Chilled-Water System Issues

Low ΔT syndrome

During the past several years the "low ΔT syndrome" debate has raged.[1,3] The symptom of the problem is that, in large systems, return-water temperature is too low, thus not allowing the chillers to fully load. Many system operators simply turn on more chillers to satisfy flow requirements. Some system designers advocate putting a check valve in the bypass line—thus putting chilled-water primary and secondary pumps in series and varying the flow through chiller evaporators. Other designers install primary pumps that are larger than necessary and "overpump" chillers at part-load conditions. These solutions are all "band-aids" and do not treat the source of the problem.

Coad[2] points to the fact that a properly operating hydraulic system will work as designed and explains the fallacies in the check valve and overpumping approaches. Taylor[5] recommends that a number of mitigating procedures be implemented to eliminate the problem. They include:

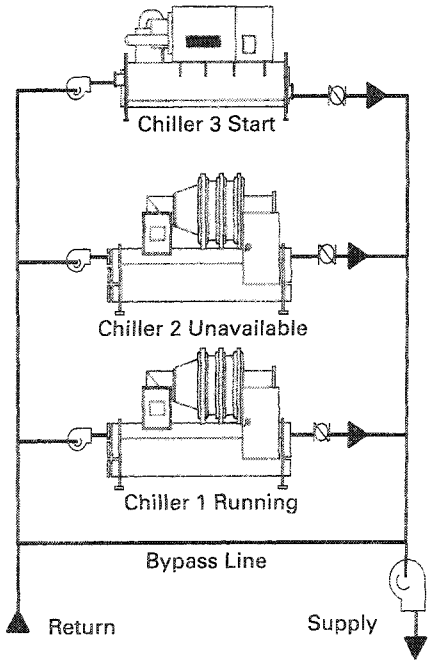
- Eliminate three-way valves
- Ensure that airside control is not causing the problem
- Properly maintain the system, including regular air filter changes, coil cleaning, control calibration, and proper setpoints

Before applying band-aid approaches to "fix" symptoms such as low ΔT syndrome, ensure that the system is operating properly using some or all of the procedures Taylor[5] discusses. In addition to these procedures, simply reducing the chilled-water supply temperature will have the effect of raising the system return-water temperature in systems using two-way valves.

Check valve in the bypass line

Some designers recommend the installation of a check valve in the bypass line of a primary–secondary system to eliminate the possibility of deficit flow in the bypass line. The premise is that if there is a system problem (low temperature differential), the check valve will put the primary and secondary pumps in series and pump more water through the chiller, thus balancing the primary and secondary flow requirements. This is not universally accepted. Coad[2] states,

> One constraint is that if the system is designed as variable flow and is experiencing operating problems related to low return water temperatures, the solution is *not* in the plant but rather in the load.
>
> **and**



Chilled-Water System Issues

> One solution that has been suggested is to install a check valve in the plant common pipe or decoupling line circuit ... However, to be realistic, all that the check valve can do is assure that no water bypasses the chillers, which in turn has the effect of increasing flow in the chiller. Thus with the installation of the check valve must be an algorithm to either slow down system pump(s) when flow increases beyond the design maximum for the on chiller or turn on additional chillers. Thus the check valve solution offers its own problems and many designers feel very uncomfortable with forcing pumps into series operation without the benefit of understanding the full impact thereof.

This manual does *not* recommend the use of check valves in the bypass line.

Failure recovery

Figure 27 Failure recovery

With all the varied approaches available to potential customers, it sometimes seems that the main idea gets lost. People purchase chilled-water plants to reliably produce chilled water to satisfy another need, such as comfort or process cooling. Therefore when the plant operates there must be a process in place to recover from the failure of a chilled- or condenser-water pump, cooling tower, or chiller. Failure recovery should be integral to the chilled-water plant control system. Refer to Figure 27. If the control sequence tries to start Chiller 2 and its pump, but the pump has an electrical malfunction, the sequence should immediately lock out Chiller 2 and its pump. The control system should then attempt to start Chiller 3 and its pump. At the same time, the control system should send a pump malfunction alarm to the system operator.

Alternative energy sources

Energy source redundancy is receiving increased attention due to rate variations and reliability issues brought about by the deregulation of electrical utilities across the country. There are two basic approaches to meet these issues:

- Provide an alternate source of internally-generated electricity to serve a system in the event of general failure or an unacceptably high temporary cost of electricity (time-of-day rates).
- Provide an alternate source of chilled-water producing capability, possibly fueled by natural gas, another fossil fuel, or even using low cost electricity as an alternative energy source.

Chilled-Water System Issues

Electricity generation

The design, construction, and operation of full-capacity, electrical-generation systems is well understood. The electrical-generation capacity can be sized to allow an entire facility to operate or it can be sized for an emergency situation. Electrical generation can be outsourced to avoid internal capitalization.

A variation of electrical generation uses an engine indirectly- or directly-coupled to a chiller. Either variation produces chilled water using an alternative fuel such as natural gas or fuel oil. The indirect-coupling method allows the chiller to operate using an alternative fuel or electricity from the grid. An engine directly-coupled to a chiller can only run using the alternative fuel.

Alternative fuel

Some designers prefer to employ chillers that use fossil fuels. Examples are absorption chillers using natural gas, steam, or hot water. Plants with these chillers, discussed in detail elsewhere[4], allow the owner to take advantage of permanently expected fuel rate separations.

Thermal storage

Another successfully applied alternative-energy source is thermal storage. Chillers make either ice or chilled water during times of decreased electricity costs. The energy is stored in tanks and then discharged to satisfy cooling loads during times of high electrical costs. Other manuals describe the use of thermal storage in detail. [6,7,8,9]

Use any of these technologies to provide value to the building owner through judicious use of alternative fuels.

Chilled-Water System Issues

Contingency

In addition to failure recovery, it may be wise for plant designers to work with building owners to develop a contingency plan for chilled water in the case of emergency shutdown or an extended breakdown. Often this is critical for process cooling applications. Such a plan can include working with suppliers to establish a short lead-time on equipment leasing. When equipment leasing is combined with, for example, piping stubs built into the chilled-water system for quick connection, a contingency plan can be put into action quickly and the system can produce chilled water again in a short period of time.

Cooling contingency planning

Today, many organizations have contingency plans for critical areas of their business. Some deal with natural disasters and others with the loss of power in critical areas. However, few have actually taken the time to think about what a loss of cooling would mean to their facility. If the cooling system failed or was suddenly grossly undersized due to weather, etc., how would that affect business? What financial risk would be involved with a loss of cooling?

Cooling contingency planning is intended to minimize the losses a facility may incur as a result of a total or partial loss of cooling. It allows a building owner to act more quickly by having a plan in place and by proactively preparing his or her facility to accept temporary equipment. Although a number of facilities are prepared after the construction phase, the construction phase provides an easy and cost-effective opportunity to prepare a facility and is a logical time to provide water stubouts and electrical connections. This helps to keep costs down and reduces the need to shut down existing equipment to make necessary building preparations.

Cooling contingency planning is the process of preparing for a loss of cooling while in a nonemergency situation. This allows common sense, rather than panic, to prevail during a critical event. The following topics are general and broad in scope. They provide a sense of what is involved in the planning process. Contingency planning itself is very detailed and situation-specific.

Minimum capacity required It is important to first identify the minimum capacity required. With multiple chillers in a facility, it may be acceptable to have less tonnage in an emergency situation. For example, a facility's chiller plant may consist of 1,800 tons [6,330 kW], but the minimum tonnage required may only be 1,200 tons [4,220 kW]. Therefore, it is also important to identify the plan of action if Chiller 1 fails, if Chiller 2 fails, if Chillers 2 and 3 fail, and so on.

Chilled-Water System Issues

Type and size of chiller The type and size of contingency cooling required by a facility are determined by several factors. In turn, the choice of chiller determines how the facility is prepared. Examples of parameters that determine the chiller are:

- Electrical requirements
- Ease of installation (air-cooled chillers are easier to set up)
- Location or available space
- Comfort or process cooling

Location of equipment Location can be a major factor in contingency planning. When selecting the location of the temporary equipment it is important to consider:

- Water and electrical connections location
- Sound sensitive areas in the facility
- Location easily accessible to service staff
- Equipment separated from the public

Water and electrical connections

- Water connection size requirements
- External stubout locations
- Sufficient power to run the temporary unit
- Possible generator requirement

Ancillary equipment

- Pumping system requirements
- Temporary hose requirements
- Electrical cable requirements

This section briefly describes some of the items to consider when establishing a cooling contingency plan. Keep in mind that there may be other considerations, depending on the application.

Condenser-System Variations

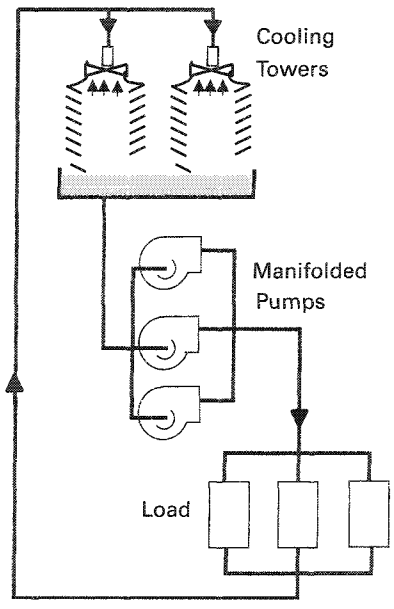
Water-cooled chillers require condenser-water-system variations to be considered. For a discussion of condenser-water temperatures and flow rates refer to the section, *Chilled-Water-Plant Basics,* page 3. Since air-cooled-chiller condenser controls are part of the chiller design, they are not discussed in this manual.

To ensure optimum heat transfer performance, the condenser-heat transfer surfaces must be kept free of scale and sludge. Even a thin deposit of scale can substantially reduce heat transfer capacity and chiller efficiency. Specifics of cooling-tower-water treatment are not discussed in this manual. Engage the services of a qualified water treatment specialist to determine the level of water treatment required to remove contaminants from the cooling tower water.

Condenser flow configurations

Most importantly, the inlet to the pump must be under sufficient net positive head. This often means locating the pump below the cooling-tower sump.

Single tower per chiller



In some applications each chiller has a dedicated cooling tower. This is most likely to occur when chillers, and their accompanying towers are purchased at different times during the facility's life — such as when additions are made.

Manifolded pumps

A much-used pumping arrangement has a single cooling-tower sump with manifolded pumps, one condenser water line, and separate, smaller, pipes for each chiller as shown in Figure 28. This provides a number of advantages:

- Pumping redundancy
- If cooling towers cells can be isolated, any cooling-tower cell runs with any chiller
- Hydraulics are generally less problematic than on the chilled waterside
- Cooling towers can be located remotely from chillers, with only a single supply and return pipe to connect them

Figure 28 Manifolded condenser-water pumps

Condenser-System Variations

Condenser water control for transient conditions

Every chiller requires a pressure differential between the evaporator and condenser in order to operate. The chiller must develop its pressure differential within a manufacturer-specified time or its controls will shut it off. During some start-up conditions, this pressure differential may be hard to produce within the time limitation.

An example of such a condition is an office building that has been unoccupied during a cool, clear, fall weekend. The tower sump water is at 40 °F [4.4 °C]. Monday is sunny and warm, which requires a chiller to be turned on. Since the chiller is lightly loaded and the tower sump is large, the pressure differential can not be reached before the chiller turns off. If the condenser flow rate for a given chiller can be reduced, this scenario is less likely to occur. The lower flow rate increases the leaving condenser-water temperature, condenser-refrigerant temperature, and refrigerant pressure.

The flow reduction options include:

- Cooling tower bypass
- Chiller bypass
- One or two throttling valves in the condenser water pipe with the pump riding its curve
- A variable-speed condenser water pump

Once the minimum-pressure differential is reached, the flow may be increased as long as that minimum-pressure difference is maintained. Some designers and operators become concerned with possible fouling of condenser water tubes during these start-up conditions. There is little to fear due to the short duration of reduced flow operation and the limited occurrences. The advantages and disadvantages of these options are discussed in a variety of publications.[1,5]

Condenser-System Variations

Cooling-tower-fan control methods

Cooling towers operate to produce the sump water temperature. As the heat-rejection load and ambient wet bulb change, the cooling tower fans must move either more or less air to produce the desired water temperature.

Cycling a single fan

Cycling a single fan on and off is one method to maintain rough water temperature control. Since airflow changes greatly between fan speeds, so does heat rejection. Temperature swings of 7 °F to 10 °F [3.9°C to 5.6°C] are not uncommon. Some chillers, especially older chillers with pneumatic controls, may operate poorly in response to these changing temperatures. Care must also be taken to ensure that the fan does not cycle too often and damage the motor, drive, or fan assembly.

Two-speed fans

The installation of two-speed cooling tower fans is an option used frequently to reduce temperature swings. Typically, the low fan speed is between 50 and 70 percent of full speed. Since the heat rejection changes roughly in proportion with the fan speed, the temperature swing will be only 50 to 75 percent of cycling a single fan. Again, care should be taken not to cycle too often between speeds — or the gear box may incur excessive wear and fail. A distinct advantage of two-speed fans is that at low speed, the fan power is greatly reduced. Since the fan power varies with the cube of the speed (approximately) the power at half speed is about 15 percent of full speed.

"Pony" motors

Another option offered by cooling-tower manufacturers is to have two separate motors available to drive the fan. The smaller motor is referred to as a "pony" motor. It operates at two-thirds of the full speed and uses about 30 percent of the full speed power. While controlling the tower, it is important to minimize cycling between speeds.

Variable-speed drives

Using variable-speed drives on cooling-tower fans offers two distinct benefits. First, the tower-water-temperature control is extremely good. Second, the fan power varies with the cube of the speed, so there is great potential for energy savings. Variable-speed drives also allow the fan speed to be changed without fear of gear box or motor wear. They may also offer acoustical advantages by significantly lowering sound power at reduced speeds.

Condenser-System Variations

Plate-and-frame heat exchanger

As previously discussed in the section *Chilled-Water-System Variations*, page 57, a plate-and-frame heat exchanger may be used in conjunction with a cooling tower to provide cooling during very low wet-bulb conditions. When it is to be used for these purposes, designers often specify a cooling tower larger than necessary for design conditions so that it can be used for many hours with the plate-and- frame heat exchanger.

Well, river, or lake water

There are times when well, river, or lake water will be pumped through the condenser. In these cases, an examination should be undertaken to balance the cost of pumping the water with the benefit the chiller gets when more water passes through its condenser. The environmental limitations imposed by local codes are another consideration. Some locales will not allow well water to be dumped after being used. Other local authorities limit the maximum water temperature that may be returned to a body of water. Flow rates need to be carefully selected to balance the economic and environmental requirements.

Condenser-water temperature control

Chiller–tower energy balance

The subject of condenser-water temperature control has been studied by a number of people. In recent years, Braun and Didderich[2]; Hydeman, Gillespie, and Kammerud[3]; and Schwedler[4] have all independently noted that balancing chiller and cooling-tower energy is important. Hydeman, et al., showed that at various loads and ambient conditions, the optimal condenser-water temperature for a specific chilled-water plant depends on both chiller load and ambient conditions, see Figure 29. All the studies showed that during many points of operation, the optimal condition is *not* the lowest water temperature the cooling tower can produce. It is important for the system designer and operator to examine the use of system-level controls to set the tower-sump-temperature setpoint to reduce the sum of chiller-plus-tower energy. This optimal chiller-tower control can be automated by a chiller-plant management system.

Condenser-System Variations

Figure 29 Chiller–tower optimization

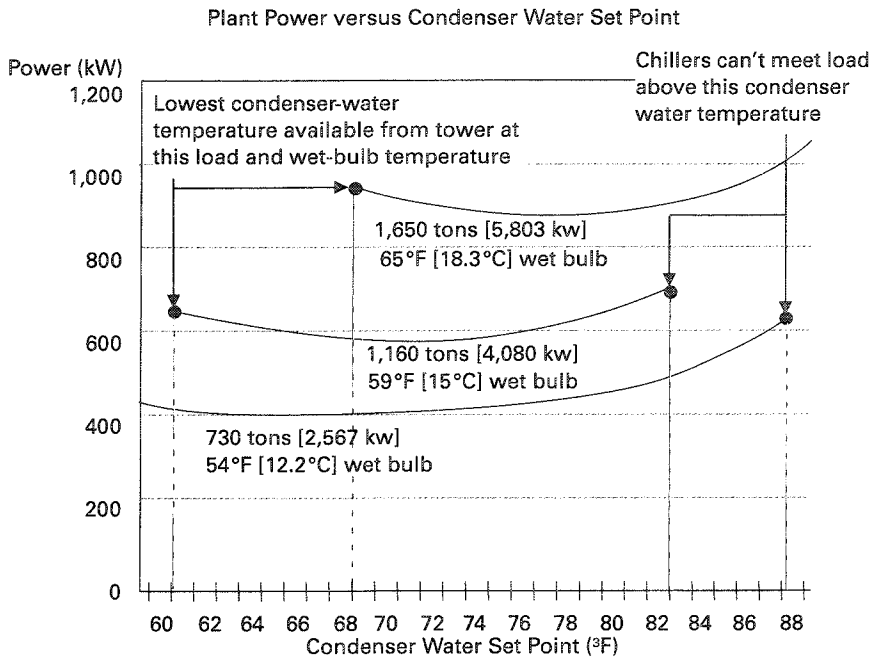


Figure 29 from Hydeman, et al., used with permission.

Condenser-water pump options

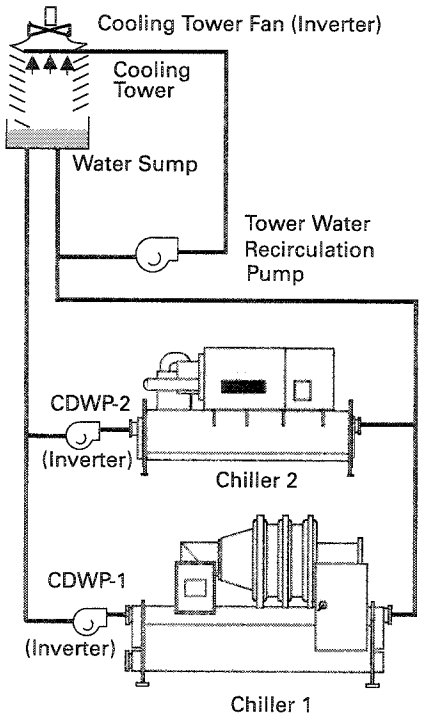
Chiller–pump balance

There are times when a system designer may choose to vary the condenser water flow in addition to, or instead of, the cooling-tower fan speed. This may be beneficial in systems with high pumping power. If a variable-speed drive is installed, the flow may be reduced and the pump power can be reduced substantially — approximately with the cube of the speed. Attempting to vary both the pump and the tower fan speeds is complex and requires adequate time for design and implementation.

Condenser-System Variations

Variable flow limitations

Care should be taken to keep the flow through the condenser above the minimum allowable flow rate for the chiller's condenser. The operator should regularly log the condenser approach temperature (the temperature difference between the condenser's refrigerant temperature and the condenser-water leaving temperature) to ensure that the tubes are not becoming fouled. The approach temperature may be monitored using a chiller plant management system.



Tower and/or tower nozzle design can affect the allowable condenser-water flow. If the flow drops below the manufacturer's specified limit, the water is no longer evenly distributed over the tower fill. This results in a decrease in cooling-tower heat-transfer effectiveness. In extreme cases, it can also result in water freezing in the cooling tower. If variable tower flow is a consideration, contact the cooling-tower manufacturer to determine the flow limit and possibly choose nozzles or cooling-tower configurations that can handle variable-water flow.

Decoupled condenser-water system

To overcome possible problems with variable-water flow across a cooling tower, some designers decouple the condenser-water system as shown in Figure 30. This arrangement allows energy optimization through a reduction of pumping power without excessively complicating the system. Because cooling towers work best with full water flow over the transfer media, a separate wetting (recirculation) pump provides a constant flow of water through the tower. This is a low energy pump, as very little lift is required.

Dedicated, variable-flow condenser pumps (CDWP-1 and CDWP-2) permit a reduction in the pumping energy whenever the temperature of condenser water results in an unproductive reduction of condenser refrigerant pressure. While the number of dedicated pumps may seem complicated at first, remember the number of valves and controls that are eliminated.

Figure 30 Decoupled condenser-water system

Condenser-System Variations

Retrofit opportunities

A tremendous retrofit opportunity can be realized if the low-flow concepts discussed earlier in the section *Chilled-Water-System Options*, page 20, is utilized. Building owners may need to increase the capacity of an existing system, for example in response to a building addition. In many of these buildings, the condenser water system (piping, pump, and tower) is in good condition, but is considered to be too small. By changing from traditional design conditions, the existing infrastructure can often be used while still providing additional capacity.

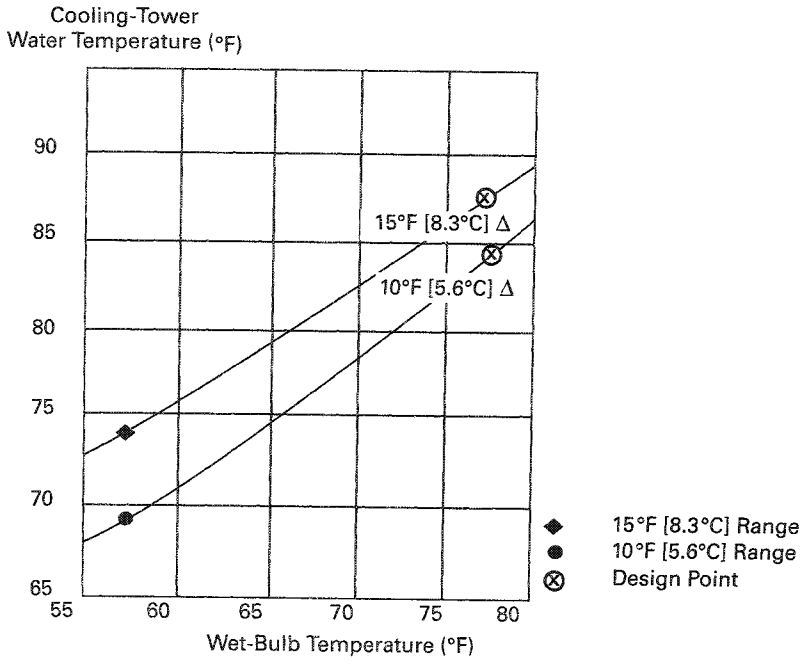
Keep in mind that a cooling tower is not limited to a specific tonnage. A cooling tower is a heat exchanger that exchanges heat between the entering water temperature and the ambient wet bulb. By varying the flow or the temperature, the tower capacity can be changed — often increased. An example can easily show this.

Example A hospital presently has a 450-ton [1,580-kW] refrigeration] chiller that needs to be replaced. The condenser water flow is 1,350 gpm [85.2 lps] The cooling-tower selection conditions are

- entering water temperature: 95°F[35°C]
- leaving water temperature: 85°F[29.4°C]
- ambient wet bulb: 78°F [25.6°C]

Recently, the cooling-tower fill was replaced. The tower, condenser water piping, and pump are in good condition. The hospital is planning an addition with 50 percent more load for a total of 675-tons [2,370-kW]. Must the hospital replace the condenser water system? The answer is "no", as long as the chiller is selected properly.

How is this possible? As long as the new chiller's condenser-water pressure drop is at or below that of the present chiller, the same amount of water can still be pumped. With the same flow rate, a 675-ton [2,370-kW] chiller may be selected with a condenser-water-temperature rise of approximately15°F [8.3°C]. Using the cooling- tower manufacturer's selection software, the same cooling tower can be selected at the elevated temperature difference. As shown in Figure 31, the new selection point will be:



- entering water temperature: 103°F [39.4°C]
- leaving water temperature: 88°F [31.1°C]
- ambient wet bulb: 78°F [25.6°C]

Condenser-System Variations

It quickly becomes evident that the same cooling tower and flow rate are adequate to reject more heat, in this case, approximately 50 percent more heat.

The design engineer can often help reduce total project costs using the existing infrastructure and selecting a chiller with a higher temperature differential.

Conclusion

Since most chilled water systems incorporate more than one chiller, it is vital to have a clear understanding of multiple-chiller concepts and their application. There is nothing particularly complex about the principles involved. Instead, system design is simply a matter of exercising a few key rules of applied physics.

A myriad of choices are available for the design and operation of chilled water systems. These choices include flow rates, temperatures, system configurations, and control options. After determining the needs and wants of the building owner and chiller plant operator, judicious use of these choices allows designers to provide solutions that add real value.

When applying the principles in this manual, it is important to remember the following rules:

- **Rule 1** Strive for simplicity. Simple does not always mean using the fewest components. Simplicity is usually elegant in its ability to be universally understood.
- **Rule 2** If the system designer can explain how a design works, there is a good chance that the system will function well. If the designer can't explain how the design works, there is *no* chance that the system will operate efficiently.
- **Rule 3** If the system operator understands the designer's explanation of how the system works, there is a good chance that the system will work. If the system operator doesn't understand the explanation, there is *no* chance that the system will operate efficiently.

Glossary

ASHRAE American Society of Heating, Refrigerating and Air-Conditioning Engineers.

building automation system A combination of controllers and other software products which communicate and control various mechanical systems to enable building management. These include the heating, ventilation, and air conditioning (HVAC) systems as well as lighting systems, access control, and miscellaneous other devices within a building. Also called a building management system (BMS).

chilled water Also know as leaving-chilled-water or leaving-evaporator-water; the cold water produced by the chiller (flowing through the tube bundle in the evaporator) and pumped to the air handler coils throughout the building. Within the evaporator, refrigerant surrounds the tube bundle and accepts heat from the return chilled water.

chiller An air-conditioning system that circulates chilled water to various cooling coils in an installation.

coil An evaporator or condenser made up of tubing either with or without extended surfaces (fins).

condenser The region of the chiller where refrigerant vapor is converted to liquid so that the temperature and pressure can be decreased as the refrigerant goes into the evaporator.

condenser water, leaving *See* cooling water.

cooling tower water *See* cooling water.

cooling water Also known as tower water, leaving-cooling water, leaving-condenser water, entering-absorber water, condenser-absorber water, entering-cooling water, or cooling tower water; obtained from the source (tower, river, pond, etc.) to which heat is rejected, flows through the tubes that run through the absorber and the condenser, and is returned to the source.

In electrically driven chillers, the cooling water picks up heat only from the condenser. In an absorption chiller, the cooling water also has to pick up heat from the absorber. The water typically flows from the source at 85°F [29.4°C], first to the absorber and then to the condenser (series flow). Associated water temperatures are referred to as entering-absorber-water temperature (or leaving-tower-water temperature) and leaving-condenser-water temperature (or entering-tower-water temperature).

COP Coefficient of Performance; cooling effect divided by heat input (dimensionless); the reciprocal of efficiency.

direct digital control Programming used by building control systems to control variable outputs, such as valves or actuators. In the HVAC industry, DDC means direct digital control by a microprocessor controller with no intermediate device.

Glossary

evaporator The region in the chiller where the system chilled water is continuously cooled down by flashing the refrigerant to vapor in a deep vacuum as it picks up heat from the returning system water.

fouling Deposits of foreign material in the water side of tubing in refrigeration condensers or chillers which affect the transfer of heat.

heat exchanger A device used to transfer heat between two physically separated fluids.

heat transfer The movement of heat from one body or substance to another. The three methods of heat transfer are conduction, convection and radiation.

load Any one of several output devices that are to be controlled by a building management panel.

mechanical-compression refrigeration cycle The electrically driven chiller makes use of an electric motor, driving a compressor to produce chilled water for cooling. It does this via a mechanical process that uses a refrigerant for a working fluid. Inside the vessel are pressure and temperature differentials, where heat is absorbed at a low temperature and then rejected at a higher temperature.

psychrometric chart A chart that shows the relationship between the temperature, pressure, and moisture content of the air.

psychrometric measurement The measurement of temperature, pressure, and humidity of air using a psychrometric chart.

pumps (system)

chilled water Circulates the chilled water through the evaporator section of the chiller and then through the building coils.

cooling water Circulates the cooling water from the source through the chiller, condenser, and back to the source.

shell-and-tube A designation for a type of heat exchangers consisting of a tube bundle within a shell or casing. Often used in chiller condensers and evaporators.

shell-and-tube flooded evaporators Evaporators that use water flow through tubes built into a cylindrical evaporator with refrigerant on the outside of the tubes.

temperature, ambient The temperature of the air surrounding the object under consideration

temperature, wet-bulb A measure of the degree of moisture in the air. It is the temperature of evaporation for an air sample, measured with a thermometer that has its bulb covered by a moistened wick.

tower water *See* cooling water.

Glossary

three-way valve A flow-control valve with three fluid-flow openings. It controls constant flow through or around the load.

two-way valve A flow-control valve with two fluid-flow openings.

valve, throttling A small valve used primarily in gauge lines to shut off the line between readings, and to throttle the line to prevent fluctuations during readings.

Preface

While mechanical refrigeration systems satisfy a wide variety of cooling needs, the chemicals (refrigerants) used in these systems are potentially detrimental to one's health if improperly handled. To address that concern, this manual promotes machinery room design practices that provide a safe environment for personnel who operate and maintain refrigeration systems. Its content may be of particular interest to architects, building owners and maintenance personnel, as well as HVAC designers.

The foundation for this manual is the ASHRAE Standard entitled "Safety Code for Mechanical Refrigeration," ANSI/ASHRAE 15–1994. However, while Standard 15 covers the full spectrum of mechanical refrigeration systems — i.e., systems of all sizes, refrigerants of all types — **this manual focuses specifically on centrifugal and helical-rotary refrigeration systems that require machinery rooms**. As described in the *Standards and Guidelines* section of this manual, ASHRAE Standard 15–1994 clearly defines when a machinery room is required.

Some refrigeration systems use ammonia as the refrigerant. Though similar to other refrigeration systems, there are enough significant exceptions in the relevant standards and design practices to make it difficult to discuss both types of systems concurrently; therefore, **ammonia systems are not addressed in this manual**.

The Trane Company, in proposing these system design and application concepts, assumes no responsibility for the performance or desirability of any resulting system design. System design is the prerogative and responsibility of the system designer.

Standards and Guidelines

The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) is an organization whose members come from all aspects of the heating, ventilation, air conditioning and refrigerating (HVAC&R) business. Together, the members draft Standards and Guidelines designed to assure safe distribution and use of HVAC&R products. These standards are frequently adopted by state and local authorities, and written into state and local codes.

Considerable time can pass between the printing of a new or revised ASHRAE Standard and the resulting local code. In the interim, it's the owner/designer's prerogative to specify design according to the Standards. However, in the event of a mishap, the legal system often views the Standards available at the time the building was designed as the minimum design practice "standard of care" ... and this standard of care may be more stringent than the current code.

Two ASHRAE Standards deal with the use of refrigerant in an equipment room: **ANSI/ASHRAE Standard 34–1992** and **ANSI/ASHRAE Standard 15–1994**. Excerpts from each (indented for easy identification) appear throughout this manual.

In addition to these two Standards, **ASHRAE Guideline 3–1990** and **Addendum 3a–1992**, "Reducing Emission of Fully Halogenated Chlorofluorocarbon (CFC) Refrigerants in Refrigeration and Air Conditioning Equipment and Applications," recommend practices and procedures for reducing CFC refrigerant leakage during operation and maintenance of HVAC equipment. Though not discussed here, Guideline 3–1990 and Addendum 3a–1992 contain valuable information, and should be reviewed by owners and designers of refrigeration systems.

ANSI/ASHRAE Standard 34–1992, "Number Designation and Safety Classification of Refrigerants"

The twofold purpose of ASHRAE Standard 34–1992 is clearly stated from the outset ...

> " ... to establish a simple means of referring to common refrigerants instead of using the chemical name, formula, or trade name. It also establishes a uniform system for assigning reference numbers and safety classifications to refrigerants." [from Section 1]

... and is further defined by its declared scope:

> "This standard provides an unambiguous system for numbering refrigerants and assigning composition-designating prefixes for refrigerants. Safety classifications based on toxicity and flammability data are included." [from Section 2]

Since this information is fundamental to our discussion of equipment room design practices, let's quickly review the refrigerant naming convention and classification scheme established by Standard 34.

Numbers, Names Used with Refrigerants

ASHRAE Standard 34–1992 clearly explains the format for refrigerant numbering. *Table 1 (page 5)* shows the chemical names and proper number designators for common refrigerants. Notice that the numeric designator can be preceded by an "R" (e.g., R–11, R–22), or by a more descriptive prefix that designates the presence, respectively, of hydrogen (H), bromine (B), chlorine (C), fluorine (F) and carbon (C). So, Refrigerant 11 — which contains chlorine, fluorine and carbon — is designated as "CFC–11" or "R–11," while Refrigerant 22 — which contains hydrogen, chlorine, fluorine and carbon — becomes "HCFC–22" or "R–22." Both aliases are equally acceptable, as is using either the number with the word "refrigerant" or a trade name.

☞ *It's good practice to use one of the proper names when referring to refrigerants to avoid confusion and misunderstandings.*

Table 1
Refrigerant/Refrigerant Blend Data and Safety Classifications

Refrigerant							Quantity of Refrigerant per Occupied Space[a]		
Prefix: "R" or...	No.	Chemical Name	Chemical Formula	Normal Boiling Point		Safety Group	lb per 1000 cu ft[b]	ppm by vol	g/m³ [b]
Methane Series:									
CFC	11	trichlorofluoromethane	CCl_3F	24° C	75° F	A1	1.6	4,000	25
CFC	12	dichlorodifluoromethane	CCl_2F_2	–30° C	–22° F	A1	12.0	40,000	200
HCFC	22	chlorodifluoromethane	$CHClF_2$	–41° C	–41° F	A1	9.4	42,000	150
Ethane Series:									
CFC	113	1,1,2–trichlorotrifluoroethane	CCl_2FCClF_2	48° C	118° F	A1	1.9	4,000	31
HCFC	123	2,2–dichloro–1,1,1–trifluoroethane	$CHCl_2CF_3$	27° C	81° F	B1[c]	0.4	1,000	6.3
HFC	134a	1,1,1,2–tetrafluoroethane	CH_2FCF_3	–26° C	–15° F	A1[c]	16	60,000	250
HFC	152a	1,1–difluoroethane	CH_3CHF_2	–25° C	–13° F	A2	1.2	7,000	20

Refrigerant No.	Composition (Weight %)	Normal Boiling Point		Safety Group	Quantity of Refrigerant Blend per Room Volume[a]: lb per 1000 cu ft[b]	ppm by vol	g/m³ [b]
Azeotropes:[d]							
500	CFC–12 / HFC–152a (73.8 / 26.2)	–33° C	–27° F	A1	12	47,000	200
502	HCFC–22 / CFC–115 (48.8 / 51.2)	–45° C	–49° F	A1	19	65,000	300

(a) Quantities are to be used only in conjunction with Section 7 of ASHRAE Standard 15–1994. The basis for the values shown in this table is a single event where a complete discharge of any refrigerant system into the occupied space occurs. The quantity of refrigerant is the most restrictive of a minimum oxygen concentration of 19.5% or as follows:

Group A1 ... 80% of the cardiac sensitization level for R–11, R–12, R–22, R–113, R–134a, R–500 and R–502; others are limited by levels where oxygen deprivation begins to occur.
Group A2, A3 ... approximately 20% of LFL (Lower Flammability Limit).
Group B1 ... 100% of the measure consistent with the IDLH (Immediately Dangerous to Life or Health) value for R–123.
Group B2, B3 ... 100% of IDLH value or 20% of LFL, whichever is lower.

(b) To correct for height above sea level, multiply values given in table by $[1 - 2.42 \times 10^{-6} H]$ where **H** is measured in feet, or by $[1 - 7.94 \times 10^{-2} h]$ where **h** is measured in kilometers.

(c) Per ASHRAE Standard 34–1992, this toxicity classification is based on recommended exposure limits provided by chemical suppliers. These ratings are provisional and will be reviewed when toxicological testing is completed.

(d) Per ASHRAE Standard 34–1992, azeotropic refrigerants exhibit some segregation of components at conditions of temperature and pressure other than those at which they were formulated. The extent of segregation depends on the particular azeotrope and hardware system configuration.

Safety Group Classifications

ASHRAE Standard 34–1992 also defines refrigerant Safety Group Classifications according to toxicity and flammability. **Toxicity** classifications are based on the Threshold Limit Value®–Time Weighted Average (TLV–TWA) established for each refrigerant. TLV–TWA is defined in Standard 15–1994 as:

> " ... the refrigerant concentration in air for a normal 8-hour workday and a 40-hour work week, to which repeated exposure, day after day, will not cause an adverse effect in most persons."
> [from Section 3]

Refrigerants are assigned to one of two classes — "A" or "B" — based on these criteria:

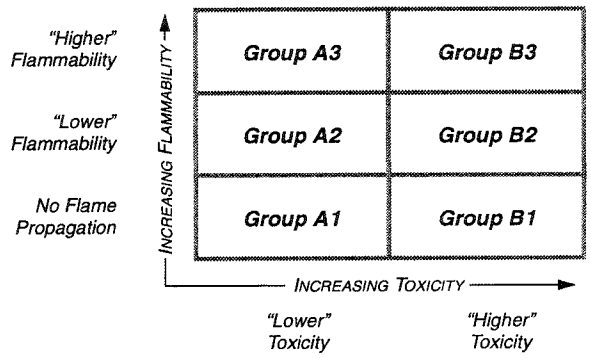
> "**Class A** signifies refrigerants for which toxicity has not been identified at concentrations less than or

equal to 400 ppm, based on data used to determine Threshold Limit Value–Time-Weighted Average (TLV–TWA) or consistent indices.

"**Class B** signifies refrigerants for which there is evidence of toxicity at concentrations below 400 ppm, based on data used to determine TLV–TWA or consistent indices." [from Section 6.1.2]

The letter designation for toxicity is followed by a number indicating its **flammability**. Refrigerants with no flame propagation potential are given a "1," lower flammability refrigerants receive a "2," and refrigerants with a higher flammability are assigned a "3." Flame propagation and Lower Flammability Limits (LFL) for each of these three categories are defined in ASHRAE Standard 34—1992 as follows:

"**Class 1** indicates refrigerants that do not show flame propagation when tested in air at 101 kPa (14.7 psia) and 18° C (65° F).



"**Class 2** signifies refrigerants having a lower flammability limit (LFL) of more than 0.10 kg/m^3 (0.00625 lb/ft^3) at 21° C and 101 kPa (70° F and 14.7 psia) and a heat of combustion of less than 19,000 kJ/kg (8,174 Btu/lb). The heat of combustion shall be calculated assuming that combustion products are in the gas phase and in their most stable state (e.g., C, N, S give CO_2, N_2, SO_3; F and Cl give HF and HCL if there is enough H in the molecule, otherwise they give F_2 and Cl_2; excess H is converted to H_2O).

"**Class 3** indicates refrigerants that are highly flammable, as defined by an LFL of less than or equal to 0.10 kg/m^3 (0.00625 lb/ft^3) at 21° C and 101 kPa (70° F and 14.7 psia) or a heat of combustion greater than or equal to 19,000 kJ/kg (8,174 Btu/lb). The heat of combustion is calculated as explained above in the definition of a Class 2 category." [from Section 6.1.3]

As shown in the matrix in *Figure 1*, the preceding designations for toxicity and flammability define six "safety groups": A1, A2, A3, B1, B2 and B3. ASHRAE Standard 15–1994 refers to these groups when specifying the design criteria for refrigeration equipment located in or near a building. See *Table 1 (page 5)* for the safety group classification of each of the common refrigerants listed there.

☞ *Standard 34–1992 describes the general safety categories for refrigerants. For more detailed information on health hazards or handling practices for a particular refrigerant, request a copy of the Material Safety Data Sheet (MSDS) from the refrigerant manufacturer.*

Figure 1
ASHRAE Standard 34–1992 Refrigerant Classifications

Note:
Table 1 (page 5) shows a partial list of the single-component refrigerants and azeotropic blends classified in this manner.

ANSI/ASHRAE Standard 15–1994, "Safety Code for Mechanical Refrigeration"

ASHRAE Standard 15–1994's stated purpose is:

" ... to specify safe design, construction, installation, and operation of refrigerating systems." [from Section 1]

In scope ...

" This code establishes safeguards for life, limb, health, and property and prescribes safety standards.

"This code applies:

"(a) to mechanical refrigerating systems and heat pumps used in the occupancies defined in Section 4* and installed subsequently to adoption of this code; and ...

"(b) to parts or components added after adoption of this code, or a change to a refrigerant of a different number designation (per ANSI/ASHRAE Standard 34–1992) after adoption of this code, and ...

"(c) to parts or components replaced after adoption of this code only if they are not identical in function." [from Section 2.1]

*Section 4 of Standard 15–1994 describes *Occupancy Classification,* and is summarized on page 7.

ASHRAE Standard 15–1994 details the design and installation requirements for a broad range of

refrigeration systems. It not only applies to new construction, but also to replacements, conversions and alterations that change the system's function. Some of the Standard's requirements — like the safeguards mandated by Section 7.2 to minimize the risk of accidental damage or rupture of system components — are general and apply to all system types. Others are specific to the type of refrigeration system and its use: Sections 8.13 and 8.14, for example, pertain only to refrigeration systems that require machinery rooms.

ASHRAE Standard 15–1994 does not apply where water is the primary refrigerant (i.e., absorption chillers).

So how do you determine what safety requirements must be met for compliance with ASHRAE Standard 15–1994? It's essentially a four-step process:

1 Identify the refrigeration system's **safety group classification.**

2 Determine the **occupancy classification** of the room that houses the refrigeration system.

3 Determine the **system probability** classification of the refrigeration system.

4 Based on the determinations made in the preceding steps, **use Table 2 of the Standard** (reproduced on page 10 of this manual) to identify the system application requirements — i.e., applicable "Refrigerant Quantity Rules" from Section 7.4.

Let's review these steps in greater detail.

Step 1: Identify the Safety Group Classification

As discussed earlier (pages 5–6), refrigerants are classified into one of six groups according to their **flammability** and **toxicity**. These safety classification criteria are thoroughly defined in ASHRAE Standard 34–1992. *Table 1 (page 5)* indicates the safety classifications of a number of commonly used single-component and azeotropic-blend refrigerants.

☞ *The safety group classification for any zeotropic blend corresponds to the worst-case fractionation.*

Step 2: Decide the Occupancy Classification

ASHRAE has defined seven occupancy classes that reflect the various uses of a building, and the ability of the people inside to respond in case of emergency. Key to proper use of these classifications is an understanding of what's meant by the terms **occupied space** and **machinery room**. ASHRAE Standard 15–1994 provides the following definitions:

> "occupied space: that portion of the premises accessible to or occupied by people, excluding machinery rooms.
>
> "machinery room: a space, meeting the requirements of (Section) 8.13 or 8.14, that is designed to house compressors and pressure vessels." [from Section 3]

In other words, **the room that contains the refrigeration equipment is *initially* considered part of the occupied space.** The room is only exempt from the occupied space if the "Restrictions of Refrigerant Use" in Section 7 (i.e., Refrigerant Quantity Rules 3, 4, 7 or 8 in Section 7.4.2) require that it satisfy the specific criteria in Section 8.13 or 8.14 which, in turn, qualify it as a machinery room.

Other than piping, all equipment in the building — or located less than 20 feet from any building opening *other* than an opening to a machinery room — is governed by one of these seven occupancy classifications:

1 **institutional**, where occupants cannot readily leave without assistance. Examples include (but are not limited to) hospitals, nursing homes and spaces containing locked cells.

2 **public assembly**, where occupants cannot quickly vacate due to large numbers. Examples include (but are not limited to) auditoriums, ballrooms, classrooms and restaurants.

3 **residential**, where occupants are provided with complete independent living facilities. Examples include (but are not limited to) hotels, dormitories and apartments.

4 **commercial**, where occupants transact business, receive personal services, or purchase food or other goods. Examples include office and professional buildings and markets (other than large mercantile). Other commercial occupancies are work or storage areas that do not qualify as an industrial occupancy.

5 **large mercantile**, where more than 100 persons congregate either above or below street level to

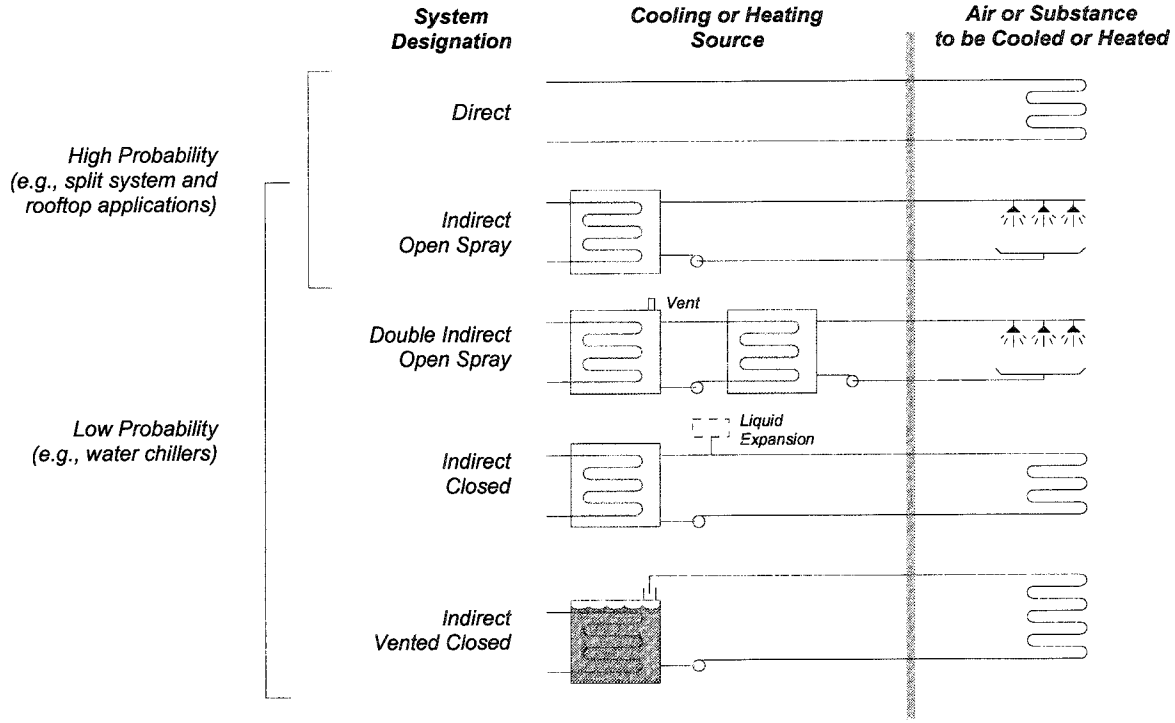
purchase merchandise.

6 **industrial**, where occupancy by the general public is prohibited and access by authorized persons is controlled. Examples include (but are not limited to) manufacturing plants, processing plants and storage facilities.

7 **mixed**, where two or more classes of occupancies share the same building.

When each occupancy is isolated from the rest of the building by tight walls, floors and ceilings, and by self-closing doors, the requirements for each occupancy apply to that portion of the building. For example, a cold storage space in a hotel might be classified as an industrial occupancy while the rest of the building is considered residential.

When occupancy areas are not isolated as described above, the occupancy with the most stringent requirements governs the entire area.



Step 3: Determine the System Probability

The "Refrigerating System Classification" section of ASHRAE Standard 15–1994 divides refrigerating systems into five categories based on the method used to extract or deliver heat. *Figure 2* identifies these five system types schematically and by name. The purpose of this categorization is to determine the **system probability**.

"System probability" indicates the likelihood of refrigerant leaking from a refrigerating system into an occupancy-classified area. As defined below, refrigeration systems are categorized as either **high** or **low probability**:

- **High-probability systems** are those in which the basic design or location of components is such that refrigerant leakage from a failed connection, seal or component could enter the occupied space. Direct-expansion split system and rooftop applications are examples of high-probability systems.
- **Low-probability systems** are any systems in which the basic design or location of components is such that it is unlikely that refrigerant leakage

Figure 2
Refrigeration System Classification (from ANSI/ASHRAE Standard 15–1994)

from a failed connection, seal or component will enter the occupied space. A typical example is a water chiller that serves a remote air handler.

Indirect open spray systems, also known as "air-washers" are considered low-probability when the secondary coolant pressure remains greater than the refrigerant pressure during all operating and standby conditions. (Information on design of low-probability air washer systems can be found in *Appendix A* of this manual.)

Step 4: Use Table 2 to Identify the Applicable Refrigerant Quantity Rules

Once a refrigerating system's characteristics — i.e., its safety group, occupancy and system probability classifications — have been determined, Table 2 of the Standard (reprinted on page 10) can be used to ascertain which of ASHRAE Standard 15–1994's **Refrigerant Quantity Rules** apply. These rules (also reprinted on page 10) define how much refrigerant can be used in each situation — often, with reference to Table 1 — and detail any restrictions that apply.

The basis for the quantities in Table 1 of the Standard (reprinted, in part, on page 5) is a single event in which a refrigeration system completely discharges its refrigerant into an occupied space. If the quantity of refrigerant in the system doesn't exceed the amount defined by the rules, the building occupants won't be exposed to a harmful level of refrigerant ... provided the refrigerant disperses equally throughout the occupied space.

The allowable "Quantity of Refrigerant per Occupied Space" is determined by the volume of that space and the method of ventilation used. A brief summary of the distinction made between unventilated and ventilated spaces follows; *Appendix B* demonstrates how the "volume of occupied space" is calculated in each instance.

Unventilated Spaces
When refrigerant-containing parts are located in unventilated spaces (as is typical of indirect systems such as water chillers), the volume of the smallest unventilated space containing part of the system determines how much refrigerant is permitted (i.e., volume, cu ft). If a building consists of several stories of unpartitioned space, use the volume of the smallest occupied story.

Ventilated Spaces
When the space is ventilated — as is typical of direct-expansion systems such as rooftop or self-contained units with an evaporator or condenser in the air duct system — the volume of the smallest occupied space served by the duct system determines the permissible quantity of refrigerant.

If the building is unpartitioned and multistory, use the volume of the smallest occupied story.

If the duct system serves several enclosed spaces, use the total volume of all spaces served in which the airflow cannot be reduced below 25% of design. Include the plenum area, too — but only that portion of the plenum that is continuous and part of the building's return air system.

System Application Requirements

For clarity, Table 2 and the accompanying "Refrigerant Quantity Rules" from ASHRAE Standard 15–1994 (which cover <u>all</u> combinations of refrigerant types and system classifications) are reprinted in their entirety on page 10. However, **the rest of this manual focuses on low-probability systems that contain either A1 or B1 refrigerants**. This subgroup encompasses most of the refrigeration systems that require a mechanical equipment room.

ASHRAE Standard 15–1994 lists a number of "general" (applicable to all systems) and "special" (system-specific) requirements and restrictions that must be met to provide for safe refrigerant use. General requirements for low-probability systems that use A1 or B1 refrigerants are addressed later in this manual; "Refrigerant Quantity Rule 4" — see *Table 2 (page 10)* — dictates the specific requirements for these systems. Rule 4 states:

> "When the quantity of refrigerant in any system exceeds Table 1 amounts, all refrigerant-containing parts, except piping and those parts outside the building, shall be installed in a machinery room constructed in accordance with the provisions of (ASHRAE Standard 15–1994 Section) 8.13." [from Section 7.4.2]

The next section of this manual, *Machinery Room Design,* reviews the application requirements presented in ASHRAE Standard 15–1994, Section 8.13, and discusses how those requirements can be met.

Table 2
System Application Requirements (See Inset Below for Rules)

Refrigerant Group	System Probability	Occupancy Classification: Institutional	Occupancy Classification: Public Assembly, Residential, Commercial, Large Mercantile	Occupancy Classification: Industrial
A1	High	Rule 2	Rule 1	Rule 3
	Low	Rule 4	Rule 4	Rule 4
A2	High	Rule 5	Rule 5	Rule 3
	Low	Rule 7	Rule 7	Rule 7
A3	High	Rule 9	Rule 9	Rule 3
	Low	Rule 9	Rule 9	Rule 7
B1	High	Rules 2 and 6	Rules 1 and 6	Rule 3
	Low	Rule 4	Rule 4	Rule 4
B2	High	Rules 5 and 6	Rules 5 and 6	Rule 3
	Low	Rule 7	Rule 7	Rule 7
B3	High	Rule 9	Rule 9	Rule 3
	Low	Rule 9	Rule 9	Rule 7

"Refrigerant Quantity Rules" from ANSI/ASHRAE Standard 15–1994, Section 7.4.2

NOTE: All table and section references cited here refer to tables and sections of ASHRAE Standard 15–1994. Refrigerant quantities shown in Table 1 of Standard 15 are provided in ***Table 1 (page 5)*** *of this manual.*

1. The quantity of refrigerant in each system shall be limited as listed in Table 1. The quantity of refrigerant per occupied space shall be the maximum amount of refrigerant that will leak into the occupied space at any one time, based on a leak from any single independent refrigeration circuit.

2. The quantity of refrigerant in each system is limited to 50% of the amount listed in Table 1. EXCEPTION: **Rule 1** applies in kitchens, laboratories, and mortuaries. If any portion of a refrigerant system containing more than one pound of refrigerant (except R–744) is in a room with a flame-sustaining device, this device shall be provided with a hood to exhaust combustion products to the open air. Otherwise **Rules 5** and **6** shall be followed.

3. For refrigerating systems of 100 horsepower (74.6 kW) or less, when the quantity of refrigerant in each system exceeds Table 1 quantities, the rules for commercial occupancy shall apply unless the following occurs:

   (a) occupancies containing machinery are separated from other occupancies by tight construction and with tight-fitting doors;

   (b) access by authorized personnel is controlled;

   (c) personnel density and means of egress are in compliance with local building codes;

   (d) detectors (refrigerant, oxygen, etc.,) are located in areas where refrigerant vapor from a leak will be concentrated so as to provide warning at a concentration not exceeding the refrigerant(s) TLV–TWA (detectors are not required for ammonia due to its self-alarming character);

   (e) when the quantity of refrigerant, except refrigerants in Groups A1 and B1, exceeds Table 1 quantities, no flame-producing device or hot surface above 800° F (426.7° C) shall be permitted; and

   (f) when the quantity of refrigerant, except Groups A1 and B1 and ammonia, exceeds Table 1 quantities, the area shall be classified as a hazardous location and all electrical equipment shall conform to the requirements of Class 1, Division 2, of the National Electrical Code.

   For refrigerating systems of greater than 100 hp (74.6 kW), the refrigerated work area shall comply with items **(a)** through **(f)** and the separate room housing compressors and related equipment shall comply with **Rule 8**.

4. When the quantity of refrigerant in any system exceeds Table 1 amounts, all refrigerant-containing parts, except piping and those parts outside the building, shall be installed in a machinery room constructed in accordance with the provisions of 8.13.

5. Refrigerant quantities and types of systems shall be limited as shown in Table 3.

6. Applications involving air conditioning for human comfort are not allowed.

7. When the quantity of refrigerant in any system exceeds Table 1 amounts, all refrigerant-containing parts, except piping and those parts outside the building, shall be installed in a machinery room constructed in accordance with the provisions of 8.14 with limitations on refrigerant quantities as follows:

   550 lb (250 kg) — Institutional
   No limit except Rule 8 — Public Assembly and Large Mercantile
   No limit except Rule 8 — Residential
   No limit except Rule 8 — Commercial
   No limit except Rule 8 — Industrial

   Otherwise, **Rule 5** limits the amount of Group A2, A3, B2 or B3 refrigerant in the system.

8. When the quantity of refrigerant in any system exceeds Table 1 amounts, all refrigerant-containing parts except piping, low-side components, condensers, and parts outside the building shall be installed in a machinery room constructed in accordance with the provisions of 8.13. In addition, refrigerants of Groups A2, A3, B2 and B3 shall meet the following requirements:

   (a) The special machinery room requirements of 8.14 shall apply.

   (b) Except for ammonia systems, amounts of refrigerant exceeding 1100 lb (500 kg) shall be approved by the authority having jurisdiction.

9. Use of these refrigerants is prohibited except in laboratories in commercial occupancies. Only unit systems containing not more than 6.6 lb (3 kg) of Group A3 or B3 refrigerant shall be used unless the laboratory is occupied by less than one person per 100 ft^2 (9.3 m^2) of floor area, in which case the requirements of industrial occupancies shall apply. Note that 7.4.1 permits a refrigerant charge of 6.6 lb (3 kg) or less (any refrigerant) of any system meeting the requirements of this rule.

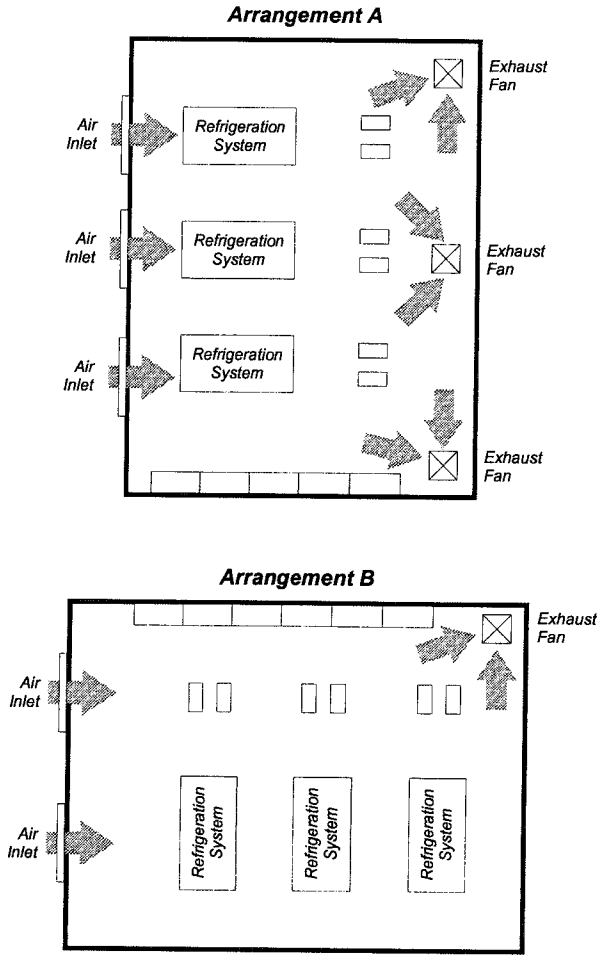
Machinery Room Design

This section discusses the machinery room design requirements for refrigeration systems subject to "Refrigerant Quantity Rule 4" of ANSI/ASHRAE Standard 15–1994 (see inset, page 10). **Rule 4 applies to all low-probability systems — in all occupancy classifications — that use either an A1 or B1 refrigerant.** As in the preceding chapter, direct excerpts from the Standard are indented for easy identification. The explanations that accompany them suggest how to interpret and implement ASHRAE Standard 15–1994 for compliance with that code.

☞ *The room housing the refrigeration system has a number of aliases: it's commonly referred to as an "equipment room," a "mechanical room," a "mechanical equipment room" (MER) and a "refrigeration room." ASHRAE reserves the term* ***machinery room*** *for those rooms that meet the requirements of Sections 8.13 and 8.14 of ANSI/ASHRAE Standard 15–1994, and are designed to house compressors and pressure vessels. As used in this manual, however, the preceding aliases are synonymous with ASHRAE's definition of a machinery room.*

☞ *The terms "chiller" and "refrigeration system" are also used synonymously throughout this chapter.*

Chiller Placement



Chiller (refrigeration system) placement in the equipment room depends on a number of factors including:

- ❑ access for service work,
- ❑ proximity to other equipment in the room, and ...
- ❑ local ventilation airflow.

Clearances specified in the chiller submittal data are the minimum values required for normal operation, maintenance, service and repair of the equipment. ASHRAE Standard 15–1994 further requires clear head room of 7.25 feet below equipment situated over passageways, and reminds the designer to contact the presiding regulatory agency for other requirements. Collectively, these clearances generally determine chiller placement. Another important consideration, however, is the airflow pattern that results from interaction of the ventilation system with equipment in the room.

Place the chillers between the ventilation inlet and outlet, and orient them to avoid creating stagnant areas. *Figure 3* shows two possible configurations for a multiple-chiller equipment room. Positioning the chillers as shown in Arrangement A provides good air movement, while Arrangement B inhibits airflow between the chillers.

Figure 3
Multiple-Chiller Machinery Room Layouts

Ventilation

Volume Requirements

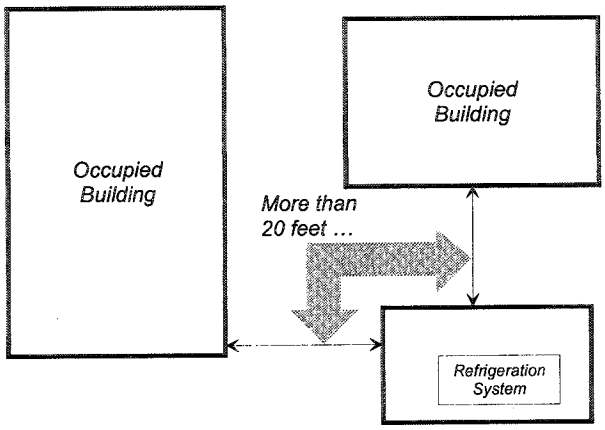
ANSI/ASHRAE Standard 15–1994 specifies the required volume of ventilation air — delivered either **naturally** or **mechanically** — based on the location of the equipment.

Natural Ventilation

ANSI/ASHRAE Standard 15–1994 states that:

> "When a refrigerating system is located outdoors more than 20 ft (6.1 m) from building openings and is enclosed by a penthouse, lean-to or other open structure, natural or mechanical ventilation shall be provided." [from Section 8.13.5]

To use natural ventilation, the structure must not be connected to any occupied building by any means including: doorways, pipe tunnels or electrical conduit raceways, ventilation or ductwork. When these conditions are met, the requirements for natural ventilation are:



> "The free-aperture cross section for the ventilation of a machinery room shall be at least:
>
> $F = G^{0.5}$ ($F = 0.138\ G^{0.5}$)
>
> where,
>
> F = the free opening area in square feet (square meters),
>
> G = the mass of refrigerant in pounds (kilograms) in the largest system, any part of which is located in the machinery room.
>
> "Locations of the gravity ventilation openings shall be based on the relative density of the refrigerant to air." [from Section 8.13.5]

Figure 4 shows an example of a remote mechanical equipment room (MER).

Mechanical Ventilation

Most mechanical equipment room designs don't permit the use of natural ventilation. When the refrigeration system doesn't meet the requirements just described for a natural ventilation system,

Figure 4
Remote Machinery Room

Lean-to or Other Structure with Natural Ventilation

mechanical ventilation must be provided. According to ASHRAE Standard 15–1994:

> "The mechanical ventilation required to exhaust an accumulation of refrigerant due to leaks or a rupture of the system shall be capable of removing air from the machinery room in not less than the following quantity:
>
> $Q = 100 \times G^{0.5}$ ($Q = 70 \times G^{0.5}$)
>
> where,
>
> Q = the airflow in cubic feet per minute (liters per second),
>
> G = the mass of refrigerant in pounds (kilograms) in the largest system, any part of which is located in the machinery room." [from Section 8.13.5]

"Q" represents the minimum airflow that the ventilation system must be capable of delivering to effectively exhaust "spilled" refrigerant from the room. For chillers with more than one isolated refrigeration circuit, "G" represents the amount of refrigerant in the largest circuit. According to ANSI/ASHRAE Standard 15–1994, it isn't necessary to run the ventilation system at this volume continuously, provided that:

> "A part of the refrigerating machinery room mechanical ventilation shall be:
>
> (a) operated, when occupied, to supply at least at 0.5 cfm per square foot (2.54L/s per square meter) of machinery room area or 20 cfm (9.44 L/s) per person and

(b) operable, if necessary for operator comfort, at a volume required to maintain a maximum temperature rise of 18° F (10° C) based on all of the heat-producing machinery in the room." [from Section 8.13.5]

In effect, ANSI/ASHRAE Standard 15–1994 defines two distinct mechanical ventilation rates for an equipment room:

- **Normal ventilation** at a rate of 0.5 cfm/sq ft is required whenever the equipment room is occupied. (A higher ventilation rate may be necessary if there's a source of excessive heat in the room.) To accomplish this, run the fan continuously, start it automatically with a motion detector, or provide a fan switch near the equipment room entrance(s).

  If you provide a switch, accompany it with a sign or other prompt to indicate the need for ventilation during occupancy.

- **Alarm ventilation** at a rate based on the mass of refrigerant in the chiller system is required whenever the refrigerant monitor indicates a build-up of refrigerant in the equipment room. Use the monitor's alarm contacts to automatically initiate ventilation at this volume. (See "Monitor Inputs and Outputs" on pages 24–25.) A switch for manual initiation is also suggested; locate it outside the main entrance to the equipment room.

Compliance with ASHRAE Standard 15–1994 can be achieved by providing one ventilation system that operates at the higher of the two rates, and is triggered by both occupancy and monitor alarm. However, when the alarm ventilation rate is significantly higher than the normal ventilation rate, consider using a fan system capable of operating at two distinct rates via multiple fans or modulation devices such as multi- or variable-speed drives.

☞ *Be sure to compensate for refrigerant gas density — which is usually 3 to 5 times heavier than air — when sizing a ventilation system for the alarm rate. This is particularly important for refrigerants with boiling points below the ambient temperature because a spill of liquid refrigerant or rupture of a vessel will quickly release a large quantity of refrigerant gas into the equipment room.*

Vent Locations

Locations for the ventilation system intake and discharge must be properly positioned to provide efficient equipment room ventilation. ASHRAE Standard 15–1994 addresses this requirement in a general manner, stating:

> "... Provision shall be made for inlet air to replace that being exhausted. Openings for inlet air shall be positioned to avoid recirculation. Air supply and exhaust ducts to the machinery room shall serve no other area. The discharge of the air shall be to the outdoors in such a manner as not to cause a nuisance or danger." [from Section 8.13.4]

Don't overlook the fundamental requirements contained in this excerpt ...

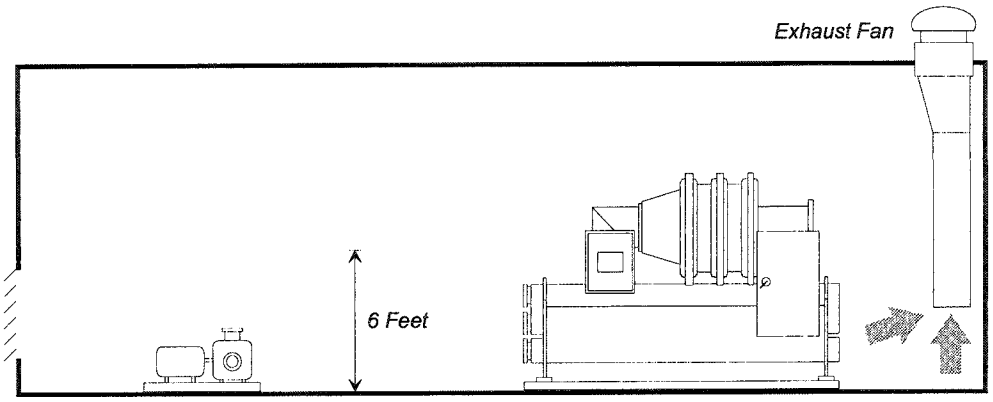
First, **the equipment room ventilation system must be separate from the systems that provide ventilation to other parts of the building**. In other words, the fans and ductwork that ventilate the equipment room must not supply or use air from any other part of the building, and the discharge must not interfere with any fresh air intakes. Because some fans may not run continuously, it's important to locate each fan's discharge where it won't be inadvertently blocked when the fan is off. Also, outdoor air used for ventilation must be properly conditioned to avoid potential equipment damage from wide, abrupt temperature swings or freezing temperatures.

Second, **the exhaust fan must remove refrigerant from the equipment room**. To remove heavier-than-air refrigerants, locate the exhaust fan inlet near the equipment (if possible) and close to the floor rather than at ceiling height. *Why?* Refrigerant released in an equipment room sinks to the floor and fills the room from the bottom up unless disturbed by air turbulence. Maximum protection for equipment room occupants is provided when the exhaust-fan inlet is situated:

- below the normal breathing zone, as shown in *Figure 5 (page 14).*
- near the potential source(s) of a refrigerant leak, and ...
- away from the outdoor air intake to create a "sweeping" airflow pattern that draws outdoor air across the refrigeration equipment to the exhaust fan.

When equipment room exhaust fans serve a cooling or smoke removal function, they're usually installed in the ceiling since both heat and smoke rise. However, if the ventilation system also exhausts

Figure 5
Suggested Exhaust Fan Location



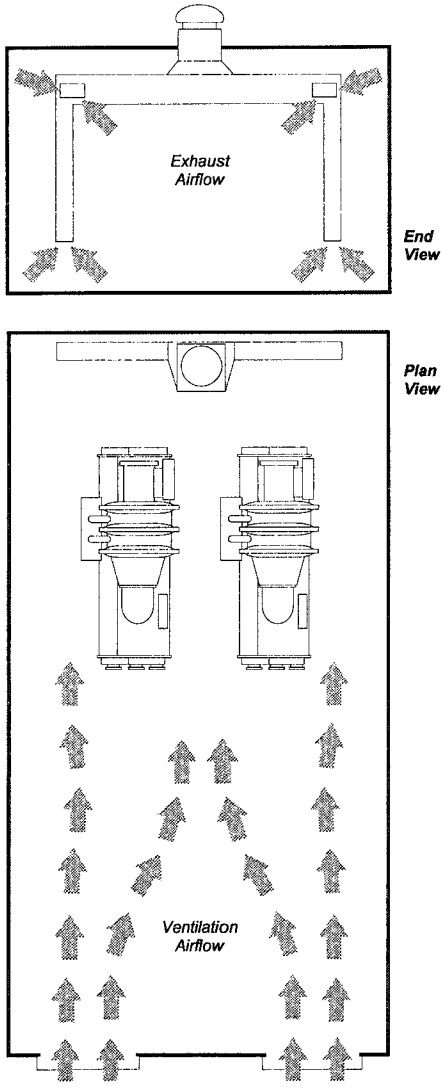


Figure 6
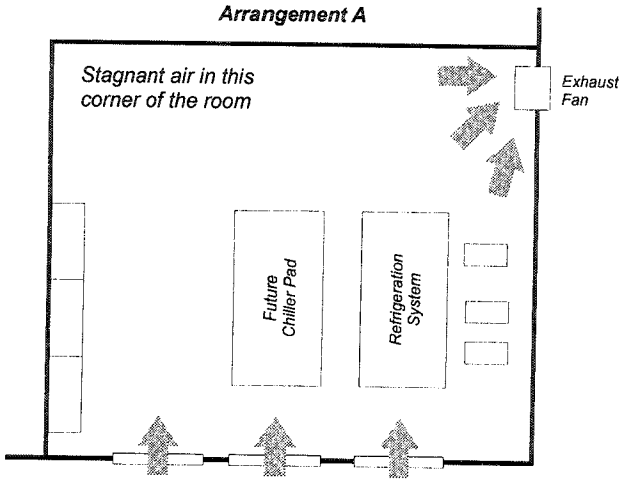
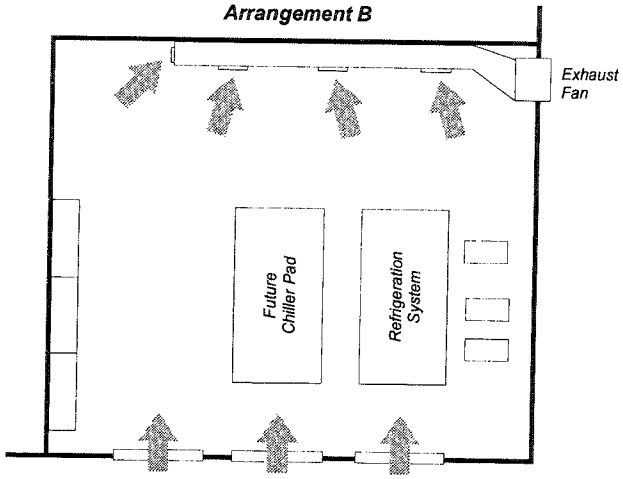
Dual-Purpose Machinery-Room Ventilation System



"spilled" refrigerant, make provisions for inlets at both floor and ceiling levels. To accomplish this, it's best to provide separate fans.

☞ *Separate ceiling and floor-level fans can be operated together to provide the total ventilation volume needed for refrigerant removal. For greatest removal efficiency, the floor-level fan should be capable of meeting the calculated alarm ventilation rate.*



It's possible to use a ducted fan with inlets at floor and ceiling as shown in *Figure 6.* If this arrangement is used, however, be sure to account for refrigerant vapor density. Flow control dampers may be required. If used, they should be designed and controlled to provide maximum exhaust from the floor-level inlet on detection of a refrigerant alarm condition.

Figure 7 (page 15) illustrates the layout of an actual equipment room situated in the corner of a building. As shown in Arrangement A, the ventilation system includes six louvered service doors along one wall (outdoor air inlet) and an exhaust fan mounted 4 feet above the floor in an adjacent wall. Continuous ventilation is provided at the alarm ventilation rate. While this arrangement provides adequate air movement past the chiller, notice that it also creates a stagnant area in one corner of the room. Ducting the exhaust fan inlet across the opposite wall, as depicted by Arrangement B, provides better airflow across the entire equipment room.

Figure 7
Correcting an Existing Ventilation System Arrangement

Air Inlet Via 3 Pairs of Louvered Doors

Air Inlet Via 3 Pairs of Louvered Doors

Doors and Passageways

ASHRAE Standard 15–1994 requires that:

> "Each refrigerating machinery room shall have a tight-fitting door or doors opening outward, self-closing if they open into the building, and adequate in number to ensure freedom for persons to escape in an emergency. With the exception of access doors and panels in air ducts and air-handling units conforming to (Section) 8.13.7, there shall be no openings that will permit passage of escaping refrigerant to other parts of the building." [from Section 8.13.2]

With these requirements in mind, review *Figure 7* again. Generally, louvered doors would not be acceptable; but in this case, they don't lead into a walkway, and are used only as an air inlet and for service clearance. However, the local code authority should still be consulted to verify compliance.

Access

Section 11.1 of the Standard limits machinery room access to authorized personnel only. Equipment access — including ladders, platforms and unobstructed space for inspection and servicing — must be provided in accordance with applicable safety standards, as well as with the requirements of the presiding regulatory agency.

Continuous Monitoring

"Continuous monitoring" refers to the use of permanently-mounted, constantly-operating area monitor(s). Equipment rooms are often unoccupied for extended periods. By detecting and alarming a build-up of refrigerant, application of a continuous monitor assures personnel that the room is free of this hazard.

According to ANSI/ASHRAE Standard 15–1994, all equipment rooms containing refrigerants must be equipped with continuous monitors that will automatically signal the existence of an alarm condition and start the ventilation system:

> "Each machinery room shall contain a detector located in an area where refrigerant from a leak will concentrate, which shall actuate an alarm and mechanical ventilation in accordance with (Section) 8.13.4 at a value not greater than the corresponding TLV®–TWA (or toxicity measure consistent therewith)." [from Section 8.13.2]

> "Detector(s), alarm(s), and mechanical ventilating systems shall be tested in accordance with manufacturers' specifications and the requirements of the jurisdiction having authority." [from Section 11.7.3]

As a demonstration of the Standard's intent to "specify safe ... operation of refrigerating systems," these excerpts apply to all refrigerants in all safety

groups, and to all equipment rooms that house refrigerating equipment and are designed in accordance with Section 8.13. Of course, an added benefit of using a monitor is early detection of refrigerant leaks — ensuring less refrigerant loss if a leak develops.

It's important to note that ASHRAE Standard 15–1994 doesn't require a "refrigerant vapor monitor" — it simply calls for a "detector" that "actuate(s) an alarm and mechanical ventilation ... at a value not greater than the corresponding TLV®–TWA." This phrasing deliberately specifies the **required function** of the "detector," not the technology used to accomplish it. Note, too, that the requirement to alarm at the TLV–TWA (Threshold Limit Value – Time Weighted Average) means that the "detector" must be able to discern relatively small amounts of refrigerant. With today's technology, this requirement is best met with a **compound-specific vapor monitor**; see page 23.

While ASHRAE Standard 15–1994 clearly defines the need for equipment room monitoring, it leaves a number of important issues to the designer's discretion. For example, the designer must decide what type of monitor to use, how many are needed, and where to install them.

General guidelines for applying a refrigerant monitor immediately follow. The next chapter, "Machinery Room Monitors" on pages 23–26, discusses monitor types and characteristics, and suggests how they can be used to provide a safe equipment room environment. For more detailed information, consult the documentation provided by the monitor manufacturer.

Refrigerant Monitor Application

☞ *This information is presented to help determine the quantity and placement of refrigerant monitors in an equipment room. It is not a substitute for instructions provided by the monitor manufacturer.*

Placement

The only instruction ASHRAE Standard 15–1994 provides for determining where to locate the refrigerant monitor is "... in an area where refrigerant from a leak will concentrate." It is necessarily vague given the countless possible mechanical equipment room layouts.

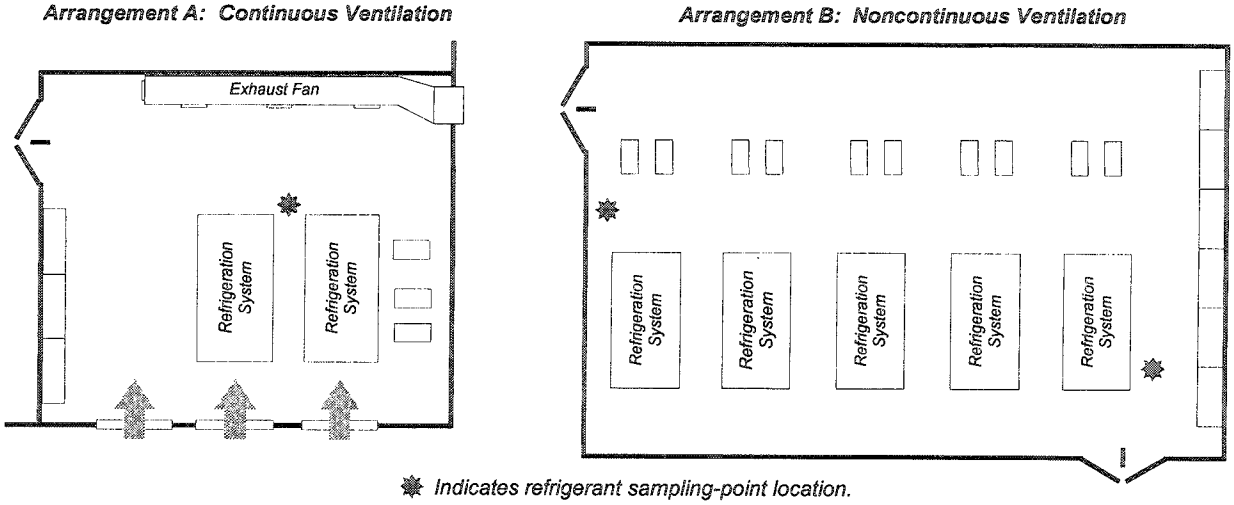
Fundamental to selecting an appropriate site for monitor mounting is the primary motive for its installation: **occupant safety**. Since equipment room occupants are most likely to be exposed to refrigerants through inhalation, proper monitor placement requires that the designer:

- ❑ determine the airflow pattern in the room, and ...
- ❑ account for the refrigerant vapor's density.

Some refrigeration equipment manufacturers offer a unit-mounted refrigerant monitor as an option. In this case, the refrigerant monitor is factory-installed on the chiller as part of the control system, and is prepiped to an appropriate sampling point. Multipoint sampling options allow other areas of the equipment room to be monitored. Aside from the obvious advantage of reduced installation costs, information gathered from the monitor can be passed to a building automation system (BAS) as part of the chiller data, eliminating the need for separate hard-wired points.

☞ *"Sampling point" refers to the location where the sample is drawn; it coincides with the monitor's location unless a sampling line is added. A "sampling line" is simply a length of tubing (usually copper) that runs from the monitor to the sampling point.*

Elevation



Position the sampling point about 18 inches above the floor. Since all commonly-used halocarbon refrigerants are three to five times heavier than air, locating the sampling point below the normal "breathing zone" (i.e., 5 feet above the floor) provides occupants an added margin of safety.

Plan Location

With a continuous stream of outdoor air flowing across the refrigeration system components, the sampling point is best positioned between the refrigeration system and room exhaust. See *Figure 8*, Arrangement A.

If ventilation is intermittent — or if the direction of airflow isn't obvious — position the sampling point close to the refrigeration system, and between the refrigeration system and entry door. For example, place the sampling point close to the perimeter of a single chiller, between two chillers, or at the center chiller in three-chiller applications.

Figure 8
Suggested Refrigerant Sampling-Point Placement

✹ *Indicates refrigerant sampling-point location.*

How Many ...

As worded, Section 8.13.2 of ANSI/ASHRAE Standard 15–1994 indicates that any "refrigerating machinery room" must contain "a detector." But is a single refrigerant monitor enough to ensure occupant safety? *Not necessarily.*

One refrigerant monitor is usually adequate for applications with three (or fewer) chillers — provided the chillers are aligned for good airflow, as shown in Arrangement A of *Figure 8*.

Systems with four to six chillers generally require two refrigerant sampling points if installed in an equipment room with either intermittent ventilation or an indeterminate direction of airflow. Sample at opposite corners of the chiller group; see *Figure 8*, Arrangement B. As a general rule, **the distance between any refrigeration system and a refrigerant sampling point should not exceed 50 feet.**

Multiple sampling points are also recommended if the equipment room is large or has multiple levels. (See *Figure 11* on page 26.) Low areas that could be occupied — such as stairwells, pits or trenches — demand dedicated sampling points, too. *Why?* Since it's heavier than air, refrigerant released to the space will sink to the floor and quickly spread. Pits and other low areas are likely to fill with refrigerant before a sampling point conventionally mounted 18 inches above the floor detects the build-up.

☞ *If an equipment room design requires several sampling points for adequate refrigerant monitoring, it may be more cost-effective to use a single monitor capable of checking refrigerant concentrations at multiple sampling points rather than several single-channel monitors.* *See "Multichannel Scanners" on page 25.*

Open-Flame Devices

Refrigerants exposed to combustion often break down into products harmful to humans and corrosive to machinery. To avoid both of these hazards, ASHRAE Standard 15–1994 strictly prohibits the use of open-flame devices in equipment rooms that house refrigerating machinery:

> "No open flames that use combustion air from the machinery room shall be installed where any refrigerant is used. The use of matches, lighters, halide leak detectors, and similar devices shall not be considered a violation of 8.13.6."
> [from Section 8.13.6]

The Standard then goes on to describe two conditions under which combustion equipment can be located in a refrigerating machinery room:

(a) "combustion air is ducted from outside the machinery room and sealed in such a manner

as to prevent any refrigerant leakage from entering the combustion chamber, or

(b) "a refrigerant vapor detector is employed to automatically shut down the combustion process in the event of refrigerant leakage." [from Section 8.13.6]

When combustion equipment, such as a boiler or direct-fired absorption machine, is designed to accept intake ductwork, the best solution may be *Condition (a):* duct the combustion air from outside the machinery room directly to the equipment. This strategy separates combustion air requirements from ventilation needs, and avoids shutting down the combustion equipment if there's a refrigerant leak or nuisance alarm.

Condition (b) describes a simple, cost-effective method for complying with ANSI/ASHRAE Standard 15–1994, and is especially useful in retrofit and replacement installations. A high-quality, compound-specific monitor — properly located — can avoid nuisance shutdowns that might be otherwise be triggered by paints, cleaning agents and other chemicals.

Pressure-Relief Piping

"Refrigerating systems shall be protected by a pressure-relief device or other approved means to safely relieve pressure due to fire or other abnormal conditions." [from Section 9.4.1]

So begins Section 9.4, entitled "Pressure-Relief Protection," of ANSI/ASHRAE Standard 15–1994. Along with these general requirements, this part of the Standard specifically describes when pressure-relief devices are needed and how to size them.

Manufacturers of packaged refrigeration systems, as well as of major components for "built-up" systems, usually engineer pressure-relief devices in their equipment designs. Despite this convenience, it's still important to verify (per ANSI/ASHRAE Standard 15–1994) that all pressure vessels are adequately protected against rupture.

Once the equipment is installed, each rupture device must be piped to a safe location in accordance with the following guidelines from ANSI/ASHRAE Standard 15–1994:

"Pressure-relief devices and fusible plugs on any system containing a Group A3 or B3 refrigerant; on any system containing more than 6.6 lb (3 kg) of a Group A2, B1, or B2 refrigerant; and on any system containing more than 110 lb (50 kg) of a Group A1 refrigerant shall discharge to the atmosphere at a location not less than 15 ft (4.57 m) above the adjoining ground level and not less than 20 ft (6.1 m) from any window, ventilation opening, or exit in any building. The discharge shall be terminated in a manner that will prevent the discharged refrigerant from being sprayed directly on personnel in the vicinity and foreign material or debris from entering the discharge piping. Discharge piping connected to the discharge side of a fusible plug or rupture member shall have provisions to prevent plugging the pipe in the event the fusible plug or rupture member functions." [from Section 9.7.8]

Although the requirements stated in this section are quite self-explanatory, their importance should not be taken lightly. Improper termination of the discharge pipe, for example, could result in the entry of rain: its accumulation may cause the relief device to malfunction or, in the case of a rupture disk, the pressure may cause the disk to rupture, allowing water to enter the chiller. Remember, too, that a large quantity of fluid and/or vapor may be discharged when a relief device functions ... an improper discharge location can result in personal injury and property damage.

Refrigerant compatibility with the materials used in relief-device piping and joints is critical. Commonly used and accepted materials include steel or DWV copper pipe. PVC piping can also be used if the related adhesives have been tested for refrigerant compatibility. Flexible connection devices used for vibration isolation must be compatible with the vented refrigerant, too; a flexible stainless steel pump connector (or its equivalent) is recommended.

Discharge Line Sizing

ANSI/ASHRAE Standard 15–1994 provides information on discharge line sizing in Sections 9.7.8.4 and 9.7.8.5. Section 9.7.8.4 reads:

"The size of the discharge pipe from a pressure-relief device or fusible plug shall not be less than the outlet size of the pressure-relief device or fusible plug. Where outlets of two or more relief devices or

fusible plugs are connected to a common line or header, the effect of back pressure that will be developed when more than one relief device or fusible plug operates shall be considered. The sizing of the common discharge header downstream from each of the two or more relief devices or fusible plugs that are expected to operate simultaneously shall be based on the sum of their outlet areas with due allowance for the pressure drop in all downstream sections."

The guidance presented in this excerpt can be summarized as follows:

1 Discharge pipe diameter must at least equal the size of the pressure-relief device. It may need to be larger depending on the length of the discharge pipe.

2 Two or more relief devices can be piped together, but the discharge line must be sized to handle all devices that could relieve at the same time.

3 When two or more relief devices are piped together, the common discharge line must be at least as large as the sum of the outlet areas of all upstream relief devices — perhaps larger if required by the pressure drop.

For a Single Chiller ...
To determine how far a discharge pipe of a given diameter can be run, ANSI/ASHRAE Standard 15–1994 provides the following equation:

$$L = \frac{9 \times P^2 \times d^5}{16 \times C_r^2} \qquad \left(L = \frac{1.95 \times 10^{-14} \times P^2 \times d^5}{16 \times C_r^2} \right)$$

where,

C_r = rated discharge capacity as stamped on the device by the manufacturer in pounds of air per minute (kg/s),

d = internal diameter of pipe in inches (mm),

L = length of discharge pipe in feet (m).

P = For relief valves and rupture disks: P = (rated pressure, psig x 1.10) + 14.7 [P = (rated pressure, kPa gage x 1.10) + 101.33]. For fusible plugs: P = (rated pressure, psig x 1.10) + 14.7 [P = (rated pressure, kPa gage x 1.10) + 101.33], which "equals the absolute saturation pressure corresponding to the stamped temperature melting point of the fusible plug or the critical pressure of the refrigerant used, whichever is smaller, psia (kPa)." [from Sections 9.7.8.5 and 9.7.7]

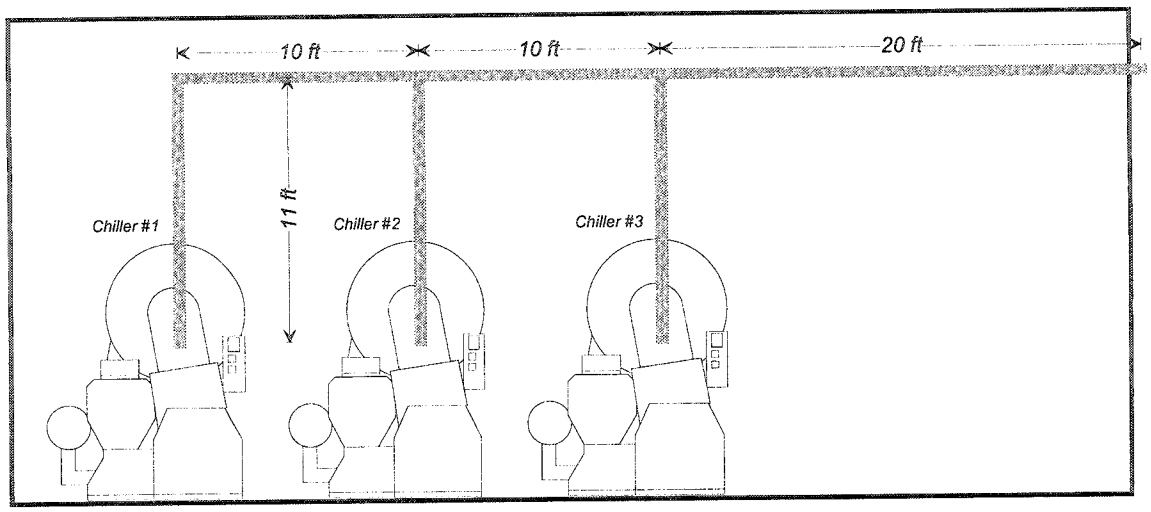
To apply this equation, calculate P using the rated pressure of the relief device. Then determine the value of C_r from the relief device or the manufacturer's literature. Starting with the **exact inside diameter of a pipe that matches the diameter of the relief device**, calculate the discharge pipe length *(L)*. Verify that the calculated pipe length is long enough to span the distance between the chiller and the outdoor termination. If L is too short, recalculate it using the next larger pipe size. Repeat this process until L is long enough.

For Multiple Chillers ...
A similar process (and equation) determines the maximum allowable pipe run for multiple units sharing a common discharge line. This time, however:

- ❑ the area provided by the discharge pipe diameter must be greater than the sum of all relief devices connected upstream, and ...
- ❑ the C_r value used to calculate L is the sum of all C_r values for upstream relief devices.

Example: Consider three low-pressure centrifugal chillers situated as shown in *Figure 9 (page 20)*. Each chiller has a 3-inch rupture disk with a discharge rating *(C_r)* of 64. The discharge line runs from one unit to the next, then another 20 feet to its outdoor termination.

First, calculate the allowable length for a 3-inch discharge pipe. (The exact inside diameter of this pipe is 3.068 inches.):



$$P = (15\,psig \times 1.10) + 14.7 = 31.2\,psi$$

$$L = \frac{9 \times 31.2^2 \times 3.068^5}{16 \times 64^2} = 36.3\,ft$$

As the preceding calculations show, the maximum allowable run for our 3-inch pipe is 36.3 feet. Since the distance between Chiller #1 and the junction with Chiller #2 is only 21 feet, 3-inch pipe is suitable for that portion of the run.

To properly size the common discharge line between Chiller #2 and Chiller #3, L must be recalculated using the sum of the C_r values. While P remains unchanged, the area of the common discharge pipe

Figure 9
Multiple Units Sharing a Common Pressure-Relief Discharge Line

must at least equal the area of all upstream rupture disks. The area of a single disk is:

$$Area = \Pi\, r^2 = 3.14 \times 1.5^2 = 7.07 \text{ sq in.}$$

Since the pipe section must accommodate the combined area of two rupture disks (14.14 sq in.), a 4-inch pipe — with an area of 3.14 x 2^2 or 12.6 sq in. — isn't large enough ... but a 5-inch pipe (with an area of 3.14 x 2.5^2 or 19.6 sq in.) is. To calculate its allowable length, *L*:

$$L = \frac{9 \times 31.2^2 \times 5.047^5}{16 \times 128^2} = 109 \text{ ft}$$

The 109-foot restriction for a 5-inch pipe can easily accommodate the required length of run between Chiller #2 and Chiller #3.

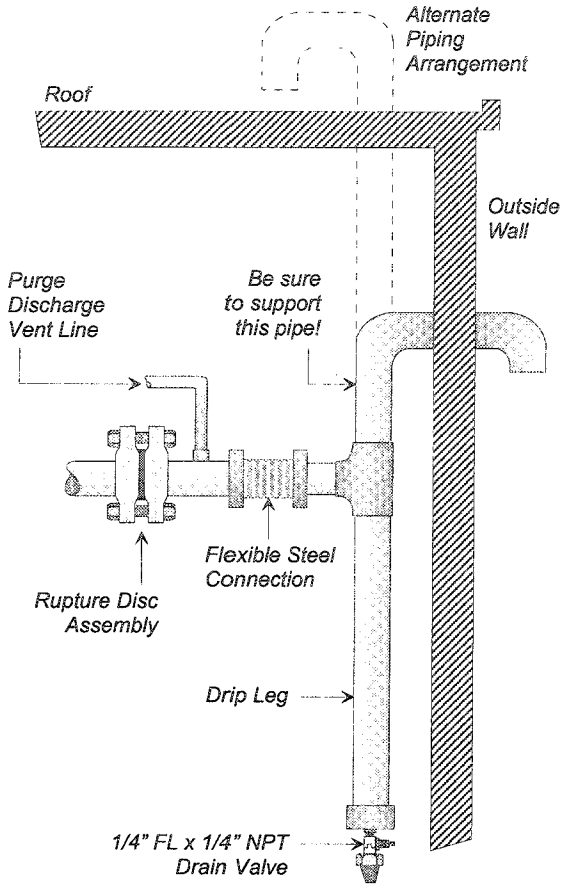
At the final junction (i.e., between Chiller #3 and the outdoor termination), the pipe must increase based on the sum of the areas of all three rupture disks (21.2 in^2). The area of a 6-inch pipe is 3.14 x 3^2 = 28.3 in^2 which is greater than 21.2 in^2 and, therefore, is large enough. To calculate its allowable length, *L*:

$$L = \frac{9 \times 31.2^2 \times 6.065^5}{16 \times 192^2} = 122 \text{ ft}$$

This is plenty of length to reach the edge of the building.

"But What If": In the preceding example, the "equivalent area" rule determined the required discharge pipe diameter. Another determinant of pipe size is the length of run. If our example equipment room had only one chiller, and the distance between it and the outdoor termination was 51 feet, the 3-inch pipe (with its 36.3-ft limit) would be too small. A 4-inch pipe, on the other hand, will easily work:

$$L = \frac{9 \times 31.2^2 \times 4.026^5}{16 \times 64^2} = 141 \text{ ft}$$



Drip Leg

Equip each discharge pipe with a drip leg capable of holding up to one gallon of liquid (i.e., 1 gallon = 231 cu in.) Use the following equation to find the length *(L)*, in inches, of pipe required for the drip leg ...

$$L = 294 / d^2$$

... where *d* is the inside diameter, in inches, of the pipe. *Figure 10 (page 21)* illustrates a properly piped refrigerant vent. To simplify draining, provide a standard 1/4" FL x 1/4" NPT capped refrigerant service valve. Accumulated liquid should be removed from the drip leg at least once every six months as a part of regular chiller maintenance. Use appropriate refrigerant handling procedures when draining the vent.

Figure 10
Suggested Refrigerant Vent Piping

Purge Discharge

Section 9.4, "Pressure-Relief Protection," of ASHRAE Standard 15–1994 also addresses the purge discharge. According to the Standard, purge units used to remove noncondensible gas from the refrigeration system must have discharge lines piped according to the requirements for relief piping. Section 8.16 states:

> "The discharge of purge systems shall be governed by the same rules as pressure-relief devices and fusible plugs (see [Section] 9.7.8) and shall be piped in conjunction with these devices."

Generally, the most convenient way to properly exhaust the purge discharge to the atmosphere is to route it into the relief-device discharge pipe. The purge discharge line must not contain any liquid traps, and should slope away from the purge unit to prevent liquid from collecting there. Connect the purge discharge pipe on the chiller side of any vibration isolation as shown in *Figure 10*. Consult the purge manufacturer for proper sizing of the purge discharge line.

Limit purge-related refrigerant loss as much as possible to minimize refrigerant discharge to the atmosphere and avoid the expense of replacing lost refrigerant. To accomplish this:

1 Choose a purge unit with a low refrigerant-to-noncondensible-gas discharge ratio that can operate while the chiller is off.

2 Routinely monitor the refrigeration system for leaks and promptly repair any that are found. Routine logging of purge operation and chiller run time provides an excellent indicator of system integrity.

3 Choose a purge unit that contains a safety system to prevent excessive purging due to malfunction or a large leak.

General Requirements

A number of important issues — applicable to all refrigeration systems and all refrigerant types — are addressed in Section 11, "General Requirements," of ANSI/ASHRAE Standard 15–1994. While these requirements do not directly affect equipment room "design," they're an integral part of safe equipment room environments. For your convenience, that section is reproduced in its entirety in the inset on page 22.

Note that Subsection 11.6, "Self-Contained Breathing Apparatus," refers to the **refrigerant quantity rules** provided in Section 7.4, "System Application Requirements," of the Standard. (See page 10 of this manual.) All refrigeration systems large enough to require a mechanical equipment room require the use of two self-contained breathing apparatus (SCBA), regardless of the type of refrigerant used.

An SCBA provides a personal air source that protects the wearer from exposure to a contaminated equipment room. Classified by the duration of its air supply, SCBA gear is generally rated for 30 minutes. ANSI/ASHRAE Standard 15–1994's requirement of such a device is intended to permit trained personnel to safely enter the equipment room and correct a malfunction. For this reason, it is important to

position the SCBA's outside but near the mechanical equipment room entrance.

Since it's unlikely that the SCBA will be used very often, it should be stored in a bright-colored, durable case to protect it from dirt and damage, and maintain its visibility. Use of SCBA's is governed by the Occupational Safety and Health Administration (OSHA); contact OSHA for a list of pertinent regulations and requirements.

11. General Requirements (from ANSI/ASHRAE Standard 15–1994)

11.1 Refrigerating Machinery Rooms. Access to the refrigerating machinery room shall be restricted to authorized personnel.

11.2 Signs and Identification

11.2.1 Installation Identification. Each refrigerating system erected on the premises shall be provided with a legible permanent sign, securely attached and easily accessible, indicating

(a) the name and address of the installer,
(b) the refrigerant number and amount refrigerant,
(c) the lubricant identity and amount, and
(d) the field test pressure applied.

11.2.2 Controls and Piping Identification. Systems containing more than 110 lb (50 kg) of refrigerant shall be provided with durable signs having letters not less than 0.5 in. (12.7 mm) in height, designating:

(a) valves or switches for controlling the refrigerant flow, the ventilation, and the refrigeration compressor(s), and
(b) the kind of refrigerant or secondary coolant contained in exposed piping outside the machinery room. Valves or piping adjacent to valves shall be identified in accord with ANSI A13.1, "Scheme for Identification of Piping Systems."

11.2.3 Changes in Refrigerant or Lubricant. When the kind of refrigerant or lubricant is changed as provided in 5.3, there shall be new signs to identify the changes in accordance with 11.2.1.

11.3 Charging, Withdrawal and Disposition of Refrigerants. No service containers shall be left connected to a system except while charging or withdrawing refrigerant. Refrigerants withdrawn from refrigerating systems shall be transferred to approved containers only. Except for discharge of pressure-relief devices and fusible plugs, incidental releases due to leaks, purging of noncondensibles, draining oil, and other routine operating or maintenance procedures, no refrigerant shall be discharged to the atmosphere or to locations such as a sewer, river, stream, or lake.

11.4 Containers. Containers used for refrigerants withdrawn from a refrigerating system shall be as prescribed in the pertinent regulations of the Department of Transportation and shall be carefully weighed each time they are used for this purpose, and containers shall not be filled in excess of the permissible filling weight.

11.5 Storing Refrigerant. The total amount of refrigerant stored in a machinery room in all containers not provided with relief valves and piping in accordance with (Section) 9.7 shall not exceed 330 lb (150 kg). Refrigerant shall be stored in approved storage containers. Additional quantities of refrigerant shall be stored in an approved storage facility.

11.6 Self-Contained Breathing Apparatus (SCBA). When a machinery room is required per the rules of (Section) 7.4, at least one approved self-contained breathing apparatus, suitable for the refrigerant used, shall be located outside of, but close to, the machinery room. A second, backup, self-contained breathing apparatus shall also be provided.

11.7 Maintenance. Refrigerating systems shall be maintained by the user in a clean condition, free from accumulations of oily dirt, waste, and other debris, and shall be kept accessible at all times.

11.7.1 Stop Valves. Stop valves connecting refrigerant-containing parts to atmosphere during shipping, testing, operating, servicing, or standby conditions shall be capped, plugged, blanked, or locked closed when not in use.

11.7.2 Calibration of Pressure-Measuring Equipment. Pressure-measuring equipment shall be checked for accuracy and calibrated prior to test and immediately after every occasion of unusually high (full scale) pressure, either by comparison with master gages or a dead-weight pressure gage tester over the operating range of the equipment.

11.7.3 Periodic Tests. Detector(s), alarm(s), and mechanical ventilating systems shall be tested in accordance with manufactures' specifications and the requirements of the jurisdiction having authority.

11.8 Responsibility for Operation and Emergency Shutdown. It shall be the duty of the person in charge of the premises on which a refrigerating system containing more than 55 lb (25 kg) of refrigerant is installed to provide a schematic drawing or panel giving directions to the operation of the system at a location that is convenient to the operators of the equipment.

Emergency shutdown procedures, including precautions to be observed in case of a breakdown or leak, shall be displayed on a conspicuous card located as near as possible to the refrigerant compressor. These precautions shall address:

(a) instructions for shutting down the system in case of emergency;
(b) the name, address, and day and night telephone numbers for obtaining service; and,
(c) the name, address, and telephone number of all corporate, local, state, and federal agencies to be contacted as required in the event of a reportable incident.

When a refrigerating machinery room is used, the emergency procedures shall be posted outside the room, immediately adjacent to each door.

Machinery Room Monitors

Various monitors are available for refrigerant detection applications. Differences in their designs and operating characteristics determine what applications best suit each monitor.

This section attempts to help the designer select an appropriate monitor for a particular equipment room application. To do this, it characterizes various monitor types and discusses how monitors can be used to provide a safe equipment room environment.

What ASHRAE 15-1994 Requires

ANSI/ASHRAE Standard 15–1994 mandates a refrigerant detector for all applications of refrigeration systems that require separate equipment rooms (see page 15). It further specifies that the monitor must activate an alarm if it detects a refrigerant concentration less than or equal to the corresponding TLV®–TWA (Threshold Limit Value–Time Weighted Average). Since these values can be quite small, the sensitivity of the "detector" must be appropriate to the refrigerant in use.

Any equipment room that contains more than one type of refrigeration system must satisfy the individual requirements of each system. For example, if an equipment room houses an R–11 chiller and an R–123 chiller, it must also contain either:

- ❑ one refrigerant "detector" capable of sensing both types of refrigerant; or ...
- ❑ two compound-specific monitors — one for R–11 and one for R–123.

Types of Monitors

At the heart of a refrigerant monitor is the sensor. Sensor technology plays a major role in determining the operating characteristics of the monitor. Refrigerant monitors typically fall into three general categories based on the type of sensor technology used.

Nonselective Monitors
"Detectors" of this type employ metal-oxide semiconductors or thermal ionization to detect the presence of refrigerant. Used for years in "pinpointing" leak detectors, this sensing method has a minimum sensitivity of approximately 20 to 30 ppm. However, an inability to differentiate between chemicals makes these detectors very susceptible to false alarms and severely limits their use as area monitors.

Halogen-Specific Monitors
These monitors typically use an ionization, element-type sensor that can be calibrated to respond only to the chlorine, fluorine and bromine found in refrigerants. Though more discriminating than nonselective monitors, they cannot differentiate between refrigerants. Halogen-specific monitors can be calibrated, and are accurate at concentrations as low as 10 ppm. Sensor operating life is typically one year, but may vary with exposure to refrigerant.

Compound-Specific Monitors
This type of monitor is virtually interference-free, offers the highest degree of selectivity, and is capable of detecting concentrations as low as 1 ppm. Presence of refrigerant is detected with infrared spectroscopy (long used in industrial applications), gas chromatography or photo-acoustic spectroscopy. Because they analyze the refrigerant's physical properties, these devices require less recalibration than other monitor types.

A compound-specific monitor (sometimes referred to as "refrigerant-specific") is the best choice for an equipment-room area monitor.

Choosing the Right Monitor

Regardless of sensing technology, refrigerant-vapor monitors can be divided into two broad categories: those intended for continuous duty, and those used periodically for short-term refrigerant leak detection. The operating characteristics associated with each group reflect the different purposes they serve in an equipment room environment.

"Short-term" monitors are used briefly, at regular intervals, to check a refrigeration system for leaks during preventive maintenance or troubleshooting. Consequently, a monitor used for this purpose must:

- ❑ withstand large doses of refrigerant;
- ❑ respond and clear rapidly;
- ❑ be portable; and ...
- ❑ be sensitive to the refrigerant being monitored (though not necessarily refrigerant-specific).

Compliance with the intent of ANSI/ASHRAE Standard 15–1994 — i.e., to provide a safe environment for equipment room occupants — requires installation of a **continuous monitor**. Refrigerant monitors suited for this type of duty possess:

- ❑ **refrigerant-specific sensitivity**. Less discriminating monitors can alarm if nonrefrigerant compounds such as cleaning agents or paints are detected.
- ❑ **stability over the expected operating range** of temperatures, voltages, humidities and barometric pressures. Calibration stability is a critical aspect of monitors used for continuous surveillance, and is provided by the electronic component that reads the sensor output. In general, monitor accuracy must be unaffected under all equipment room conditions.
- ❑ **low zero drift or an "auto-zeroing" capability.** To be suitable for continuous equipment-room duty, the monitor must provide a means of setting the "zero" reference point — i.e., either a very small zero drift (parts per million, ppm, between inspections) or an "auto zero" feature.
- ❑ **long service life with minimal maintenance.**
- ❑ **alarm limits that correspond to the refrigerant being monitored.**
- ❑ **outputs to signal that an alarm condition exists and start auxiliary equipment.** ANSI/ASHRAE Standard 15–1994 requires that the monitor *"actuate an alarm and mechanical ventilation"* to alert equipment room occupants that the refrigerant concentration exceeds the TLV® or AEL (acceptable exposure limit).

Monitor Inputs and Outputs

Remote Reset Input

Often, the alarm state initiated by the monitor triggers a latching alarm that requires manual reset. Some refrigerant monitors contain a remote reset input that can be used to cancel the alarm from a distance — provided the refrigerant build-up that triggered it has dispersed.

☞ *If the alarm doesn't reset, steps should be taken to assure occupant safety on entry — i.e., provide additional ventilation, don the proper personal protective equipment (respiratory protection, goggles, gloves, protective suit, boots), and use a hand-held monitor to determine the room's refrigerant concentration.*

Locate the remote reset button outside the equipment room door so that an operator can reset the alarm *before* entering the room.

Alarm Relay Output

☞ *Follow the local regulatory requirements and equipment manufacturers' alarm level recommendations when establishing alarm settings and actions. The following recommendations are based on ASHRAE Standard 15–1994 and a Trane document entitled "Low-Pressure Refrigerant Emergency Spill Procedures."*

"Single-Stage" Alarm

The alarm relay output energizes when the refrigerant concentration exceeds the preset alarm limit. **To satisfy ASHRAE Standard 15–1994, the alarm must energize at or below the TLV–TWA (or equivalent toxicity measurement) for the refrigerant in use. It must also activate an alarm and mechanical ventilation at the alarm rate.** When only one level of alarm is available, the general recommendation is to set the alarm limit at 30 ppm. This meets the TLV–TWA requirement for

most commonly used refrigerants, and provides early warning of refrigerant loss. Remote alarm indication can also be provided by connecting this relay to the building automation system (BAS).

In some cases, personal protective equipment requirements may change as refrigerant concentrations increase; a single alarm level can't signal the presence of higher refrigerant levels that require protective gear. Personnel must either check the refrigerant level (if displayed on the monitor or at a separate device), or assume the worst and don appropriate protective gear. Multiple alarm levels, on the other hand, can be used to indicate these changing requirements.

"Two-Stage" Alarm
If the monitor provides two levels of alarm, set the first level low enough to provide early leak detection (i.e., generally at 30 ppm). Alarm-rate ventilation should also be energized at this point, as well as an indicator light to notify personnel of the leak.

Set the second level of alarm to the concentration at which personal protective equipment is required for personnel in the room. This level should also notify the remote area supervisor, *and* energize an alarm indication outside the equipment room to notify personnel that the room is not safe to enter without proper personal protective equipment.

"Three-Stage" Alarm
Monitors with three levels of alarm provide greater notification flexibility. As above, the first level is set low enough to provide early leak detection; it's also used to start alarm-rate ventilation and energize an indicator to notify personnel of the leak. Alternately, alarm-rate ventilation and activation of an indicator can be performed by the second level of alarm; this allows a lower first-level setting and provides even earlier notice of a refrigerant leak. Of course, the second alarm level could, instead, be used to indicate the need for an intermediate type of personal protective equipment.

Set the third alarm level to the concentration at which personal protective equipment is required for personnel in the room. Use this level to notify the remote area supervisor, as well, and to energize an alarm indication outside the equipment room notifying personnel that the room is not safe to enter without proper personal protective gear.

Failure Relay Output

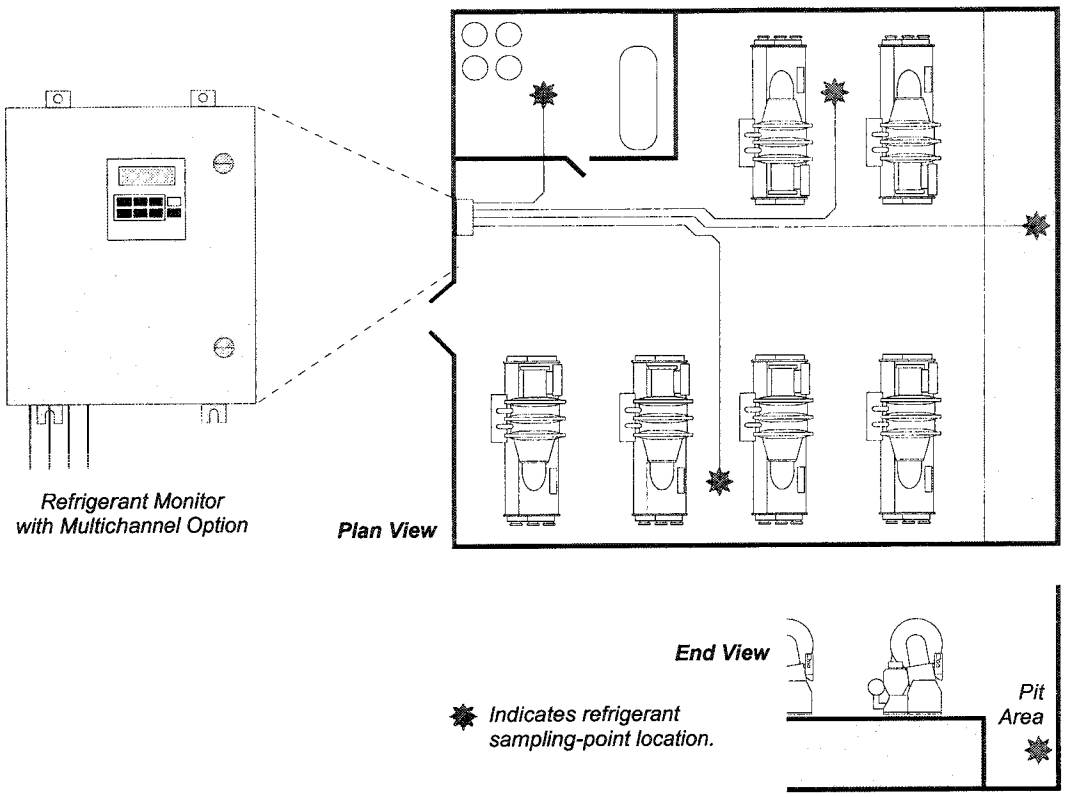
This relay energizes if the monitor malfunctions due to low airflow, circuit failure or a saturated (or absent) sensor signal. It can also indicate loss of power if these contacts are normally powered open. Use the failure relay output to visually or audibly signal the building operator that the monitor must be checked and returned to operation.

☞ *As part of monitor checkout, the operator should bring a portable detector to the equipment room to ascertain refrigerant concentration.*

Refrigerant-Monitor Analog Output

Some monitors provide a 0–10 vDC, 4–20 mA or serial signal proportional to the level of refrigerant detected. Use this output to provide a remote indication of the equipment room's refrigerant level — perhaps by "driving" a meter installed outside the equipment-room entry. The meter can help operating personnel assess the need for breathing apparatus, or whether the ventilation system successfully cleared leaked refrigerant from the room.

When connected to a building automation system, this output can alert operating personnel of a leak, initiate alarm-rate ventilation, and enable automatic logging of the equipment room's refrigerant level.



Multichannel Scanners

To adequately monitor a large refrigeration system, an equipment room with several chillers, or an equipment room with two or more levels, it may be necessary to sense refrigerant concentration at various locations. A **multichannel scanner** connected to a single monitor or a monitor with a multichannel option provides an alternative to mounting several individual monitors in the equipment room.

Typically, two or more sampling tubes are routed from the scanner to other parts of the room, as shown in *Figure 11 (page 26)*. Equipment design determines the length of each sensing-tube run and the number of "pickup" points that can be monitored.

Multichannel scanning enables the monitor to check the air sampled at each location by individually "connecting" each sampling tube to the monitor on a rotating basis.

Figure 11
Typical Multichannel Scanner Application

Benefits of a BAS Interface

Building owners and operators insist on efficient, documentable building performance ... the state-of-the-art energy and information management capabilities provided by a building automation system (BAS) help address this demand. Equipment-room monitoring for refrigerant build-up is a natural candidate for system-level control, and is attractive for a number of reasons:

1 **Automatic logging and documentation of refrigerant monitor readings.** Automatic trend logging of refrigerant concentrations in the equipment room:

(a) assures employees that they're working in a safe environment.

(b) confirms, in writing, that refrigerant concentrations are maintained below the applicable TLV®–TWA (or equivalent toxicity measurement).

(c) satisfies EPA-imposed regulations requiring verification of the operating procedures used to control CFC and HCFC equipment room emissions. Automated control reports offer unquestionable proof that even minute concentration levels of refrigerant have been measured and recorded.

2 **Automatic dial-out on alarm detection.** The BAS not only monitors refrigerant level and initiates necessary alarms from a central, remote location, but can also automatically dial the service contractor when an alarm occurs. In this way, a trained expert — one who can take quick and appropriate corrective action — can constantly oversee equipment room operation.

3 **Purge rate surveillance for early leak detection.** Leaks are the number one cause of refrigerant loss from refrigeration systems. While the refrigerant vapor monitor can detect a leak before a significant amount of refrigerant is lost, a BAS can provide an even earlier indication by monitoring, logging and plotting operation of the chiller's purge unit. It can also display a diagnostic message for the operator if the purge rate exceeds a preset limit.

Sample Equipment Room Design Specification

☞ *The following specification sections are written to demonstrate wording that could be used to bring equipment room and chiller specifications into compliance with ANSI/ASHRAE Standard 15–1994 and ANSI/ASHRAE Standard 34–1992.* ***It applies only to low-probability refrigeration systems that contain Group A1 or B1 refrigerants and require a machinery room.*** *If used as a guide for specifying and designing an equipment room, check local codes to avoid any conflicts or deficiencies.*

PART 1 GENERAL

1.01 Section Includes

A. Entrance Door Requirements

B. Equipment Room Ventilation

C. Refrigerant Detectors

D. Remote Refrigerant Alarming and Equipment Shutdown

E. Chiller Plant Management

F. Self-Contained Breathing Apparatus

G. Open Flame Devices

H. Equipment Room Signs and Identification

A. ANSI/ASHRAE STANDARD 15–1994, "Safety Code for Mechanical Refrigeration"

B. ANSI/ASHRAE STANDARD 34–1992, "Number Designation and Safety Classification of Refrigerants"

PART 2 PRODUCTS

2.01 Summary

A. The design, installation and operation of the machinery room containing the refrigeration system shall meet ANSI/ASHRAE Standard 15–1994 as a minimum design criteria. Additional equipment and controls shall be added as required to protect the occupants of the machinery room from hazardous exposure to refrigerants. Access to the machinery room shall be restricted to authorized personnel.

2.02 Entrance Door Requirements

A. All equipment doors shall be tight-fitting and open outward. Doors leading to the building shall be self-closing. There shall be no openings to permit passage of escaping refrigerant to other parts of the building.

2.03 Equipment Room Ventilation

A. **General:** Ventilation systems that serve the machinery room must be entirely separate from other portions of the building. Air discharged from the machinery room shall be to the outdoors, and shall not cause inconvenience or danger. Sufficient inlet air shall be provided to replace the air being exhausted. Openings for air inlets shall be positioned to avoid intake of discharged air. Inlet air shall be treated as required to avoid equipment damage caused by freezing temperatures and/or large, rapid temperature swings.

Ventilation inlets and outlets for the machinery room shall be placed to provide an air sweep across refrigeration equipment. Unit spacing and positioning shall be coordinated with ventilation inlets and outlets to avoid areas of stagnation around the refrigeration equipment.

All exhaust fans used to meet the maximum ventilation rate shall have inlets located no more than 4 feet above floor level. In addition, at least 50 percent of the air used for normal ventilation shall be exhausted from less than 4 feet above floor level.

B. The ventilation system shall be capable of exhausting a build-up of refrigerant from

the machinery room at the maximum rate. The air volume required for exhausting at the maximum rate shall be _____ cfm at _____ inch static.

Or ...

B. The ventilation system shall have two speeds. It shall be capable of exhausting a build-up of refrigerant from the machinery room at the maximum rate. The normal ventilation volume shall be _____ cfm at _____ inch static. The air volume required for exhausting at the maximum rate shall be _____ cfm at _____ inch static.

C. The ventilation system shall be operated as follows:

1. When the equipment room is occupied, the ventilation system shall [operate at low speed and] supply at least 0.5 cfm per square foot of machinery room area or 20 cfm per person (whichever is greater).
2. When necessary for operator comfort, the ventilation system shall maintain a maximum temperature [rise of 18° F based on all heat-producing machinery in the room] [of 75° F].
3. If the ventilation system is not run continuously at the maximum rate, exhaust ventilation must be automatically triggered by the refrigerant monitor whenever a refrigerant concentration above the TLV®–TWA (or toxicity measurement consistent therewith) is detected in the machinery room.

Include the following section here if the mechanical contractor is supplying the refrigerant monitor. Move it to the chiller specification if the chiller manufacturer is supplying the refrigerant monitor.

2.04 Refrigerant Detector(s)

A. A minimum of one permanently-mounted, continuously-operating refrigerant vapor monitor [as supplied by the installing mechanical contractor] [as supplied by the chiller manufacturer] shall be mounted in the machinery room to detect leakage of refrigerant from locations where the refrigerant is either stored or used.

B. Multiple monitors or monitor pickup points shall be used to limit the distance between the sensor and the refrigerant source to not more than 50 feet. Pits, tunnels or trenches in the machinery room that are accessible to personnel shall also be monitored. Monitor sampling point(s) shall normally be located 18 inches above the floor in a location near the refrigerant source, and shall be situated between the refrigerant source and the exhaust fan inlet.

C. Refrigerant Monitor Performance

1. Refrigerant monitor shall be capable of detecting concentrations of 1 ppm for low-level leak detection and for insuring the safety of operators. It shall be supplied factory-calibrated for the appropriate refrigerant.
2. All monitors shall be capable of continuously monitoring the machinery room for the refrigerant used in the system. Monitor design and construction shall be compatible with temperature, humidity, barometric pressure and voltage fluctuations of the machinery room operating environment.

---

3. The refrigerant monitor shall provide an alarm relay output which energizes when the monitor detects a refrigerant level at or above the TLV–TWA (or toxicity measurement consistent therewith). This relay shall be used to initiate the following events:

---

   a. Energize an alarm consistent with other warning devices in the building to signal machinery room occupants.

   Or ...

   a. Energize a light on or near the monitoring device; a second light, outside the machinery room

entrance, shall be used to provide an additional warning. [(If the machinery room is not checked on a routine basis,) A signal shall be sent to a remote location where it will be detected by a building operator.]

---

b. Energize all exhaust fans required to achieve the maximum rate of exhaust. Exhaust fans shall remain energized until manually deactivated by an operator.

Or ...

3. The refrigerant vapor monitor shall provide three levels of alarm with a relay output for each level:

a. The first level of alarm shall be set at ____ ppm (at or below the TLV®–TWA, or toxicity measurement consistent therewith) of the refrigerant in use; and shall energize the ventilation equipment at the maximum rate and illuminate an indicator light.

b. The second level of alarm shall be set at ____ ppm; and shall energize an alarm indication outside the equipment room.

c. The third level of alarm shall be set at ____ ppm; and shall energize an audible and visual alarm that signals evacuation of the equipment room, and notifies personnel that the room is not safe to enter without proper personal protective gear. An alarm signal shall also be sent to a remote area supervisor to indicate that a possible large leak or spill is occurring or has occurred.

---

4. The refrigerant vapor monitor shall provide a failure relay output, separate from those described above, that energizes when the monitor detects a fault in its operation. Examples of faults include low airflow through the monitor, circuit failure, and a saturated or absent sensor signal. This output shall signal an alarm condition to the building operator so that the monitor can be checked and returned to operation.

5. Operating instructions that detail the calibration and maintenance requirements of the refrigerant vapor monitor in use shall be accessible to machinery room maintenance personnel. Calibration and maintenance of the refrigerant monitor shall be included in the general maintenance procedures for the machinery room.

---

*The following section is **optional**. Include it in this section of the specification if it is the mechanical contractor's responsibility. Move it to the chiller specification if the chiller manufacturer is supplying the chiller plant management.*

2.05 Remote Refrigerant Alarming and Equipment Shutdown

A. A control panel that contains the following items shall be located at all main entrances to the machinery room:

1. A blue light that is energized by "alarm level 1."

2. A yellow light that is energized by "alarm level 2."

3. A red light that is energized by "alarm level 3."

4. A momentary push-button used to reset the alarm at the monitor. This shall only reset a past alarm condition and shall not disable the monitor. The alarm must reactivate within 10 seconds if the alarm condition still exists in the machinery room.

5. A separate shutdown switch for every chiller or refrigeration system compressor.

---

*The following section is **optional**. Include it in this section of the specification if it is the mechanical contractor's responsibility. Move it to the chiller specification if the chiller manufacturer is supplying the chiller plant management.*

2.06 Chiller Plant Management

A. When the building is equipped with a Building Automation System (BAS), the following features shall be provided at the central control:

1. The BAS shall track the level of refrigerant sensed by the monitor. This signal shall be used to generate an electronic log of the refrigerant level in the machinery room. Any increase in that level shall trigger an informational diagnostic indicating that the refrigeration system should be checked for leaks.
2. The BAS shall monitor the alarm status of the refrigerant monitor and provide an alarm condition for each of the following:
   a. Monitor malfunction.
   b. Refrigerant alarm triggered at the TLV®–TWA (or equivalent toxicity measurement) for the refrigerant in use.
   c. Refrigerant alarm triggered at 3 times the TLV–TWA (or equivalent toxicity measurement) for the refrigerant in use.
3. The BAS shall be tied to the machinery room ventilation system to provide control of both normal and maximum-rate ventilation of the machinery room. This control shall parallel the primary control of the fans provided by the refrigerant monitor.

2.07 Self-Contained Breathing Apparatus

A. Two approved self-contained breathing apparatus (SCBA) [as supplied by the installing mechanical contractor] [as supplied by the chiller manufacturer] shall be mounted outside of, but close to, the machinery room by the installing mechanical contractor.

2.08 Open Flame Devices

A. No open flames or apparatus to produce an open flame installed in the machinery room shall use combustion air from the machinery room except as permitted below.

B. Open flame devices (e.g. boilers or direct-fired chillers) shall be permitted when:

1. Combustion air to the device is from outside the machinery room so that no air from the machinery room can enter the device; or ...
2. The device is tied to a refrigerant monitor such that when the monitor alarms, the device is shut down.

2.09 Equipment Room Signs and Identification

A. Each refrigerating system erected on the premises shall be provided with an easily legible, permanent sign that is securely attached, easily accessible and indicates the following:

1. Name and address of the installer.
2. Proper name and amount of refrigerant.
3. Lubricant identity and amount.
4. Field test pressure applied.

B. Systems that contain more than 110 lbs of refrigerant shall be provided with durable signs that have letters not less than 0.5-inch in height and identify the following:

1. Valves or switches that control refrigerant flow.
2. Switches that control ventilation.
3. Switches that control operation of the refrigeration compressor(s).
4. The kind of refrigerant or secondary coolant contained in the exposed piping outside the machinery room.
5. Valves or piping adjacent to valves shall be identified in accord with ANSI A13.1, "Scheme for Identification of Piping Systems."

(End of Specification)

Appendix A —

Indirect Open-Spray Systems

Indirect open-spray systems (air washers) are occasionally used in industrial processes — most commonly those associated with textile manufacturing. **Air washers are considered "low-probability" systems provided the water pressure in the chiller evaporator is *always* greater than the refrigerant pressure in that same vessel.** Under this condition, it's almost impossible for refrigerant to enter the process air stream.

This appendix discusses how to design an indirect open-spray system that uses R–123 centrifugal chillers, and complies with the criteria established for low-probability systems in ANSI/ASHRAE Standard 15–1994 and ANSI/ASHRAE Standard 34–1992.

Temperature/Pressure Relationships

Table A–1 shows the temperature/pressure characteristics of saturated HCFC–123. Notice that it boils at 83° F under atmospheric pressure. As long as the evaporator water temperature is below 83° F, there's no chance of violating the "low probability" criterion — i.e., refrigerant pressure will never exceed water pressure at the evaporator.

Table A–2 shows the conversion between gauge pressure (psi) and water column pressure (ft H_2O). The pressure-relief device on all standard Trane centrifugal HCFC-123 chillers is designed to relieve at 15 psi. Any system water pressure greater than 15 psi is almost certain to exceed the evaporator refrigerant pressure. Therefore, any system with a

Table A–1
Temperature/Pressure Characteristics of Saturated HCFC–123

Temperature	*Pressure*
40° F	*18.2 in. Hg vac*
50° F	*15.0 in. Hg vac*
60° F	*11.2 in. Hg vac*
70° F	*6.6 in. Hg vac*
80° F	*1.1 in. Hg vac*
83.0° F (boiling point)	*0 in. Hg vac*
90° F	*2.6 psi*
100° F	*6.3 psi*
110° F	*10.5 psi*
119.2° F	*15.0 psi*

Table A–2
Gauge-Pressure-(PSI)-to-Water-Column-Pressure-(FT) Conversion

Gauge Pressure	*Water Column Pressure*
0 psi	*0 ft H_2O*
2 psi	*4.6 ft H_2O*
4 psi	*9.2 ft H_2O*
6 psi	*13.9 ft H_2O*
8 psi	*18.5 ft H_2O*
10 psi	*23.1 ft H_2O*
12 psi	*27.7 ft H_2O*
14 psi	*32.3 ft H_2O*
15 psi	*34.7 ft H_2O*

static hydraulic head of at least 34.7 feet at the evaporator guarantees low-probability system status.

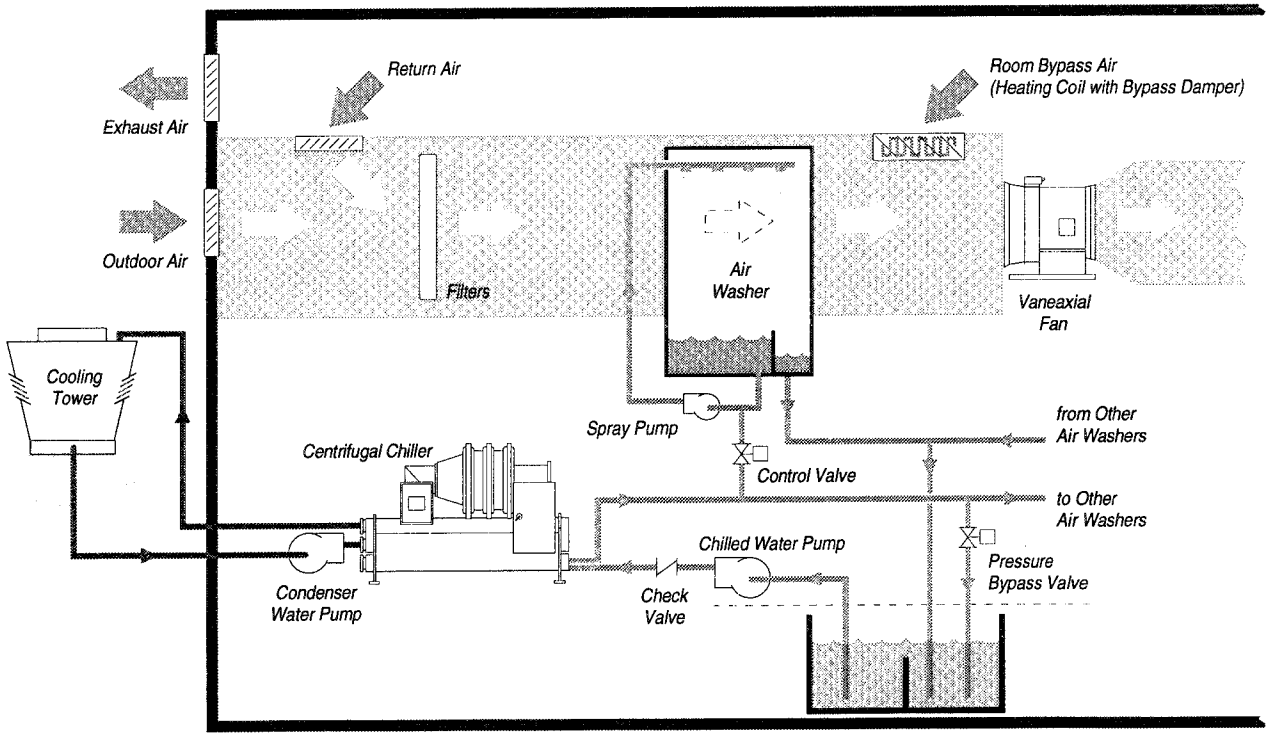

Figure A–1 illustrates a typical chilled-water air washer system. Base the design of such a system on one of the following premises to assure its "low probability" classification:

- ❑ **Static (at rest) hydraulic head equals or exceeds 34.7 feet.** Many such systems meet this criteria by virtue of the physical location of the chilled water system components. In these cases, no special configurations are needed.
- ❑ **When the "natural" static head is less than 34.7 feet, add a standpipe or expansion tank to the chilled water supply riser.** While this arrangement is static and doesn't require external controls, a check valve *is* needed at the chilled water pump discharge to prevent reverse drain-down when the system is at rest. See *Figure A–2 (page A–3).* If an expansion tank is used, set the automatic pressurizing valve to maintain 15 psi at the chiller evaporator.
- ❑ **Use a special low-pressure relief valve (disc) to reduce the minimum required system water pressure.** For example, a 10-psi relief valve can be used to lower the required static head from 34.7 feet to 23.1 feet. This also lowers the maximum evaporator equilibrium temperature at which refrigerant venting occurs to 108.8° F, but this temperature is still well above that which could be reasonably expected in a normal environment.
- ❑ **Operate the chilled water pump to produce a dynamic head greater than 15 psi at the evaporator.** The system's low-probability status can be maintained simply by starting the chilled water pump whenever the evaporator leaving-water temperature exceeds the refrigerant saturation temperature associated with the static hydraulic head. For example:

  (a) If the air washer has a static head of zero when at rest, control the chilled water pump to start whenever the evaporator's leaving-water temperature exceeds 83° F. At this saturation temperature, HCFC–123 develops a vapor pressure of 0.0 psi.

  (b) If the air washer's piping configuration results in a static head of 18 feet when the system is at rest, control the chilled water pump to start whenever the evaporator's leaving-water

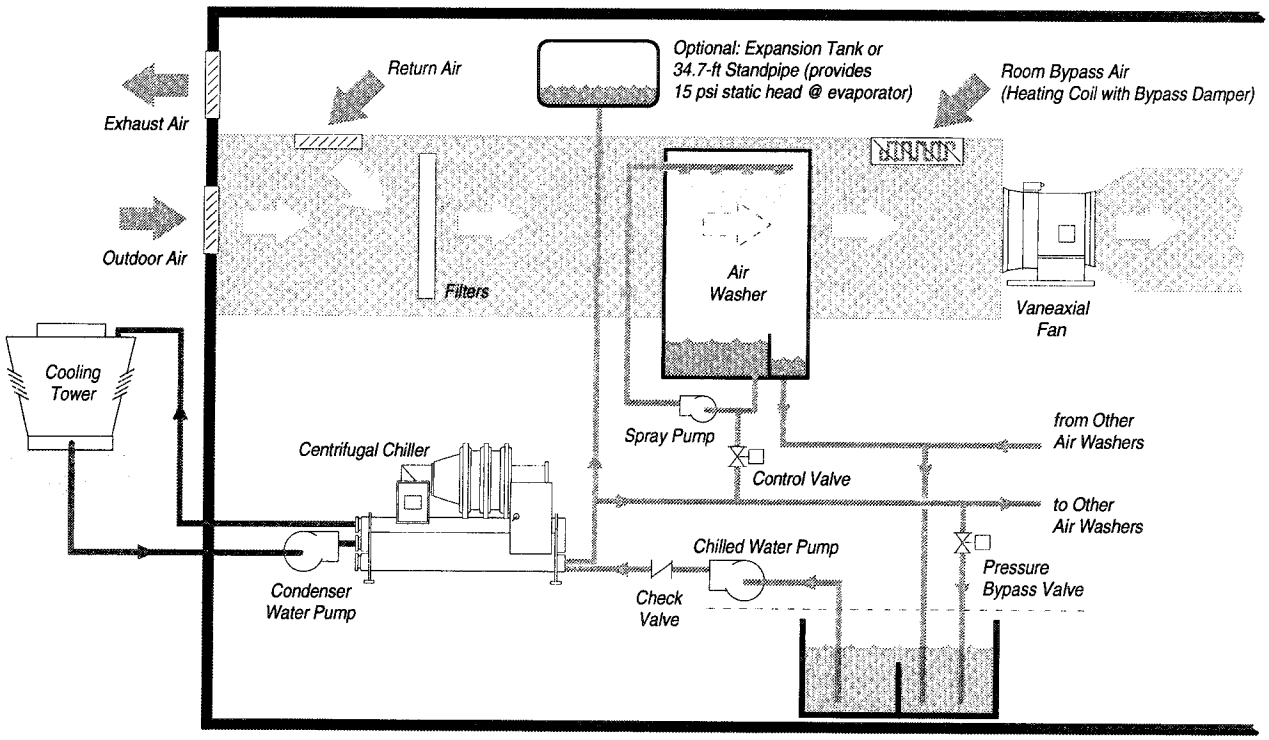
Figure A–1
Typical Chilled-Water Air Washer System

temperature exceeds 103.6° F. This control point is determined by converting the static head of 18 feet into 7.79 psi (1.0 psi = 2.31 ft H_2O), then calculating the equivalent saturation temperature of HCFC–123 at 7.79 psi (i.e., 103.6° F).

Pump-induced pressurization is easy to implement: it depends only on the action of a two-position chilled-water-temperature thermostat. In the closed position, the thermostat starts the chilled water pump; it also energizes an alarm light or message to notify operators of this event.

☞ *As a control medium, water temperature is preferred over refrigerant pressure because it allows the use of a more robust, less expensive controller.*

Further Assurance ...



In practice, it's unlikely that refrigerant could ever leak through the chilled water loop into the process air stream. For it to do so, several improbable events must occur simultaneously:

1 *A significant leak must develop in an evaporator tube.* Evaporator tube leaks are not only rare, but easily detected, too — i.e., the presence of water in the refrigerant triggers immediate operation of the chiller's purge monitoring station.

2 *Refrigerant pressure must significantly exceed evaporator pressure.* This condition can only occur when the evaporator water temperature is highly elevated — usually well above the normal plant ambient, especially when the plant is occupied and in operation.

3 *Refrigerant must be in its vapor state to escape into the process air stream.* This could only occur while the air washer is operating, when the chilled water contacts air. Since the air washer always functions as a cooler, chilled water temperatures in the washer rarely exceed 55° F ... well below the 83° F boiling point of HCFC–123.

Figure A–2
Typical Chilled-Water Air Washer System with Expansion Tank (for Applications with "Natural" Static Hydraulic Head of <34.7 Ft)

Refrigerant Containment

Of greater safety and economic concern is the entire issue of refrigerant containment. Use of "low-probability" systems doesn't address this issue: this classification refers only to the likelihood and consequences of a refrigerant leak.

Refrigerant containment can only be achieved through proper equipment design, manufacture, installation and maintenance. Therefore, effective leak *prevention* requires that members of the HVAC community:

- ❑ design for minimum leak opportunities (e.g., use hermetic construction, avoid flare fittings wherever possible, construct welds correctly and use proper materials);
- ❑ design for manufacturability;
- ❑ assure manufacturing quality;
- ❑ use low-pressure refrigerants (i.e., to permit application of near-zero emission purge/ monitoring systems); and ...
- ❑ practice leak prevention and refrigerant containment maintenance procedures. For example, monitor purge system operation with an automation system (e.g., a Tracer® or Tracer Summit™ building management system); fix leaks if and when they occur; and follow the maintenance procedures suggested by the chiller manufacturer.

For additional information on refrigerant containment, refer to ASHRAE Guideline 3–1990, "Reducing Emission of Fully Halogenated Chlorofluorocarbon (CFC) Refrigerants in Refrigeration and Air Conditioning Equipment and Applications."

Appendix B —

How Much Refrigerant per Occupied Space?

To determine if your HVAC system meets the requirements of the *Refrigerant Quantity Rules* in ANSI/ASHRAE Standard 15–1994, you must first identify which rules apply ... and to do that, you must:

1 Identify the refrigeration system's **safety group classification**.

2 Determine the **occupancy classification** of the room that houses the refrigeration system.

3 Determine the **system probability** classification of the refrigeration system.

4 Based on the determinations made in the preceding steps, **use Table 2 of the Standard** (reproduced on page 10 of this manual) to identify the applicable *Refrigerant Quantity Rules* found in Section 7.4.

When an applicable rule refers to a Table 1 refrigerant quantity, you must then determine the amount of refrigerant per 1,000 cu ft of occupied space for the proposed system. And to do *that,* you must determine how much refrigerant the largest single chiller — or largest refrigeration circuit — contains, then calculate the volume of the occupied space. Different calculations must be used for unventilated and ventilated spaces.

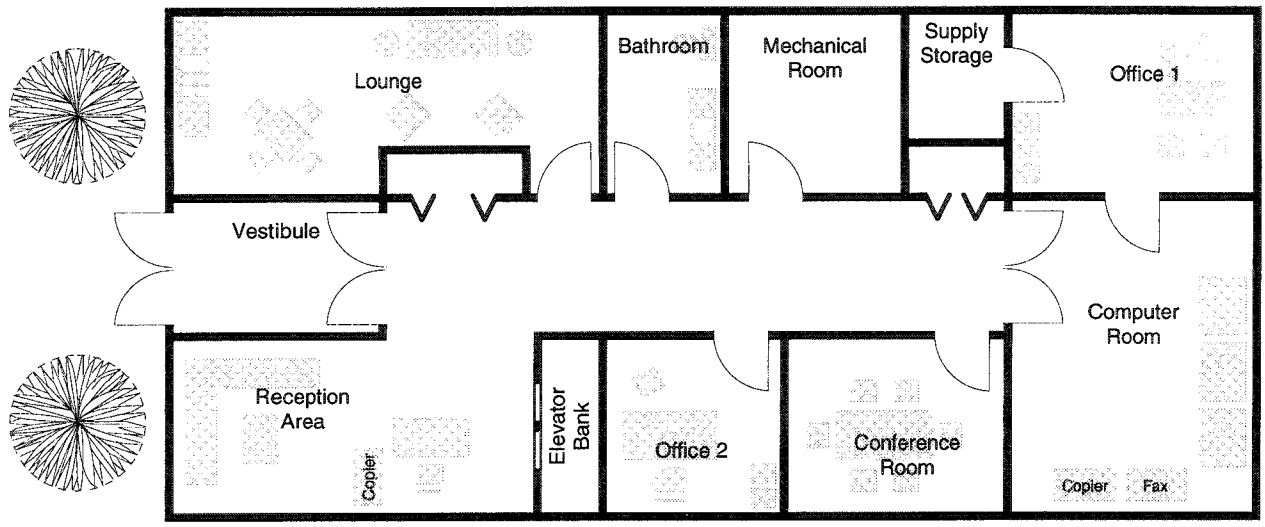
Unventilated Occupied Spaces

When the room that houses the refrigeration equipment is unventilated, the occupied volume is simply the volume of the room. In the case of a PTAC unit in a hotel room, the volume of the occupied space equals the hotel room's volume.

Similarly, for a chiller located indoors, the volume of the occupied space again equals the room's volume. However, if the amount (lbs) of refrigerant per 1,000 cu ft of room volume exceeds the limit set in Table 1 — and it typically does — the room must be converted to a "machinery room" per Section 11, and is no longer considered an "occupied space."

Ventilated Occupied Spaces

The term "ventilated space" applies when a refrigeration system's evaporator or condenser is located within the duct system, as is the case in direct expansion (DX) systems. For such systems, the "occupied space" comprises the entire space served by the duct system, *with these restrictions:*



- ❑ Any space in which the airflow can be reduced below 25% of design must be omitted from the total occupied space volume; **and** ...
- ❑ Plenum space cannot be included unless it is continuous, and part of the return air system.

For example, let's assume the following:

> *A 20-ton packaged cooling-only rooftop air conditioner with variable air volume (VAV) control serves the small office building shown in Figure B–1 (page B–2). The unit contains two 10-ton refrigeration circuits, each of which holds 20 lbs of R-22. VAV boxes with a 25% minimum flow setting deliver supply air to all rooms except the conference room, which is served by a VAV box with a minimum flow setting of 0%. An open plenum provides the return air path to the unit.*
>
> *The building's occupied spaces have 9-ft ceilings with an 18-in. plenum above them. This plenum is interrupted over the mechanical room where the walls extend from the floor slab to the roof.*

Based on this information, we can deduce that the relevant safety group classification is **A1**, that it's a

Figure B–1
Example Small Office Building

commercial occupancy, and that it's a **high-probability** system. With these facts, Table 2 of the Standard tells us that *Refrigerant Quantity Rule 1* describes the relevant system application requirements. Rule 1, in turn, states that the allowable refrigerant quantity is limited to the value shown in Table 1 — i.e., 9.4 lbs per 1,000 cu ft of occupied space.

To find the total occupied-space volume, calculate the volume of each occupied room and add the resulting values:

Lounge	*15' x 50' x 9'*	=	*6,750 cu ft*
Office 1	*15' x 30' x 9'*	=	*4,050 cu ft*
Bathroom	*15' x 18' x 9'*	=	*2,430 cu ft*
Computer Room	*15' x 25' x 9'*	=	*3,375 cu ft*
Office 2	*15' x 15' x 9'*	=	*2,025 cu ft*
Reception Area	*15' x 45' x 9'*	=	*6,075 cu ft*
Continuous Plenum (less mech room, elevators)		=	*6,925 cu ft*
Total Volume		=	***31,630 cu ft***

Notice that the volumes of the unventilated spaces — the mechanical room, supply storage, vestibule and elevator bank — weren't included. The conference room was omitted as well since its airflow can be lower than 25% of design.

Having determined the volume of the occupied space, we can now calculate the quantity of refrigerant in our rooftop unit for every 1,000 cut ft of space:

$$20\ lbs \div \frac{31{,}630\ cu\ ft}{1{,}000} = \frac{0.6\ lbs}{1{,}000\ cu\ ft}$$

This value is well below the 9.4 lbs/1,000 cu ft limit set by Table 1.

The refrigerant limits listed in Table 1 can also be used to determine the minimum volume of occupied space a particular refrigeration system requires. For example, when the 9.4 lb/1,000 cu ft limit is inverted, it indicates that 106.4 cu ft of occupied space is required for each pound of R–22 in the system (i.e., 1,000 ÷ 9.4 = 106.38). Since our example rooftop unit contains 20 lbs in its "largest" circuit, the occupied space it serves must be at least 2,128 cu ft (i.e., 20 × 106.4 = 2,128).

Appendix C —

Glossary and Acronyms

accessible
easy to approach for service or use ... see also *readily accessible*

ACGIH
American Conference of Governmental Industrial Hygienists

AEL
acceptable exposure limit

ANSI
American National Standards Institute

ASHRAE
American Society of Heating, Refrigerating and Air-Conditioning Engineers

azeotropic
blends comprising multiple components of different volatilities that, when used in refrigeration cycles, do not change volumetric composition or saturation temperature as they evaporate or condense at constant pressure ... see also *zeotropic*

BAS
building automation system

blends
refrigerants consisting of mixtures of two or more different chemical compounds, often used individually as refrigerants for other applications

BOCA
Building Officials and Code Administrators

CFC
chlorofluorocarbon

corridor
an enclosed passageway that limits travel to a single path

EEL
emergency exposure limit

EPA
Environmental Protection Agency

equipment room
as used in this manual, is synonymous with **machinery room**

fractionation
a change in composition of a blend by preferential evaporation of the more volatile component(s) or condensation of the less volatile component(s)

fusible plug
a plug containing an alloy that will melt at a specified temperature and relieve pressure

halocarbon
a hydrocarbon derivative containing one or more of the halogens bromine, chlorine or fluorine; hydrogen may also be present

hydrocarbon
a compound containing only the elements hydrogen and carbon

HVAC&R
heating, ventilating, air conditioning and refrigerating

ICBO
International Conference of Building Officials

IDLH (immediately dangerous to life or health)
the maximum concentration from which unprotected persons are able to escape within 30 minutes without escape-impairing symptoms or irreversible health effects

lower flammability limit (LFL)
minimum concentration of the refrigerant that is capable of propagating a flame through a homogeneous mixture of the refrigerant and air under test conditions ... normally expressed as refrigerant percentage by volume

machinery room
a space, meeting the requirements of Section 8.13 or 8.14 of ASHRAE Standard 15–1994, that is designed to house compressors and pressure vessels

material safety data sheet (MSDS)
provides the following information about a substance: its chemical name, hazardous ingredients, physical characteristics, fire/explosion data, reactivity, health hazards, usage/handling/storage, and special protection/precautions

means of egress
a continuous and unobstructed path of travel from any point in a building or structure to a public way

MER
mechanical equipment room; as used in this manual, is synonymous with **machinery room**

NFPA
National Fire Protection Association

NIOSH
National Institute for Occupational Safety and Health

occupied space
that portion of the premises accessible to or occupied by people, excluding machinery rooms

OSHA
Occupational Safety and Health Administration

PEL
permissible exposure limit

pressure-relief device
a pressure- (not temperature-) actuated valve or rupture member designed to automatically relieve pressure in excess of its setting

readily accessible
capable of being reached safely and quickly for operation, repair and inspection without requiring those to whom ready access is required to climb over or remove obstacles or to resort to the use of portable access equipment ... see also *access*

refrigerant
the fluid used for heat transfer in a refrigerating system — i.e., the refrigerant absorbs heat and transfers it at a higher temperature and a higher pressure, usually with a phase change

SBC
Southern Building Code

SCBA
self-contained breathing apparatus

self-contained system
a complete, factory-assembled and factory-tested system that is shipped in one or more sections and has no refrigerant-containing parts that are joined in the field by other than companion or block valves

STEL
short-term exposure limit

threshold limit value (TLV®)
registered trademark of the American Conference of Governmental Industrial Hygienists ... refers to the airborne concentrations of substances and represents conditions under which it is believed that nearly all workers may be repeatedly exposed day after day without adverse health effects

threshold limit value - time-weighted average (TLV-TWA)
the time-weighted average concentration for a normal 8-hour workday and a 40-hour workweek, to which nearly all workers may be repeatedly exposed, day after day, without adverse effect

toxicity
the ability of a refrigerant to be harmful or lethal due to acute or chronic exposure by contact, inhalation or ingestion ... effects of concern include (but are not limited to) those of carcinogens, poisons, reproductive toxins, irritants, corrosives, sensitizers, hepatoxins, nephrotoxins, agents that act on the hematopoietic system, and agents that damage the lungs, skin, eyes, or mucous membranes

zeotropic
blends comprising multiple components of different volatilities that, when used in refrigeration cycles, change volumetric composition and saturation temperatures as they evaporate or condense at constant pressure ... see also *azeotropic*

SERVICE TRAINING MANUAL

TRANE™

Reference

ANSI/TRANE WIRING SYSTEM

© THE TRANE COMPANY 1984

ANSI/TRANE WIRING SYSTEM

This manual serves as a guide to understanding the design and usage of Trane electrical schematic wiring diagrams that are based on the ANSI System.

The manual is intended for anyone involved with installing and/or servicing Trane commercial HVAC products.

Specific coverage includes basic diagram layout in terms of line description, road mapping, prefix location coding, wire identification, legend description and device identification logic.

A comprehensive reference list of device abbreviations and symbols is included.

What Does ANSI Stand For?

"ANSI" stands for the American National Standards Institute which is a nationally recognized standards organization which dwells in setting up standards for weights and measures, automobiles, manufacturing and electrical standards. The "ANSI" style is generic in terms of drafting, symbol and nomenclature design. In essence, this common style is applicable to any HVAC equipment and is being utilized by several manufacturers at the present time. This is a tremendous benefit for all personnel involved with installing, servicing, and maintaining today's HVAC equipment.

The question arises as to what the purpose of a wiring diagram is. The first thing that comes to mind is that it shows where the wires go. It also shows the proper sequence of operation and provides a basis for understanding troubleshooting procedures. There has been and still are many styles of wiring diagrams. No matter what style one is looking at, that particular diagram has its own set of graphic symbols, line structure and frustrations.

It is very difficult for the HVAC technician to keep track of every manufacturer's style and that's where the frustations arise. How about a "Common Style"?

Diagram Layout

"ANSI" diagrams are constructed with their own drafting, symbol and nomenclature design. In trying to understand a format such as ANSI, a look at the basic drafting construction can serve as a good starting point.

Line Description

Each wiring diagram in the "ANSI Electrical Wiring System" will contain a series of line numbers. These numbers serve as a reference for locating wires and load components. Line circuit numbers will appear in the wiring diagram's left hand columns as shown in Figure 1. These numbers are consecutive regardless of the number of sheets:

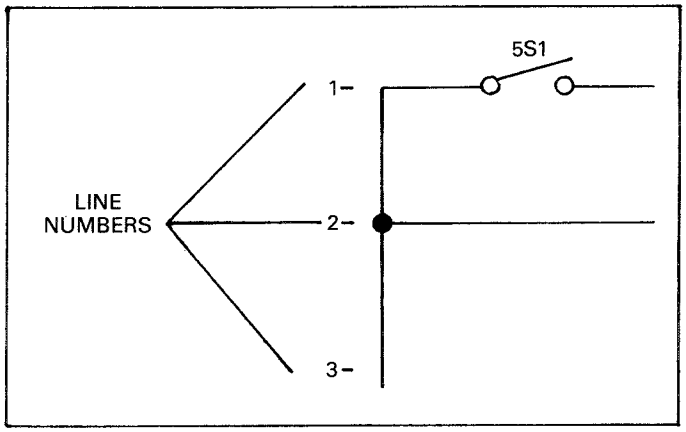

Figure 1

The electrical flow path is drawn between two parallel vertical lines which represent the source of control power with the power side on the left and the neutral on the right. The source of power shown in Figure (2) required for circuit operation shall be described at the top of the diagram between the two parallel vertical source lines and are described as volts/hertz/phase. See Figure 2.

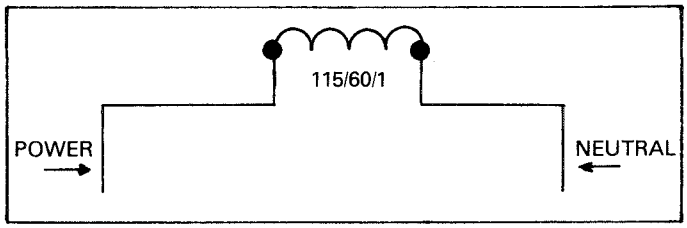

Figure 2

Road Mapping

Shown in Figure 3, one will notice the temperature control symbol and an associated relay device on one line and the relay contacts and solenoid coil on the next. If the load device is a relay, its contacts will be found on a separate horizontal circuit line.

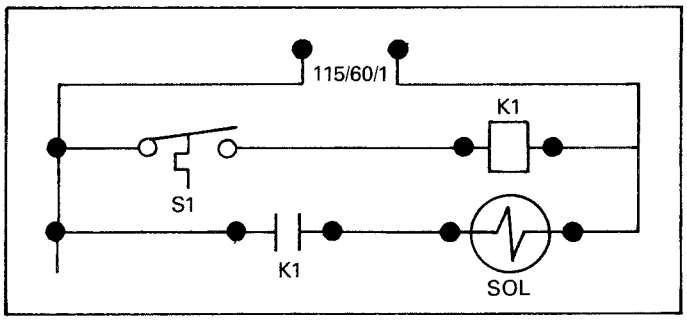

Figure 3

The next step in understanding the construction of the ANSI electrical diagram is to look at Figure 4 and notice the alphanumeric notation to the right hand side of the neutral wires. The symbol K1-3 translates to relay one and has its contact located on line 3. If there is more than one contact, the associated line numbers would follow the number 3 IE: K1-3, 6, 10. If a line number is underlined, the contact on that line number is in a normally closed position. If it is not underlined, then the contact is normally open.

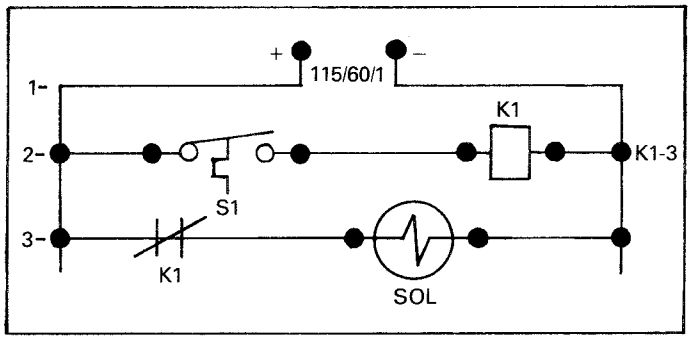

Figure 4

The next item of discussion is the description of a set of contacts. Referring to Figure 5. The K is the coded symbol for a relay. The 1 means that it is the #1 relay out of many used within the unit. The (AUX) states that this is an auxilliary contact physically mounted to the side of the contactor. The numbers 1 and 3 are physical terminal identifications. The

method of tracing relays to their associated contacts is called road mapping.

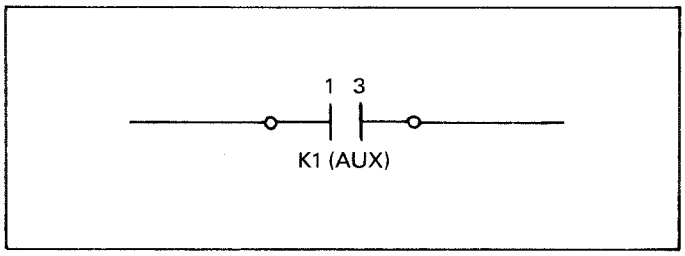

Figure 5

Prefix Location Code
Items shown on a schematic diagram may be located in various areas of a unit. For convenience purposes, these areas may be identified by numbers. For example: 1K1, 1 is the location number. A table listing the locations and prefixes is shown on the first sheet of the schematic diagram. (Shown in Figure 6). The use of the prefix location code is helpful on units with more than one electrical control panel.

Prefix Location Code	
Area	Location
1 or None	Control Panel RAUA Unit
5	Control Panel Air Handler
6	Outside Control Panel Air Handler
7	Control Panel Elect. Heat Sect.

Figure 6

Node Identification
The nodal numbering system is one of the more significant changes encountered in this new diagram style. Simply stated, for each area of the circuit of like potential (node), a number is assigned. Every individual wire found within that node is given a designation consisting of the node number and a suffix letter. (Shown in Figure 7). For example, the neutral side of the 115 volt circuit on the diagram below has the node number 19. Four individual wires are found to make up the node. Wire 19A runs from the transformer to 1K9, 19B runs from the transformer to chassis ground, 19C from 1K9 to 1K10, and 19D from 1K10 to 1K11.

Wire Identification
Each wire attached to a node is assigned to node number as it's wire number plus a suffix letter to insure its individuality as an aid to service. These suffix letters begin with "A" and follow in alphabetical order. For example, if a node has only one wire, the nodal wire number includes the suffix letter A, IE: 16A (shown in Figure 8A). If a node has 2 or more wires, the wires shall be identified with additional suffix letters, IE: 17A, B, C, and D shown in Figure 8B.

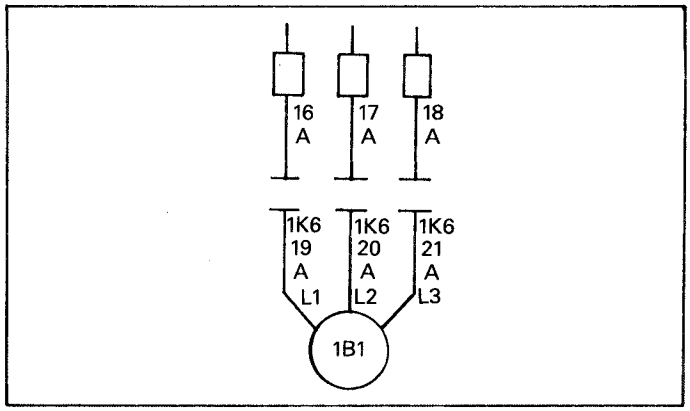

Figure 8A

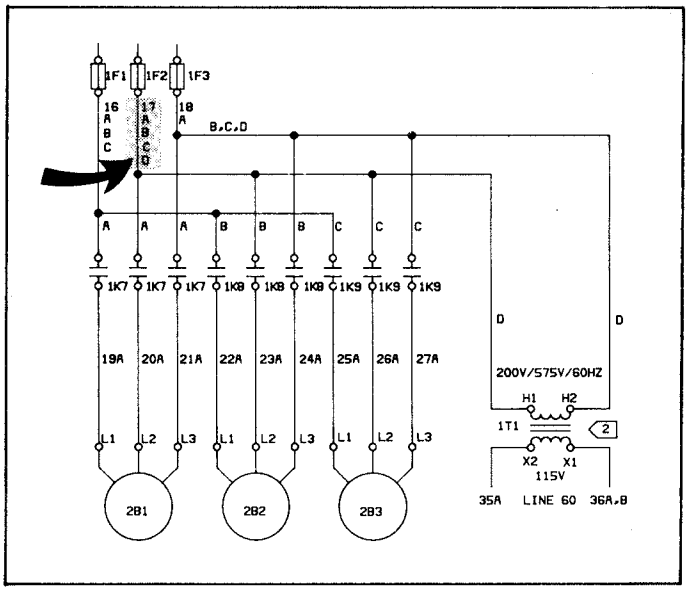

Figure 8B

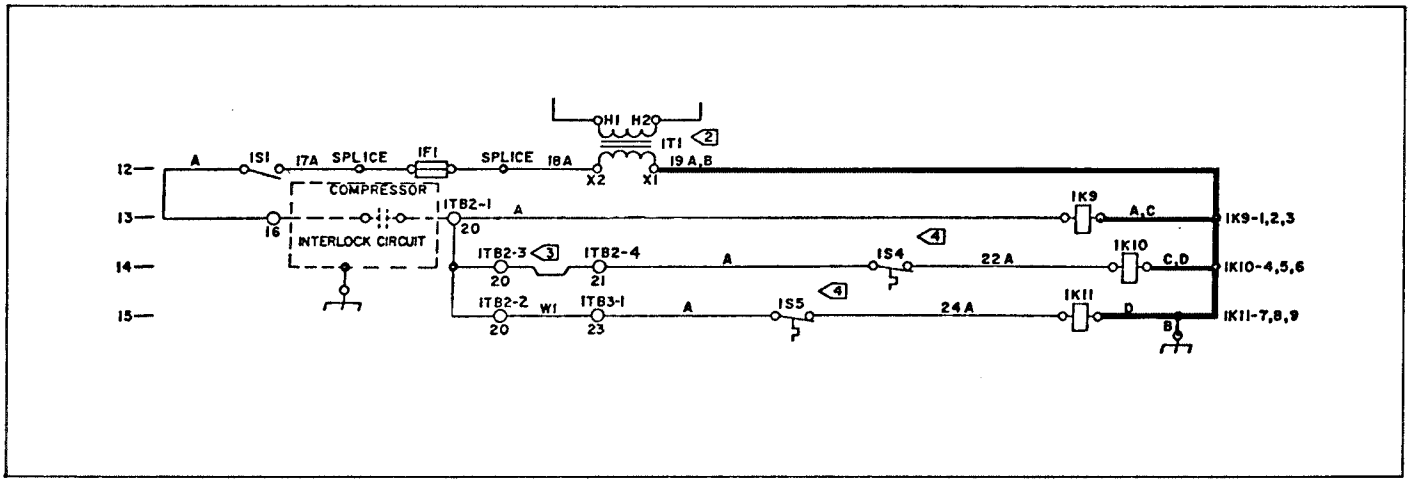

Figure 7

What is actually occuring in Figure 8B is that wire 17, A, B, C, and D is composed of 4 separate wires. These wires shown in a pictorial diagram should be connected as 4 separate wires at the 1F2 fuse terminal connection. For ANSI schematic drawing design reasons, the wires are segregated for electrical flow purposes (schematic method) only. These wires as they actually appear in the unit may be bundled together or wire tied. Each wire would be labeled individually, IE: 17A, 17B, 17C, and 17D. The open dot symbol "○" stands for an actual terminal connection. The closed dot symbol "•" stands for a wire chase where two wires are bundled together but not electrically connected at that point.

Legend Description
A legend box is always shown on the first sheet of the schematic diagram. The legend entries consist of the device designation, a description which briefly states its function. The legend is placed to the right of the schematic diagram shown in Figure 9.

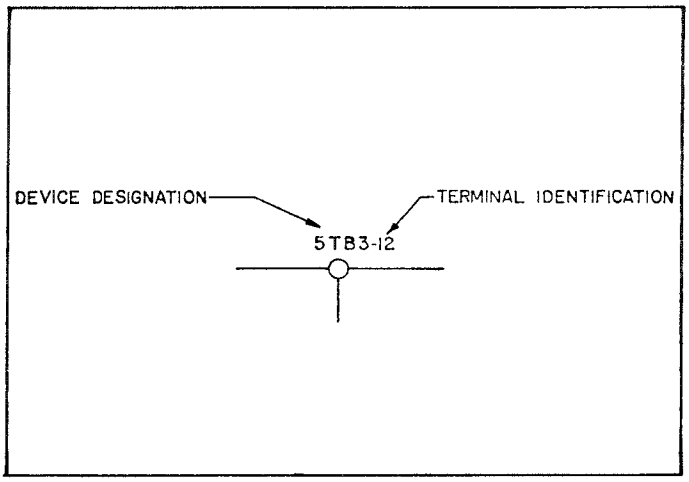
Legend	
Device Designation	Description
5K1	Supply Fan Starter
5K2	Ret or Ex Fan Starter
5K3	Supply Fan Relay
5K4	Night Set Back Relay
5K5	Heat Relay Step 1
5K6	Heat Relay Step 2
5K7	Heat Relay Step 3
5K8	Heat Relay Step 4
5K9	Freezestat Relay
5K10	Cooling Relay
5S1	Control Circuit Switch
6S2	Enthalpy Control
6S3	Filter Light Switch

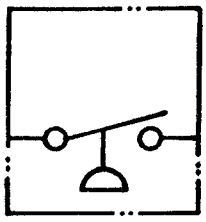
Figure 9

The legend will contain every electrically active device within the specified unit.

Device Identification
All switches are shown in their "at rest" position with all power turned off, and after a normal shutdown has occurred. Looking at the following symbols shown in Figure 10, note the description of each device. The actual temperature, pressure or timing changeover point can be found in the electrical sequence of operation portion of the wiring booklet.

Terminal Blocks
Terminal identification for terminal blocks are shown in Figure 11. The 5 stands for the location of the terminal board in the unit. The TB is the coded symbol for terminal board. Three is the 3rd terminal board found in the unit and the 12 is the terminal number of that board.





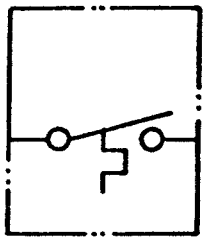


Figure 11

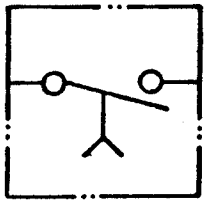

The use of metal terminal block jumpers may be shown two ways on schematic diagrams. When the jumper is used to connect two terminal strip node points to allow for optional hook-ups, no wire number is assigned but a jumper symbol is used. This symbol is found between nodes 20 and 21 on Figure 12 (note the identification flag).

Pressure Switch
Normally open, closed on pressure drop.

Temperature Control Switch
Normally open, closes on temperature drop.

Time Delay Contact
Normally open, time to close.

Figure 10

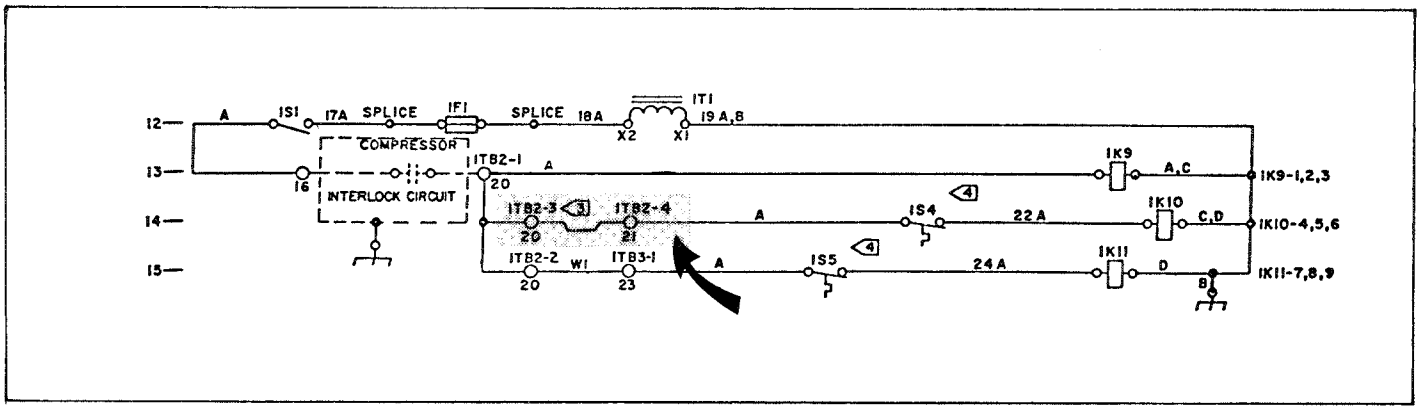

Figure 12

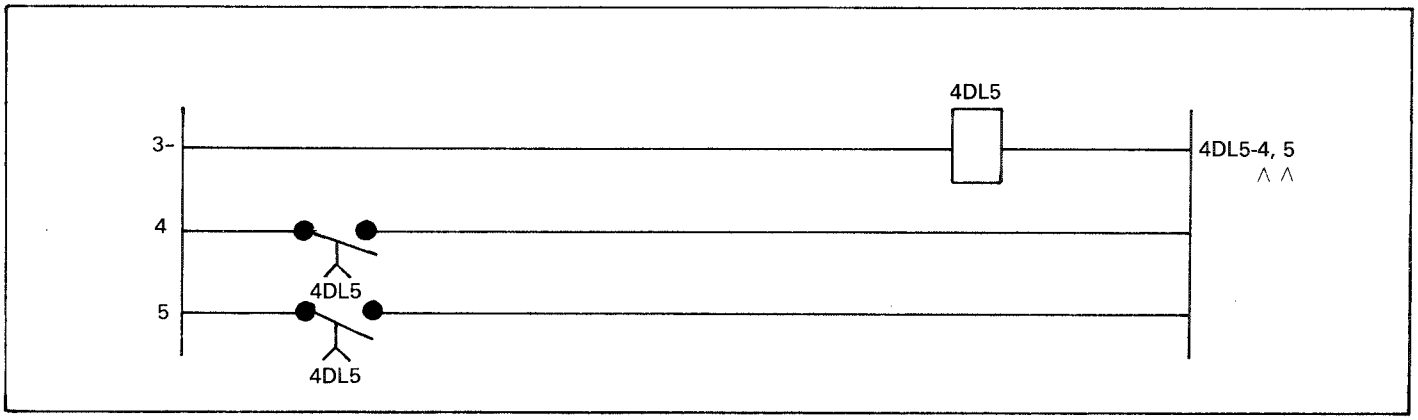

Figure 13

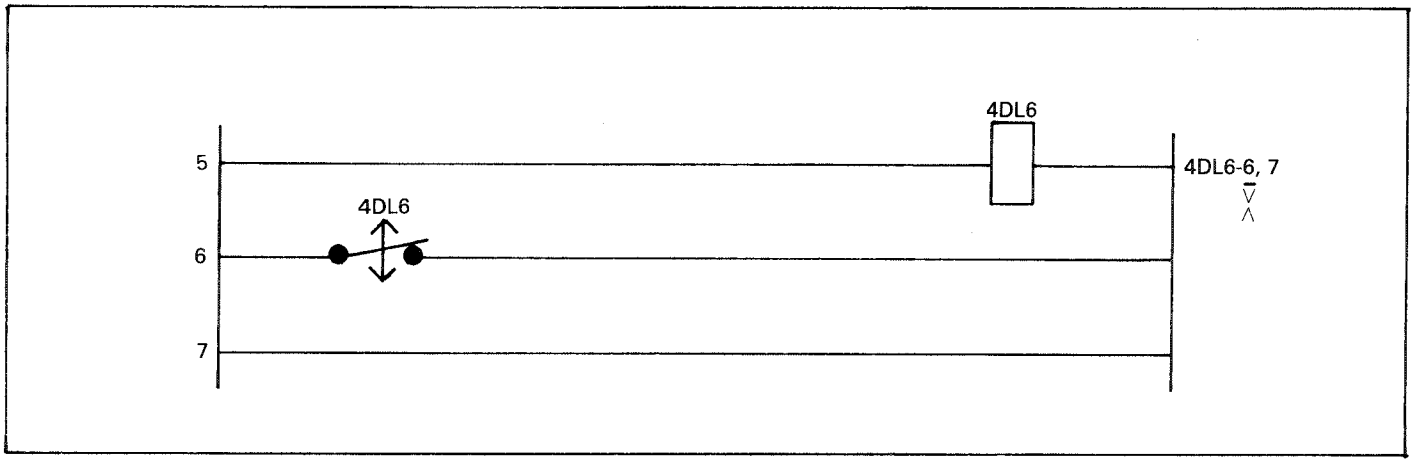

Figure 14

Time Delay Relay

Time delay relay logic appears in several forms in the wiring diagrams. A look at some of the particular highlights should help in understanding them. For example, looking at Figure 13, the time delay relay 4DL5 has two sets of contacts which are found on lines 4 and 5. The line numbers have an arrow underneath each of them pointing up. This serves as an indicator of the timing logic. Since there is no line underneath the number, the individual contact is a normally open type. The arrow pointing up indicates a time to close contact. In essence, the relay contacts 4 and 5 are both normally open-time to close. A look at the actual contacts on lines 4 and 5 also show that the contacts are found to be in the normally open position when deenergized, and time to close. This is noted by the arrow pointing up.

In Figure 14, a similar time delay relay scheme is shown. Relay 4DL6 contact number 6 is underlined. This indicates that this is normally closed contact when deenergized. Note however, that there are two arrows opposing each other below the number 6. That means the contact is a time to open-time to close type. On line 6 the contact itself has two arrows which confirms this logic.

The actual timing interval period is normally called out in the written sequence of operation section of the applicable wiring booklet. Other similar timed devices are called out in the last section of this manual under the heading "Device Graphics".

Miscellaneous Descriptive Items

Descriptive or informative messages required in the "body"

of the schematic are in the form of a note at the bottom of the sheet in which it appears and referenced at the point it applies with the note flag. See Figure 15. Notes are numbered consecutively.

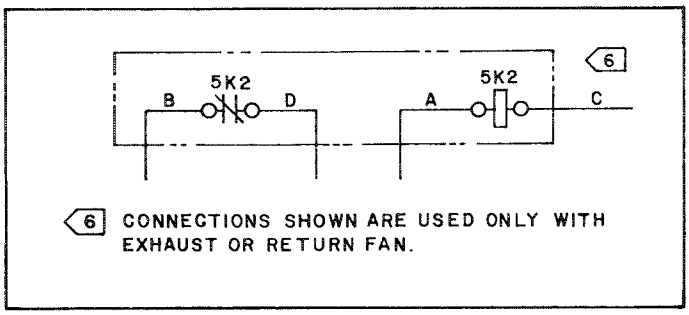

Figure 15

Device ratings, temperature and pressure switch points, time delays, etc. may be included on the schematic diagram in the form of an identified note.

What has been discussed in this manual, covers the inner workings of the ANSI format. Like anything new, it is sometimes difficult to understand a new wiring diagram code system. The benefit of using this style of wiring diagram is that it is a common style used in Trane equipment and has been or will be utilized by many other manufacturers in the HVAC industry. After working with this manual as well as a few unit wiring diagrams, the level of comfort and proficiency of the user should increase.

The following is a more complete listing of device graphics and reference designation abbreviations than the one's discussed so far in this manual.

CenTraVac® Starters - General Requirements

Every CenTraVac® requires a starter. It may be remotely-mounted or unit-mounted. Unit-mounted starters are avilable in the low voltage, star-delta type with a maximum rating of 606 RLA.

CenTraVac starters must:

• be compatible with the characteristics of a hermetic, centrifugal compressor motor and with the electrical circuitry of a CenTraVac.

• have a control power transformer for providing 120 VAC control power for the starter control circuitry and for the CenTraVac control circuitry.

• be pilot relay operated. It must start the compressor only on a "start" request from the CenTraVac control circuitry. A push-to-start pushbutton starter is not permitted. The starter must stop the compressor on a "stop" request from the CenTraVac control circuitry or in response to the starter safeties.

• provide motor current level signals for overload protection and for current limiting fuctions.

• contain appropriate interlocks for starter condition monitoring, purge operation and oil pump operation.

• have correctly labeled terminals to agree with Trane Company installation wiring diagrams.

All of these general requirements are addressed specifically in the The Trane Company CenTraVac Starter Specifications.

History

Prior to 1968, the starter manufacturers relied on Trane unit schematic wiring diagrams to design appropriate starters.

The first formal starter specification was written in 1968. In this specification, certain parts of the starter were clearly defined.

1. Control power transformer size
2. Overload relay type
3. Pilot relay operation defined
4. Oil pump starter
5. Required interlocks
6. Current limiting signal
7. Terminal designations

The starter construction and circuitry were left to the starter manufacturer. Only those parts that interfaced with the CenTraVac were defined.

This starter specification, Table 1, has been re-written through the years with each basic CenTraVac design change.

Table 1 - Starter Specifications

Year	Trane Specifications	CenTraVac	Capacity Control	Overload
1968-1973	SES 14-11.00	CV,PCV	Pneumatic	Inverse Time Magnetic
1973-1980	SES 14-18.00	CVHA,CVHB	Pneumatic	Inverse Time Magnetic
1980-1986	SES 14-18.09	CVHE, CVHB	Electric	Solid State (Cutler Hammer)
1986- (Direct Purchase)	*Low Voltage-* E.S S13340261 *High Voltage-* E.S. S13340262	CVHE, CVHB	Electric	Electronic (Function Of Micro Control)
1986- (Purchased Thru Trane)	*Low Voltage-* S6516-0066 *High Voltage-* S6516-0067			

Starter Types

The following is a starter tabulation followed by an explanation of the sequence of operation of the various starter types.

Table 2 - Starter Types

Starter Type (All Closed Transition)	Inrush Current (%LRA)	Percent Of Rated Torque	Frequency Of Use (%)	Advantages	Disadvantages	Typical Acceleration Time*
Low Voltage 208-600 Volts						
Star - Delta Closed Transition	33	33	95	1. Equal Reduction Of Torque & Inrush Current 2. Low Cost 3. Can Be Unit Mounted	1. Not Applicable To Voltages Over 600	6-12 Seconds
X - Line	100	100	_	1. Low Cost 2. Least Complex Least Maintenance	1. Draws Highest Current During Startup	3-5 Seconds
Auto-Transformer 65% Tap**	45	42	5	1. Almost Equal Reduction of Torque And Inrush Current	1. Most Expensive	3-8 Seconds
High Voltage 2400 - 4160 Volts						
X - Line	100	100	30	1. Low Cost 2. Least Complex Least Maintenance	1. Draws Highest Current During Startup	3-5 Seconds
Primary Reactor 65% Tap**	65	42	60	1. Good Compromise Between First Cost & Inrush Current Reduction	_	3-8 Seconds
Auto-Transformer 65% Tap**	45	42	10	1. Almost Equal Reduction Of Torque & Inrush Current 2. Lowest Inrush Current	1. Most Expensive	3-8 Seconds

* The acceleration time will vary accoring to the refrigerant temperature in the evaporator, the exact chiller configuration and other factors.
**The 65% tap is the minimum tap that will develop sufficient torque to successfully accelerate the compressor under any operating conditions.

Starter Types

Across -The- Line Starter (Figure 1)

A "start" signal from the CenTraVac®control panel energizes the pilot relay (PR). The pilot relay contacts close to energize the start/run contactor (1M). The 1M contacts close to connect the compressor motor directly to the line.

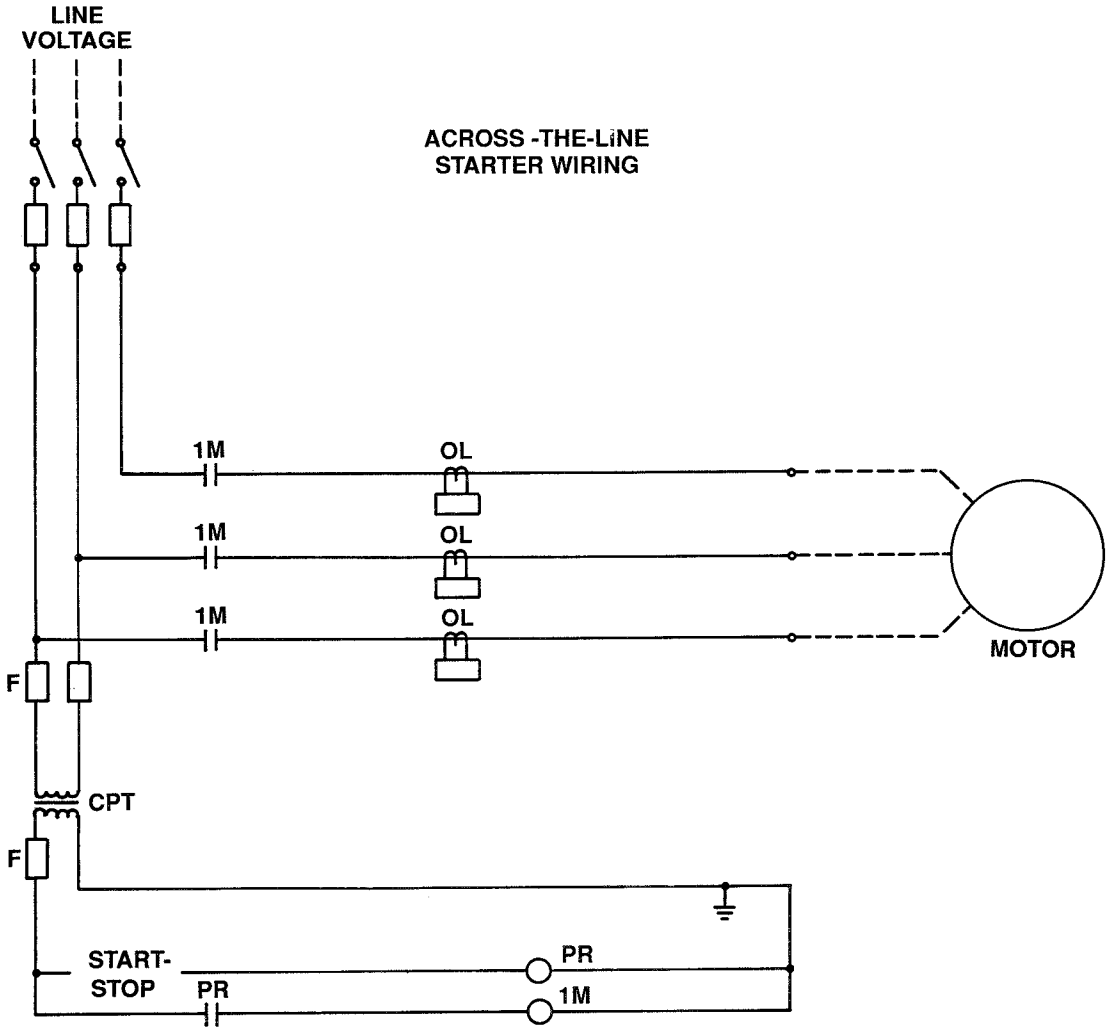

Figure 1

Auto - Transformer Starter (Figure 2)

A "start" signal from the CenTraVac control panel energizes the pilot relay (PR). The pilot relay contacts close to energize the shorting contactor (S). The S contacts close to complete the auto - transformer circuit. An S interlock closes to energize the start contactor (1M). The 1M contacts close to connect the compressor motor to the line with the motor in series with the auto - transformer. A time delay relay or current monitoring device initiates transition by energizing the transition relay (T). The T contacts open to deenergize the S contactor. The S contacts open to open the auto - transformer circuit. The auto - transformer is now connected as a series reactor with the motor. Now, a second T interlock and a second S interlock both close to energize the run contactor (2M). The 2M contacts close to bypass the auto - transformer and connect the compressor motor directly to the line.

Since the motor is not disconnected from the line during transition, this is a closed transition starter.

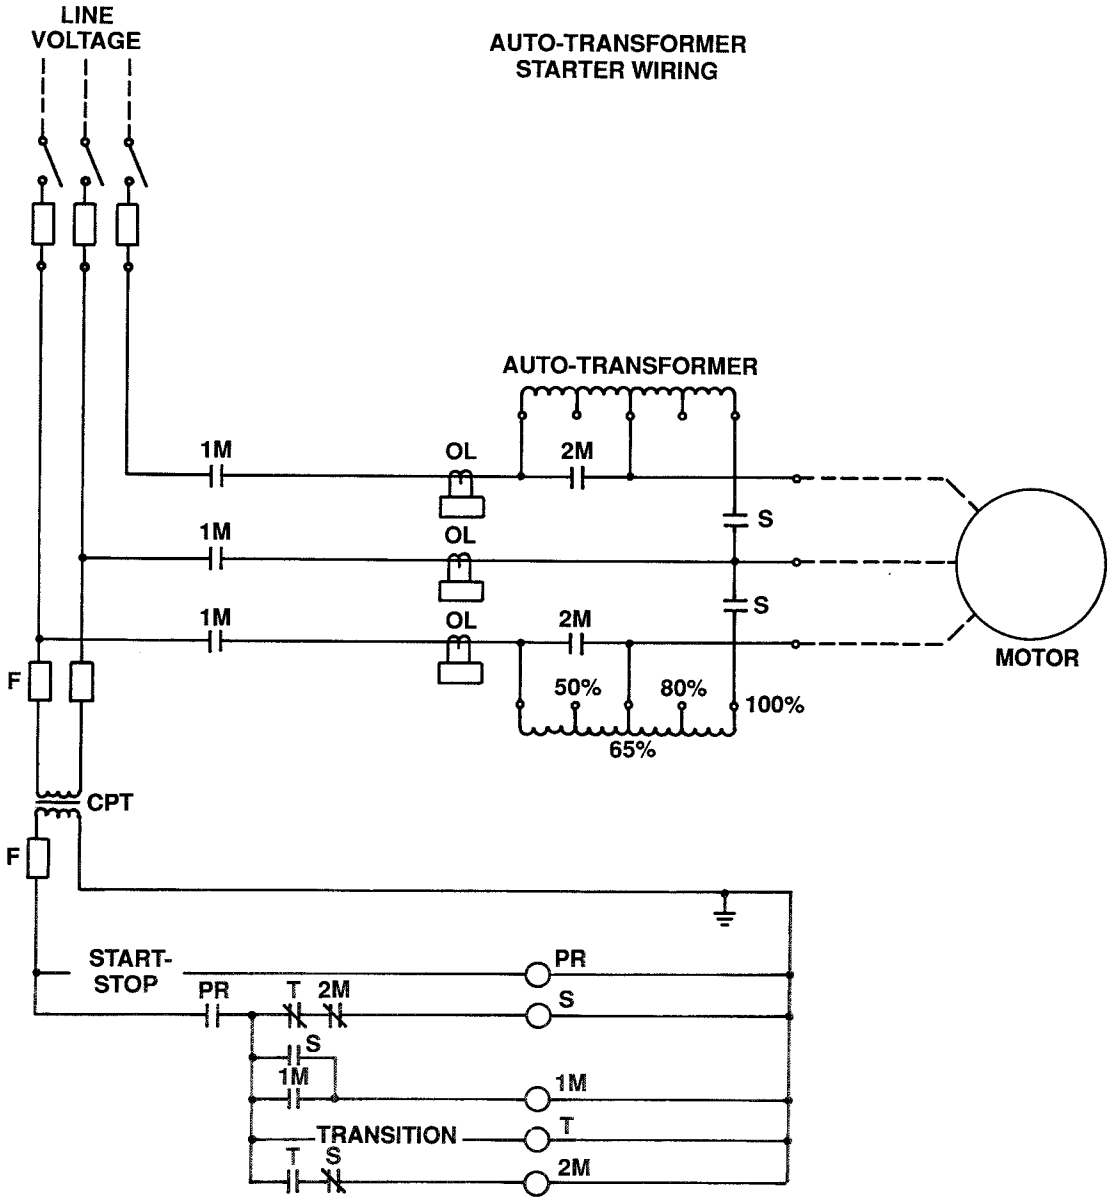

Figure 2

Starter Types

Primary Reactor Starter (Figure 3)

A "start" signal from the CenTraVac® control panel energizes the pilot relay (PR). The pilot relay contacts close to energize the start contactor (1M). The 1M contacts close to connect the compressor motor to the line with the motor in series with the reactor. A time delay relay or current monitoring device initiates transition by energizing the run contactor (2M). The 2M contacts close to bypass the reactor and connect the compressor motor directly to the line.

This is an inherently closed transition starter.

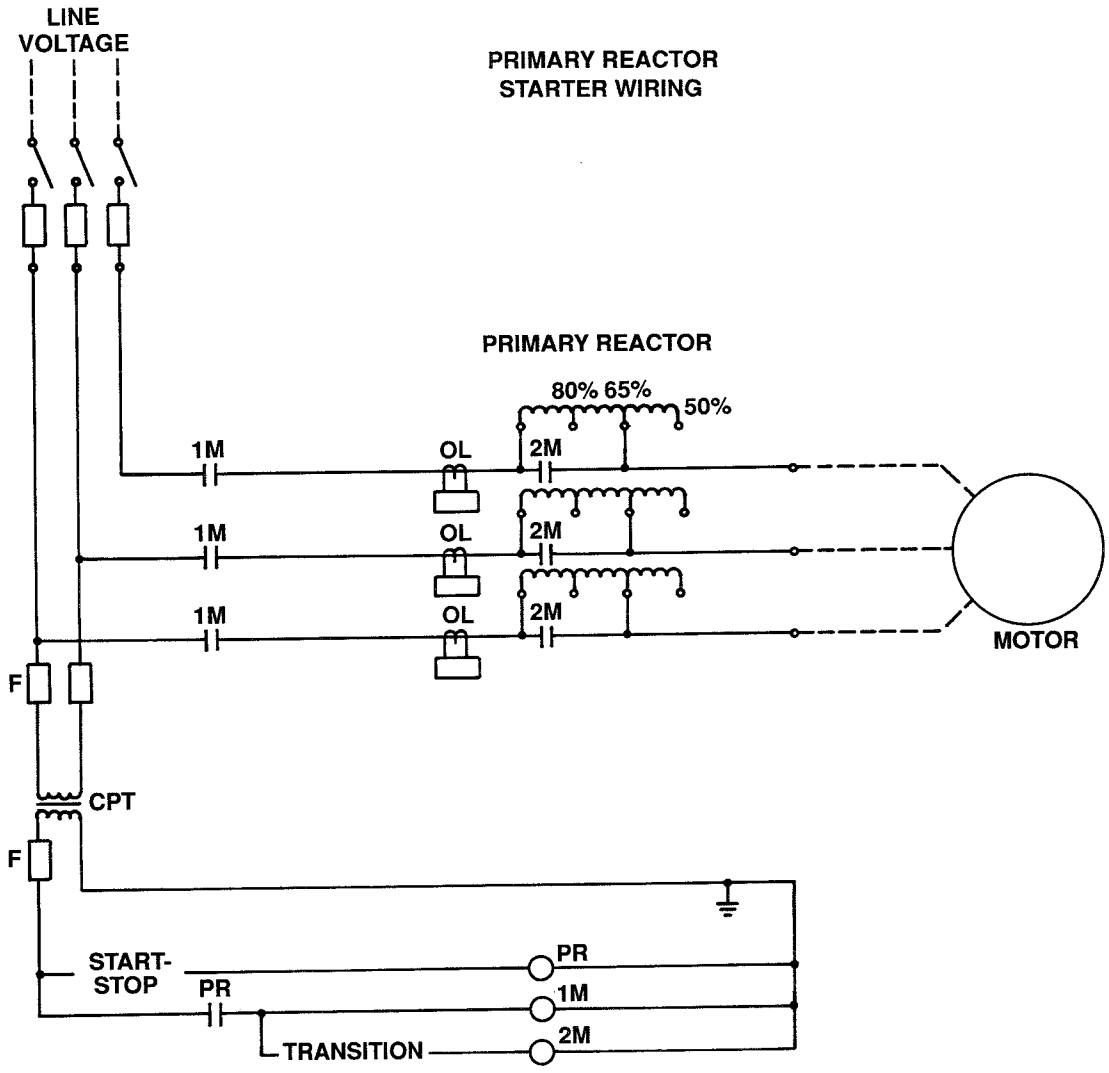

Figure 3

Star - Delta Starter (Figure 4)

A "start" signal from the CenTraVac control panel energizes the pilot relay (PR). The PR contacts close to energize the star contactor (S). The S contacts close to connect the motor in the star configuration. An S interlock closes to energize the start contactor (1M). The 1M contacts close to connect the motor to the line.

A time delay relay or current monitoring device initiates transition by energizing the resistor contactor (1A). 1A contacts close to connect the resistors to the line in the star configuration and in parallel with the compressor motor. A 1A interlock now opens to deenergize the S contactor. The S contacts open to connect the resistors and motor windings in series in the delta configuration. An S interlock closes to energize the run contactor (2M). The 2M contacts close to bypass the resistors and connect the compressor motor directly to the line in the delta configuration.

Since the motor is not disconnected from the line during transition, this is a closed transition starter.

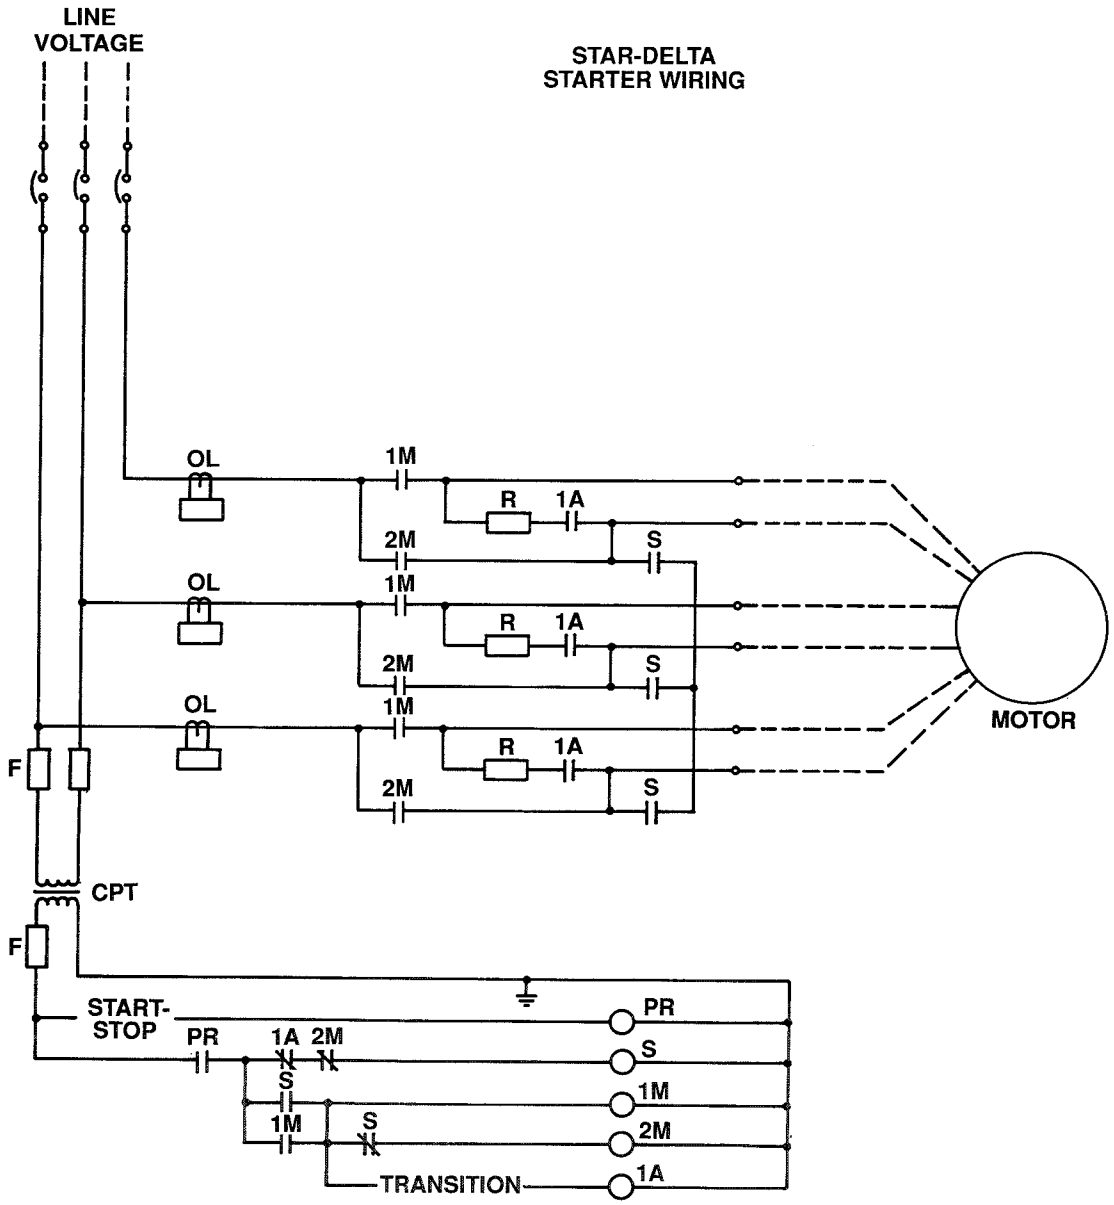

Figure 4

Disconnect Means And Short Circuit Protection

The following is a discussion of the various disconnect and short circuit protection devices.

Isolation Switch ... A manual switch that is capable of isolating the starter from the main incoming power. An isolation switch has no interrupting rating.

Load Break Disconnect Switch ... A manual switch so constructed that it has an interrupting rating and can be used to safely interrupt a live circuit.

Disconnect Means - High Voltage ... All high voltage starters have an isolation switch as standard. All high voltage starters have a mechanical interlock to prevent opening the isolation switch while the main contactor is closed and the compressor is running. In order to open the high voltage compartment door, the compressor must be turned off and then the isolation switch may be opened. When the isolation switch is opened, its stabs separate from the high voltage bus. Baffles slide over to cover the stab slots and the high voltage bus is completely isolated behind shielding panels. Now the high voltage compartment door may be opened safely. The high voltage compartment door must be closed before the isolation switch can be reclosed.

A load break disconnect switch may be furnished as an option on high voltage starters. The load break switch is mounted in an additional section of the starter cabinet assembly. The switch is spring loaded as the handle is moved. When spring pressure is sufficient, a device releases the switch mechanism. The spring loading provides rapid, positive opening and closing of the contacts.

Circuit breakers are not available for voltages over 600 VAC.

Disconnect Means - Low Voltage ... Typically, low voltage starters have no means of interlocking to prevent the opening of an isolation switch under load. A plain isolation switch has no interrupting rating and may not successfully quench the arc that may develop if the isolation switch were opened under load (i.e., while the compressor is running). An arc could result in sudden expansion of the air in the starter and could blow the door open, endangering personnel.

A circuit breaker, on the other hand, does have an interrupting rating. In fact, a circuit breaker is constructed to safely interrupt even fault current (i.e., short circuit) and may be opened safely at any time. Therefore, when a fused disconnect or non-fused disconnect is specified on a low voltage CenTraVac® starter, a "gutless" circuit breaker (a circuit break without a current trip device) will be furnished. When a circuit breaker is specified, it serves both as the short circuit protector and the disconnect switch. A low voltage starter door may be opened only if the circuit breaker is in the "off" or open position.

Short Circuit Protection ... Short circuit protection provides a means of safely disconnecting the CenTraVac and the starter from the main electrical supply in the event of a short circuit.

High Voltage
All high voltage starters contain current limiting fuses for short circuit protection. The current limiting fuses and isolation switch furnished as standard fulfill the request for a fused disconnect.

Low Voltage
A circuit breaker, or a "gutless" circuit breaker with fuses, provides short circuit protection.

When a low voltage starter is ordered with a circuit breaker, the starter manufacturer furnishes a standard circuit breaker sized at approximately 125 percent of compressor RLA. The trip current of a circuit breaker is adjustable so that it will not trip during startup and acceleration, but will trip instantaneously (typically 1 cycle) if a short circuit occurs.

The interrupting capacity of a circuit breaker must also be considered. The interrupting capacity is the maximum fault current the circuit breaker can interrupt without being destroyed. An analysis of an installation may be done by others to calculate the maximum current that could be delivered to a short circuit.

A standard circuit breaker can interrupt 30KA (30,000 amps) @ 480V. If the calculated fault current exceeds the interrupting capacity of a standard circuit breaker, the starter will require a high interrupting capacity circuit breaker (35KA @ 480V) or a current limiting circuit breaker

(200KA @ 480V). The actual circuit breaker interrupting capacities may vary by manufacturer.

A high interrupting capacity circuit breaker has contacts and arc extinguishers specifically designed to interrupt high current.

A current limiting circuit breaker uses a standard circuit breaker that incorporates three current limiting devices that are coordinated with the interrupting capacity of the breaker. A fault current below the interrupting capacity of the circuit breaker will be interrupted by the breaker. However, a fault current in excess of the interrupting capacity of the circuit breaker will cause the fuse links of the current limiters to blow quickly to interrupt the fault current. A plunger in the current limiters will release to trip the circuit breaker. The circuit breaker then cannot be reset until the blown current limiters are replaced.

When a low voltage starter is ordered with a fused disconnect, a "gutless" circuit breaker with fuse clips is furnished. A "gutless" circuit breaker can only be opened or closed manually and serves as a safe disconnect switch.

The NEC allows a maximum fuse size of 175 percent RLA. However if that is not large enough to start a motor, the NEC allows the maximum fuse size to be increased to 225 percent RLA. The fuse clips furnished will accept fuses sized at 150 percent to 195 percent of compressor RLA. Fuses above 600A are bolted directly into the bus work instead of being mounted in fuse clips.

The following is a list of compressor RLA and fuse clip or fuse provisions:

125 - 250 RLA ... 225 - 400A fuse clips
251 - 375 RLA ... 450 - 600A fuse clips
376 - 510 RLA ... 601 - 800A fuse provisions
511 - 1300 RLA ... 1000 - 2000A fuse provisions
1301 - 1560 RLA .. 2500A fuse provisions

Dual element fuses must be used, since one-time fuses may be blown by inrush current. Shawmut "Tri-onic" or Bussman "Fusetron" dual element fuses may be used up to 600A. Bussman type KRP-C dual element class L dimension fuses may be used above 601A. Fuses are furnished and installed by others.

When a low voltage starter is ordered without a circuit breaker or disconnect, a terminal block is furnished for connecting incoming power leads to the starter. Short circuit protection and disconnect means must be furnished and installed by others, upstream of the starter.

Power Wiring

Power wiring is divided into two categories:

- Incoming power leads to the starter
- Power leads from the starter to the compressor motor

Incoming power leads to the starter are sized using this formula:

$$\text{Minimum Ampacity} = \frac{\text{Compressor RLA} \times 125\%}{\text{Leads Per Terminal}}$$

Leads must be in multiples of three and all leads must be of the same size and length.

Motor leads for compressors used with across-the-line, primary reactor or auto - transformer starters are sized in the same manner as incoming power leads to the starter.

Motor leads for compressors used with star-delta starters are sized using the formula:

$$\text{Minimum Ampacity} = \frac{\text{Compressor RLA} \times 125\% \times 58\%}{\text{Leads Per Terminal}}$$

Leads must be in multiples of six and all leads must be of the same size and length.

The accompanying wire selection table, Table 3, may be used to help select power wiring for starters and compressor motors. The table is read directly in compressor motor RLA. All safety factors and derating factors for more than three conductors in one conduit are already figured. The current draw of the control power transformer is amply covered by the safety factor.

Example #1

- 460 volt compressor drawing 300 RLA using an across-the-line starter.
- Starter leads and motor leads are the same size.

Referring to the wire selection table, the following could be used:

1 conduit containing 3 - 500 MCM conductors,
1 conduit containing 6 - 250 MCM conductors,
2 conduits each containing 3 - #000 conductors,
etc.

Example #2

- 460 volt compressor drawing 300 RLA using a star-delta starter.
- Starter leads are the same size as in Example #1.

Motor leads could be:

1 conduit containing 6 - 300 MCM conductors,
2 conduits each containing 3 - #0000 conductors, 2 conduits each containing 6 - #0 conductors, etc.

* Conductors to the starter and motor connected in parallel (electrically joined at both ends to form a single conductor) must be of size #0 (1/0) or larger (NEC 310-4). Each phase must be equally represented in each conduit.

Starter Options

The following is a list of options available for a starter. Some options are listed in the Price Sheet as standard options and the price is quoted. Those options not quoted in the current Price Sheet must be quoted by the La Crosse CenTraVac Sales Group.

Where necessary, some options are explained in the "Definitions" section of this manual.

Following the list of options are a number of wiring diagrams showing how some of the options are wired in a typical starter.

Options:

- Additional Starter Interlocks (2 SPDT Switches)
- Adjustable Undervoltage Relay With Reset
- Ammeters
- California Code Compliance
- C.S.A. Label
- Differential Protection (Figure 5)
- Ground Fault Protection (Figures 6 and 7)
- Indicating Pilot Lights (Press To Test Type)
- Lightning Arresters (Figure 8)
- Overvoltage Relay With Reset
- Power Factor Correction Capacitor (Figure 9)
- Surge Capacitors (Figure 8)
- Transducer, Current Type, 4 -20Milliamp (Figure 10)
- Transducer, Voltage Type, 4-20 Milliamp (Figure 11)
- Transducer, Watt Type, 4-20 Milliamp
- U.L. Label
- Undervoltage Relay With Reset
- Voltmeters
- Watt Hour Meter,Including Current Transformers, (Figure 12)
- Watt Hour Meter With Demand Register
- Watt Hour Meter With Pulse Initiator
- Wattmeter

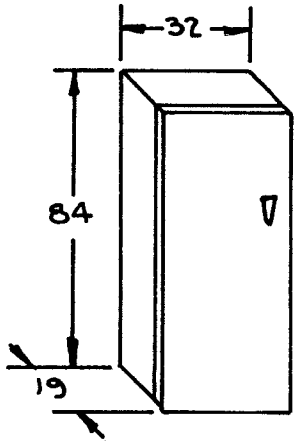
Submittals

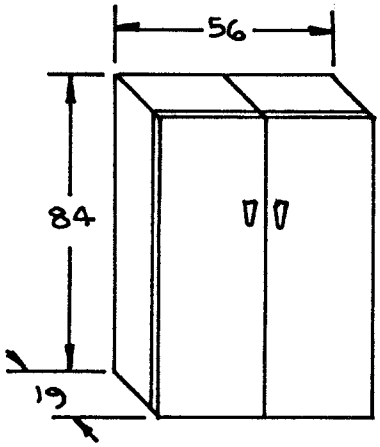
All remotely-mounted starters require a set of submittal prints, showing a wiring schematic, cabinet size, wiring entrance and exit areas and lugs furnished. All starters ordered through Trane must have their submittals reviewed by Applications Engineering. The submittals are filed by sales order number and shipment year.

All starters ordered by others must have their submittals sent to the Trane Applications Engineering Department in La Crosse for review. This free service will help keep Trane, the customer and the starter manufacturer out of trouble.



The following are typical cabinet dimensions for free-standing starters.

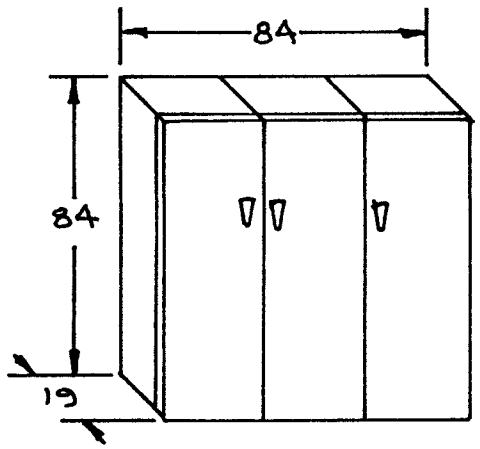
Low Voltage



208 - 600 Volt
Star-Delta Starter
Cable Entry - Top Or Bottom

These dimensions are for reference only. Refer to the particular starter submittal for exact cabinet size, cable entry area and lug sizes.

Disconnect Means	Max. RLA
Main Lugs Only	606
Circuit Breaker	606
Non - Fused Disconnect	606

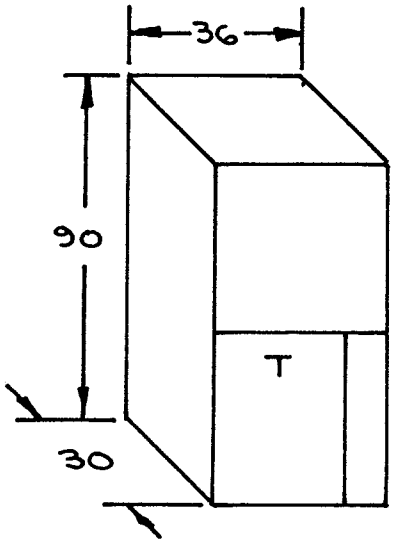


Disconnect Means	Max. RLA
Main Lugs Only	2100
Circuit Breaker	960
Non - Fused Disconnect	1043

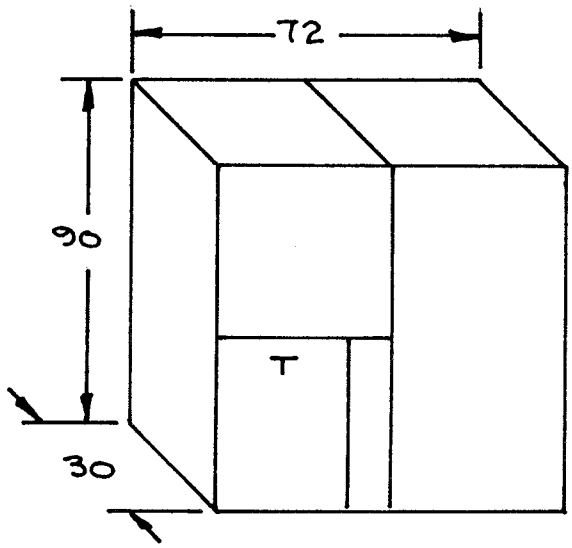
Submittals

Low Voltage (Continued)

Disconnect Means	Max. RLA
Circuit Breaker Non - Fused Disconnect	1600 2104



High Voltage



2300 - 4160 Volt

These dimensions are for reference only. Refer to the particular starter submittal for exact cabinet size, cable entry area and lug sizes.

Across -The-Line Starter.
Cable Entry - Top Standard,
Bottom Entry Available On Request.

Primary Reactor Or
Auto-Transformer Starter.
Cable Entry - Top Standard,
Bottom Entry Available On Request.

Definitions

In this section, the following listing of terms commonly associated with starters, motors, accessories and electrical power service is defined.

- Amps
- Anti-Recycle Protection
- Bus
- California Code
- Circuit Breaker
- Contactor
- Control Power Transformer
- Corona
- Current Limiting Fuse (See Fuse)
- Current Transformer
- Differential Protection
- Differential Relay
- Disconnect
- Distribution Fault
- Enclosure
- Fuse
- Ground Fault
- Ground Fault Protection
- Grounding
- Gutless Circuit Breaker
- Inrush Current
- Interlock
- Interrupting Capacity
- Ionization
- I Q 2000™
- I Q Data Plus™
- Isolation Switch
- Kirk Key
- Lightning Arrester
- Locked Rotor Amps
- LOD TRAK™
- Lug
- Minimum Circuit Ampacity
- Overload Protection
- Overload Relay
- Phase Failure
- Phase Imbalance
- Phase Reversal
- Phase Failure/Phase Reversal Relay
- Pilot Relay
- Power Factor
- Power Factor Correction Capacitor
- Rated Load Amps
- Relay
- RTD
- Short Circuit
- Shunt Trip
- Single Phase
- Solid State Overload (See Overload Protection)
- Solid State Starter
- Starter
- Stress Cone
- Surge Capacitor
- Switch Gear
- Transducer
- Transition - Closed And Open
- Vacuum Breaker
- Voltage
- Voltage Monitoring Relays (Overvoltage And Undervoltage)
- Wattmeter
- Watt Hour Demand Register
- Watt Hour Meter
- Watt Hour Meter With Pulse Initiator
- Withstand Rating

Acceleration Time ... the time it takes a motor to reach full design speed from the moment power is applied to the motor. Typical CenTra-Vac® motor acceleration times associated with various starter types are listed in Table 2, page 3.

Advanced Motor Protection System ... motor protection provided, as standard, by the CenTra-Vac® microprocessor-based control panel. By monitoring current in each of the three motor power phases, the panel provides protection throughout the motor starting and running modes from the adverse effects of phase imbalance, phase failure, phase reversal or electrical distribution fault. Sensing any of these faults, the panel trips-out the motor instantaneously and provides a diagnostic display. Automatic restart is provided after restoration of power when the stoppage is caused by distribution fault or extended power loss.

Air Break ... contacts exposed to open air that rely on an air gap to keep an electrical circuit open (see "Vacuum Break", page 27).

Aluminum Conductors ... Trane requires that copper conductors only be used for power wiring. Aluminum conductors are not suitable for the following three reasons:

Definitions

1. Galvanic corrosion
2. Probability of connection failure
3. Terminal block design

Further discussion of this subject may be found in Trane Engineering Bulletin EB-MSCR-40.

Amps - Current

LRA - Locked Rotor Amps ... the current a motor draws when it is connected to the line and the rotor shaft is held stationary. LRA is typically 5 to 7 times full load amps (FLA).

FLA - Full Load Amps ... the current a motor draws when it is loaded to its rated capacity.

RLA - Rated Load Amps Or Running Load Amps ... the current a motor draws when performing a specific task. For example, the current drawn to develop a rated tonnage or capacity of a CenTraVac®. RLA is always equal to or less than FLA. RLA is shown on the CenTraVac nameplate and is used to size conductors.

Anti-Recycle Protection ... a control or control method that limits the number of compressor starts within a given time period. Traditionally, a CenTraVac is limited to one start every 30 minutes (30 minutes from start-to-start). This protection is a standard feature of the CenTraVac control panel.

Bus ... a bar of conductive material, usually copper, used to carry large electrical currents to supply multiple circuits or components.

California Code ... a list of requirements for electrical devices:

1. All overloads must have external resets.

2. All control circuits must be disconnected when main circuit breaker or disconnect switch is open.

If no circuit breaker of disconnect switch is supplied:

A. Each control circuit must have a pull-apart fuse block or toggle switch on all control fuses.

B. Separate source control power requires a pull-apart terminal block and "foreign circuit" label clearly displayed.

3. The top of any fuse and the center of any pull -apart fuse handle, circuit breaker or disconnect handle must not be more than 78 inches from the floor in the handle's highest position.

4. All components that must be renewed, operated or repaired must be arranged so that it is unnecessary to reach over, through or past energized bus (or lugs) to work on de-energized parts and arranged to prevent accidental contact with eneregized parts caused by a tool slipping during maintenance.

If energization of parts of the equipment is necessary or likely during maintenance:

A. Insulate all bus bars

B. Relocate or rearrange components in stand-off mounting panels.

5. Label all components.

Label all fuses, indicating which control circuit each is in.

Label all toggle switches and pull-apart fuse blocks, indicating which control circuit each is in.

6. Insulation on wires terminating in compression or crimp type lugs is to be stripped back only to the end of the lug barrel. Wires must not be nicked or have strands missing.

Circuit Breaker ... a device that protects a circuit by opening its contacts when its current responsive element senses over-current or short circuit current. A circuit breaker protects wires and electrical components from further damage if any one component experiences a short circuit. See "Disconnect Means And Short Circuit Protection", page 8.

Contactor ... essentially a multi-pole relay whose contacts are rated to carry line current. A contactor connects a motor to and disconnects it from line power. The coil of a contactor may be operated by line voltage, control voltage or through a rectifier, DC voltage.

Control Power Transformer (CPT) ... a device that reduces line voltage to control voltage (i.e., 480V to 120V). The control power transformer of a CenTraVac is usually located in the starter. A 3KVA transformer is provided as standard in current CenTraVac starters.

Corona ... a visible, pale glow surrounding an insulated conductor carrying high voltage (over 2000V). Ozone odor is present and the air around the wire becomes ionized. An increase in voltage may cause the corona effect of adjacent wires to increase until spark-over occurs. (See "Stress Cone", page 25.)

Current Limiting Fuse ...See "Fuse."

Current Transformer ... a device that produces a reduced current signal that is proportional to motor current. A current transformer may resemble a square or round doughnut. The motor lead passes through the hole of the current transformer and a reduced, proportional current signal is obtained at the current transformer leads. There is no direct electrical connection from the line to the current transformer. The voltage in the output circuit of a current transformer will be whatever voltage is necessary to drive the output current through the load with the voltage limited only by the line power or saturation level of the current transformer. Therefore, the secondary of a current transformer must never see an open circuit.

Differential Protection ... a means of detecting current leakage in a motor from winding-to-winding or from winding-to-ground. This requires that the motor be 6 lead. Three current transformers, one on each motor phase, monitor the current in and the current out of each of the motor windings. If, due to leakage, the current in and the current out are not identical in each winding, a current will be induced in the secondary of one or more of the current transformers. This induced current will energize a current sensitive relay which will open a contactor and de-energize the motor.

Differential protection can be furnished for high voltage starters as an option.

Differential protection is not applicable to low voltage, star-delta starters.

Differential Relay ... a current sensitive relay that has three coils, each connected to one of the current transformers used for differential protection. Energizing any one of the three coils will operate the relay.

A differential relay is furnished with the differential protection option.

Disconnect ... a device for manually isolating an electrical circuit. (See "Disconnect Means And Short Circuit Protection", page 8).

Distribution Fault ... a loss of main power. When main power is lost, a motor acts as a generator while its magnetic field persists during coast-down. Under certain circumstances, a CenTraVac motor, upon a power loss, can support the control circuitry for up to 60 cycles. During this time, the main contactor is closed , but the motor is slowing down. If power is restored within this 60 cycle period, the motor may be subjected to very high torques as the motor tries to align itself with the newly reestablished rotating magnetic field.
These high torques may be damaging to motor windings, keyways and impellers.

Distribution fault protection is provided as standard on all CenTraVacs with the solid state overload or the microprocessor control panel.

Enclosure ... the starter panel. The standard enclosure is NEMA Type 1, general purpose-indoor. Other enclosure classifications to meet requirements of different environments are available as special options.

Fuse ... a device that protects a circuit by fusing (melting) open its current-responsive element due to an overcurrent or short circuit current. A fuse protects wires and components from further damage if any one component experiences a short circuit.

A dual element fuse is a fuse having current-responsive elements of two different fusing characteristics, in series, in a single cartridge. A dual element fuse is required to carry 500 percent of its current rating for a minimum of 10 seconds. Therefore, one of the current-responsive elements will have inverse time characteristics while the other element will handle larger currents without intentional time delay. Since all CenTraVacs draw inrush currents in excess of this rated minimum ampacity during acceleration, all low voltage CenTraVacs with fuse protection must use dual element fuses.

The NEC code allows a fuse rating that is a maximum of 175 percent of RLA, but allows a maximum of 225 percent, if necessary, to allow a motor to accelerate without blowing the fuses.CenTraVac dual element fuses are sized at 150 percent to 195 percent RLA.

Definitions

A current limiting fuse is a fuse that recognizes the rate of current increase and will fuse its element and open the circuit in less than one-quarter of an electrical cycle in the event of a short circuit. Thus, the total short circuit current available never passes through the current limiting fuse. CenTraVac® high voltage starters contain three current limiting fuses as standard.

Ground Fault ... a leakage of line current to ground. Typically ground faults are caused by breakdown or cracking of wire insulation.

Ground Fault Protection

Low Voltage ... ground fault protection consists of a ground fault sensor, a ground fault relay and a disconnect device (circuit breaker) equipped with a shunt trip device.

The ground fault sensor is a specially rated current transformer and must be applied only with a ground fault relay. Ground fault sensors cannot be used with any other equipment.

The ground fault relay is a relay designed to work with a ground fault sensor. The current level required to activate the ground fault relay is adjustable. The response speed (time delay) is also adjustable to avoid nuisance trips. All ground fault relays require a manual reset. The time-current tripping curve of a ground fault relay is nearly instantaneous when the current setting and time delay have been exceeded. The contacts of the ground fault relay energize a shunt trip device to open the circuit and isolate the ground.

The shunt trip device is a circuit breaker with a shunt trip coil. Such a circuit breaker can be opened manually, opened by its current sensing element (short circuit) or opened by energizing its shunt trip coil. A circuit breaker is used to open the circuit because it is capable of successfully interrupting fault current and the current to ground may be catastrophic.

High Voltage ... ground fault protection consists of a ground fault sensor and ground fault relay. The relay contacts interrupt control power to the main contactors. All high voltage starters are equipped with current limiting fuses. In the event of a catastrophic ground, the current limiting fuses would react much faster than the ground fault protection relay.Therefore, the fuses would perform the act of interrupting the circuit and isolating the ground.

The minimum setting of the ground fault protection system should be 20 percent of the disconnect rating with a 10 cycle time delay.

Grounding ... Electrical refrigeration components such as motors and control panels must be grounded for the protection of maintenance and service personnel.

Equipment ground connection bolts are provided in the control panel, the motor junction box and in the starter of all CenTraVacs. On those CenTraVacs where the control panel is isolated, grounding straps are installed to ground the control panel to the chiller frame. Thus, all pieces of a CenTraVac are provided with an individual equipment ground.

It is the responsibility of the installing contractor to ground the CenTraVac equipment to an earth ground per NEC and local codes. NEC specifies minimum ground conductor sizes in Tables 250-94 and 250-95 (1987 NEC).

"Gutless" Circuit Breaker ...a circuit breaker without a thermal or magnetic overcurrent element. It is used solely as a manual disconnect means. See "Disconnect Means And Short Circuit Protection", page 8.

Inrush Current ... the current drawn by a motor during acceleration. Inrush current for various types of starters (in percent of LRA) is given in Table 2, page 3.

Interlock - Electrical ... auxiliary contacts on a contactor, used typically in control voltage circuits, to monitor the position of the contactor. These auxiliary contacts may be normally open or normally closed or convertible.

Interlock - Mechanical ... bars, levers or catches that physically prevent operation of a device under certain circumstances. (i.e., CenTraVac starter door may not be opened if a circuit breaker is closed.)

Interrupting Capacity ... the rated maximum current that a device can successfully interrupt without damage to itself.

Ionization ... Insulated conductors carrying high voltage (over 2000V) are subject to ionization.

Ionization results in the formation of pockets of gas in the layers of the insulation creating areas of unequal stress that may lead to premature breakdown of the insulation. (See "Stress Cone", page 25.)

I.Q. 2000™ ... a Westinghouse device. It is a microprocessor controlled motor command system designed to be used in a Westinghouse Ampgard® starter. It uses current, voltage (optional) and motor temperature (optional) inputs to provide motor overload, overtemperature, monitoring and control functions.

All necessary controls and safeties for a CenTraVac are provided with the standard CenTraVac controls. The I.Q. 2000 is redundant. If an I.Q. 2000 is specified, its overload function should be set at 150 percent RLA. It may then act as back-up overload protection.

I.Q. DATA PLUS™... a Westinghouse device. It is a microprocessor-based monitoring and protective device. It provides digital readout of selectable phase current, phase voltage, megawatts, power factor, frequency and megawatt demand. It also provides system voltage protection - namely phase loss, phase imbalance, phase reversal, overvoltage (adjustable from 105 to 140 percent) and undervoltage (adjustable from 95 to 60 percent). This device has dry SPDT trip contacts and SPDT alarm contacts.

Isolation Switch ... a device used to connect and disconnect a load to and from the line. Since an isolation switch does not have an interrupting rating, it must not be opened under load. See "Disconnect Means And Short Circuit Protection", page 8.

Kirk Key ... a locking arrangement between a remote disconnect switch and a starter that is designed to prevent the closing of the remote switch and the powering of a starter that is being serviced.

A single key is used. It is held captive in the disconnect switch. The disconnect switch must be opened and then locked open. The key may then be removed and used to unlock the starter. The key remains captive in the starter until the starter door is closed and locked. The key may then be removed and used to unlock the disconnect switch. The switch may then be closed.

Lightning Arrester ... a device that protects electrical equipment from high voltage spikes by providing a high resistance path (an air gap) to ground. The device provides protection by consistently conducting to ground when the magnitude of the voltage exceeds a predetermined value.

Although lightning arresters may be used alone, they are used usually in conjunction with surge protection capacitors.

The function of a lightning arrester is to limit the magnitude of a voltage spike. The function of a surge capacitor is to limit the rate of rise of a voltage spike. See "Surge Capacitor", page 26.

Lightning arresters are a starter option.

Locked Rotor Amps (LRA) ... See "Amps", page 20.

Lod Trak™... a General Electric electronic device that monitors current and (optionally) motor temperature. Lod Trak provides motor overload, ground fault, phase failure, phase reversal, phase imbalance and (optionally) motor overtemperature protection. All of the functions (except ground fault) are performed by the CenTraVac microprocessor control panel. Thus, the functions of the Lod Trak are redundant. If Lod Trak is used, its overload trip setting should be set at 150 percent RLA. The Lod Trak may then serve as a back-up overload relay.

Lug ... a device used to mechanically connect a conductor (wire) to a piece of electrical equipment. Lugs are furnished by the starter vendor. The range of wire sizes that the lugs will accept are listed in the starter submittals.

The range of wire sizes indicates the maximum size wire that will fit into the lug hole and the minimum wire size that the screw can securely clamp in place.

Minimum Circuit Ampacity ... This term appears on a CenTraVac nameplate and is used to determine the size and number of conductors bringing line power to the starter. The formula for minimum circuit ampacity is 125 percent RLA of the largest motor plus 100 percent RLA of all other loads (control power transformer, oil pump motor, purge motor).

Definitions

Overload Protection ... a scheme or device that monitors motor current and interrupts control power to the main contactor(s), disconnecting the motor from the line, if motor current exceeds preset limits of current and time. Motor current may be monitored directly or through current transformers.

Overload protection may be performed by a device called an overload relay or it may be a function of a multi-purpose device such as the CenTraVac® microprocessor control module.

Overload relays may be thermal, magnetic or electronic.

Thermal overload relays are not suitable for use on a CenTraVac because of uncertain action caused by the varying acceleration times of individual chillers. Thermal overloads are also influenced by ambient temperature.

Magnetic overload relays are predictable and absolute. Inverse time magnetic overload relays can be set to pass inrush current at start-up without tripping, but still provide adequate running overload protection. Allen Bradley Bulletin 810 dashpot type magnetic overload relays were standard equipment in CenTraVac starters until 1980. They used an electromagnetically operated piston in a silicone liquid filled chamber (dashpot) to provide preset time delay functions.

The CVHB and CVHE CenTraVacs used a solid state overload relay from 1980 to 1986. This solid state overload relay was manufactured by Cutler Hammer. It performed several functions beyond overload protection.

1. Protection from excessive acceleration time.

2. Initiation of transition after the motor reached full speed.

3. Distribution fault protection.

Since 1986, CVHB and CVHE CenTraVacs have been equipped with a microprocessor control module. All overload relay functions that were performed by the solid state overload relay are now performed by the microprocessor control module in the CenTraVac control panel.

All CenTraVac overload trips require manual reset.

Overload Relay ... a device that senses current flow to a motor. The relay can be set to trip at a certain value. If the motor attempts to draw current in excess of this value, the relay will trip, de-energizing the contactor coil, disconnecting the motor from the line.

Phase Failure ... an opening in one of the three main power leads caused by a blown fuse or broken conductor. This results in only one phase being delivered to the load. Thus, phase failure is the same as single phasing. Phase failure protection is standard on CenTraVacs with microprocessor control panels and is available as a starter option on other generations of CenTraVacs. (See "Advanced Motor Protection System", page 19.)

Phase Imbalance ... an imbalance in the current level or voltage level among the three phases. Phase imbalance can cause motor overheating. (See "Advanced Motor Protection System", page 19.)

Phase Reversal ... a change in the desired electrical phase relationship. Phase reversal causes motors to rotate in the wrong direction. (See "Advanced Motor Protection System", page 19.)

Phase Failure/Phase Reversal Relay ... a device that monitors the phase relationship and opens a contact to stop the compressor motor in the event of phase failure, phase reversal or phase imbalance.

A phase failure/phase reversal relay was a starter option before the introduction of the microprocessor-based CenTraVac panel. The advanced motor protection provided by the microprocessor performs the functions of a phase failure/phase reversal relay.

Pilot Relay ... a term describing the fact that all CenTraVac starters start and stop the compressor by means of a relay that responds to commands from the CenTraVac control panel. Push-to-start pushbuttons or any other forms of manual starting of the compressor are not allowed. The CenTraVac safeties in the control panel must not be bypassed.

Power Factor ... the ratio of real power (watts) to apparent power (volt-amps). Induction motors, such as CenTraVac compressor

motors, require some energy for magnetizing that does no actual work and is not registered on a wattmeter.

For example, a CenTraVac in a 480 volt system, drawing 200 amps at full load, has a total apparent power requirement of 480V x 200A = 96,000VA. A wattmeter in this installation may read 86,400 watts at full load. The power factor is:

$$PF = \frac{\text{Working Power (Watts)}}{\text{Total Power (Volt-Amps)}} =$$

$$\frac{86{,}400 \text{ Watts}}{96{,}000 \text{ VA}} = 90\%$$

A utility must furnish 96,000 VA of power, but it will only be paid for measurable power used - 86,400 watts. Therefore, installations with poor power factors may be charged a premium for electrical power. (See Trane Engineering Bulletin CTV-EB-44.)

Power Factor Correction Capacitors ... may be used to improve the power factor of a CenTraVac by furnishing some of the wattless magnetizing energy required by the motor.

Power factor correction capacitors are a starter option. They are mounted in or on the starter and are wired to the load side of the compressor contáctor. Since the capacitors are wired in parallel with the motor, the maximum capacitor size is determined by the motor manufacturer.

The capacitors furnished as a starter option will correct the compressor motor to approximately 95 percent power factor at full load.

Rated Load Amps Or Running Load Amps (RLA) ... See "Amps", page 20.

Relay ... an electrically-operated device whose contacts switch electrical circuits. A relay is always used as a switching device within a control circuit.

RTD ... resistance temperature device. A device whose electrical resistance varies with its temperature. RTD's may be used to monitor motor winding temperature.

Every CenTraVac motor has three RTD's buried within its stator windings. These RTD's are connected to the CenTraVac control panel. There, a device monitors the resistance (hence, the temperature) of the RTD's and will stop the compressor if the motor winding temperature exceeds a preset level. These are dedicated RTD's and cannot be used for any additional functions.

If motor winding RTD's are required for any other function (I.Q. 2000, LOD TRAK, etc.), the RTD's required must be described and ordered. Then, a specially built motor will be provided.

Short Circuit ... an unintentional direct electrical connection from phase-to-phase or from phase to ground, resulting in low resistance and very high current flow. Short circuits can result in destruction of conductors and components. Short circuits are caused by the breakdown of insulation or poor wiring mechanics.

Shunt Trip ... a tripping coil added to a circuit breaker to provide a means of tripping the circuit breaker with an external signal. See "Ground Fault Protection", page 22.

Single Phase (Single Phasing) ... See "Phase Failure", page 24.

Solid State Starter ... a starter that starts and accelerates a motor at a preset acceleration rate and current limit. A solid state starter performs this function by modulating the current/voltage wave form delivered to the motor.

At the present time, no solid state starter is approved by The Trane Company for use with a CenTraVac with microprocessor controls. If a solid state starter is approved for such use in the future, an Engineering Bulletin will be issued.

Starter ... a device consisting of both a contactor and an overload protection system or device whose purpose is to start and stop a motor and protect that motor from overcurrent.

Stress Cone (Stress Relief Cone) ... Cables carrying above 2000V must have a metallic shield unless the cable is specifically listed or approved for non-shielded use. Shielding is necessary because of the danger of corona or ionization. The purpose of shielding a cable is to confine its dielectric field to the inside of the cable or conductor insulation. The shielding must be grounded at one end.

Definitions

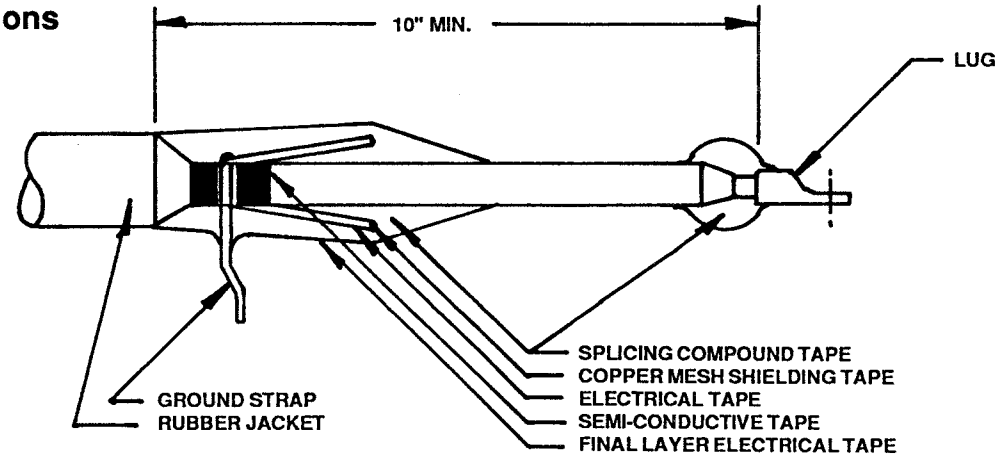

Figure 13

Stress cones are used to reduce and control longitudinal and radial electrical stresses at the cable end to values within safe working limits for the material used to make-up the termination. A typical stress cone, Figure 13, is over 9 inches long. An oversize junction box at the motor is required to accommodate stress cones. Usually the starter can accommodate stress cones in its normal enclosure.

Surge Capacitor ... a device that protects electrical equipment from high voltage spikes by absorbing the peak energy of the spike and then releasing it into the tail of the spike.

Although surge capacitors may be used alone, they are usually used in conjunction with lightning arresters. See "Lightning Arrester", page 23.

Lightning arresters limit the magnitude of a voltage spike. Surge capacitors limit the rate of rise of a voltage spike.

Surge capacitors are a starter option.

Switchgear ... A switchgear type starter is an across-the-line starter that uses a circuit breaker to connect and disconnect the compressor motor to and from the line. Usually a separate power source (i.e., 125 VDC from a battery bank) is used to open and close the circuit breaker on demand.

Switchgear starters should be used with caution. Some switchgear starters contain a relay that will trip the circuit breaker if auxiliary power is lost. Others do not contain this auxiliary power monitoring relay. It may then be impossible to automatically disconnect the compressor motor from the line in case of a compressor, chiller or starter fault, if auxiliary power is lost while the compressor is running.

Transducer ... a device that converts a control signal from one form to another. For example, conversion of a 0 to 20 psig pneumatic control signal to a 4 to 20 milliamp electrical control signal.

Transition

Transition is the action taken by a starter when changing from one configuration to another, such as changing (transitioning) from the star configuration to the delta configuration.

Open Transition ... a term indicating that the motor is disconnected from the line, transition is performed and then the motor is reconnected to the line.

Closed Transition ... a term indicating that the motor remains connected to the line during transition.

All CenTraVac® starters must be closed transition. Open transition starters cause stresses in the motor windings that shorten motor life. CenTraVacs with the solid state overload or microprocessor control will interpret open transition as a distribution fault.

Starters using electro-mechanical overloads initiate transition with a timer set at approximately 25 seconds.

Inrush current is nearly constant during acceleration and then drops quickly to less than RLA when the motor reaches full speed. Starters using the Trane solid state overload or microprocessor control monitor motor current continuously and initiate transition when the motor current drops below 85 percent of RLA.

Vacuum Break ... contacts are encapsulated in an evacuated, ceramic bottle. Since the contacts operate in a vacuum, arcs are quickly extinguished because there are no ionized gases present to support conduction. The claimed advantages are no contact maintenance, long contact life and safety, since there is no exposed arcing.

Vacuum break contacts (when used) are used typically only on high voltage starters.

Voltage ... The following voltages apply to CenTraVacs:

Control Voltage	120VAC
Low Voltage	208 - 600VAC
High Voltage	601 - 6000VAC

The electrical power industry refers to 2000V to 7200V as medium voltage.

Voltage Monitoring Relays

Overvoltage Relay ... a relay and an adjustable line voltage monitor that will stop a CenTraVac if line voltage exceeds a preset value. This overvoltage monitoring system is a lock-out system that requires manual reset at the starter.

Undervoltage Relay ... a non-adjustable relay that is powered directly by line voltage. If line voltage drops below 55 percent nominal voltage, the undervoltage relay will stop the CenTraVac. This relay requires a manual reset at the starter.

Adjustable Undervoltage Relay ... a relay and an adjustable line voltage monitor that will stop a CenTraVac if line voltage drops below a preset value. This undervoltage monitoring system is a lock-out system that requires manual reset at the starter.

These relays are all starter options.

Wattmeter ... a device that displays instantaneous power (watts) in the form of a dial meter or a digital display. When a wattmeter is ordered for a starter, the wattmeter option includes all necessary transformers.

Watt Hour Demand Register ... an option on a watt hour meter that has a dial and pointer that indicates the total power used per time period (i.e., 15 minutes). The movement of the pointer is proportional to the electrical energy used in the unit's time period. At the end of the time period, the mechanism drops back to its starting position while the pointer remains stationary. The pointer will only be moved further when the power demand in a new time period exceeds the power demand in any previous time period. Thus, the demand register indicates the largest power demand in any time period. The demand register may be manually reset to zero to monitor a new series of time periods.

Watt Hour Meter ... a device that measures and registers the cumulative amount of electrical energy used in terms of watt hours (or kilowatt hours).

When a watt hour meter is ordered for a starter, this option includes all necessary transformers.

Watt Hour Meter With Pulse Initiator ... Watt hour meters may be ordered with a pulse initiator. A pulse initiator is a device that generates pulses (contact closures) that are proportional to a definite energy value (watt hours per pulse). Output contacts of pulse initiators are normally connected to pulse-operated demand recorders or used to feed energy consumption information to computers and load controllers.

When ordering pulse initiators, the type of pulses and the pulse rate the end devices will accept must be indicated.

Withstand Rating ... When a short circuit occurs, there is a period of time that the short circuit current passes to the shorted circuit before the protection device (circuit breaker or fuse) can open. This time can be as long as .020 seconds (1 cycle). The withstand rating of a starter is the maximum short circuit current that it can pass safely. Components within the starter may be destroyed, but the starter cabinet will safely contain any sparks or flying debris. U.L. listed starters also have a listed withstand rating.

What Can Contact Failures Teach You?

KLOCKNER-MOELLER

What can contact failures teach you?

by Dr. G. F. R. GALLE, manager, testing department, Klockner-Moeller

Seventeen specific causes of contact failure are illustrated in this exclusive article. Accurate colour reproductions show normal characteristics of each; and ways are suggested to avoid the same trouble in the future.

The life of contactors is essentially dependent on the behaviour of the contacts. Pure silver as contact material has proved highly satisfactory due to many outstanding properties. The shape of the contacts is chosen to guarantee that all required properties (resistance to welding, breaking capacity, continuous current rating, etc.) are maintained. For satisfactory service life, the contacts are designed as butt contacts thus avoiding friction. Contacts in modern control are designed for a relatively long service life and specifications are based on specific current duty diagrams indicating definite service conditions and maximum values for frequency of operations and continuous current. If one of these factors is neglected, a shorter service life or breakdown will result.

A critical examination of the appearance of the contact surfaces will yield many valuable hints as to the nature of the service conditions under which the contacts operated, especially during the most recent period of operation. It is then often possible to make the necessary corrections in order to obtain the utmost economy. Such an examination will also indicate whether or not the contact is nearing the end of its useful life. In the case of breakdown, careful scrutiny of the surfaces often reveals the cause of the trouble.

It is a common occurrence to have users complain about the appearance of contacts, assuming that they are no longer fit for service and that in consequence the unit has not completed the promised service life. In examining these complaints we often find that either the equipment has not nearly reached the end of its useful life or that some incorrect application has caused an excessive load on the apparatus. Often valuable material — sometimes entire contactors which would have given satisfactory performance for many more years — is spoiled. Also, it is often exceedingly difficult to convince the user that his conclusions were incorrect. A convincing explanation of the cause of these defects must be given immediately to the user, since complaints of this nature may prove harmful to the good reputation of control equipment and shake the confidence of the customers in the validity of the equipment life guarantees. The user will be saved further considerable material losses in most cases by a clear presentation of the facts.

At what point has the life of the apparatus ended? The life of an airbreak contactor has come to an end when the over-travel of the contacts has gone down to .5 mm (.02"). Over-travel of the contact assembly is that part of the stroke which the moving contacts would cover after touching the fixed contacts — propelled by the actuating device — if they were not blocked in their movement by the latter. The remaining over-travel of a contactor can be measured by actuating the control mechanism by hand and by determining the distance which the actuating device will cover, applied to the contacts, after the contacts have touched. Measuring the over-travel is the only means of determining whether or not the contacts are approaching the end of their useful life. This procedure is of the utmost importance. It is by no means true that the pure silver used as contact material can be allowed to wear to the last trace for contact making.

These explanations are, however, not meant to invite the making of tests from time to time on our contactors to see whether the end of their service life has been reached. The life of the apparatus can readily be determined in advance by careful selec-

tion of suitable control based on life expectancies as given in our catalogues. Testing should only be necessary after the specified life term has expired, and then only for the purpose of determining whether, due to special circumstances (for example light load conditions) the apparatus may yield a longer service life than indicated in the catalog.
Endurance tests, continuously carried out in our test laboratories, plus the experience gained in actual service confirm with a high degree of probability that equipment used at rated loads will reach the specified life span.
If it is found on checking that the end of the service life has been reached before the apparatus has performed that total number of operations it is rated for, the cause can only be due to a too heavy load or a defect. It is a fortunate fact, however, that contacts of control in normal service or under overload conditions or under the effects of a fault, assume specific appearances, thereby indicating clearly one of these causes.
Most users lack the opportunity of becoming familiar with these characteristics of contacts. For this reason, we pass on the experience gained by a larger number of critical examinations performed on airbreak contactors. To do this, we have selected some typical cases where the appearance of the contacts permits definite conclusions regarding the duty to which the contactors were subjected during their useful life. We trust, however, that before beginning our task, a few words concerning the appearance of pure silver butt contacts of airbreak contactors under normal duty, will be allowed.
The appearance of pure silver contacts, even under normal service conditions is a surprise to many users accustomed to copper contacts. The surface of pure silver contacts constantly changes in colour under normal duty, starting from a light blue hue at the beginning, to a dark colouring toward the end of their useful life.
Many users from the appearance of the contact surfaces, are led to believe that the apparatus will not work reliably and is consequently useless. Our comments on these objections are as follows: The colour changes in the pure silver contact surfaces is a natural phenomenon. It is a very thin film of silver oxide and silver carbonates produced by the effects of arcing. This colouring has no harmful effects whatsoever on the performance of the equipment. It may be said on the contrary that the making capacity of the contactor is considerably increased by the film. We will show later that this film has originally a blue tinge, changing to a deep brown with progressive operative life. No single case has so far come to our knowledge where the discolouration of the contacts has had a harmful effect on the properties of the contactor. Above all, we have found no instance where the current carrying capacity of the contact assembly was in the least diminished through this film.

The following examples are divided into four groups, each group illustrated and each discussed in the following paragraphs.

The first group represents contacts of apparatus having been operated within the permissible ranges of switching capacity, frequency of operations and continuous current rating. The control voltage was kept constant between 90 to 100 per cent of the rated value. These examples will illustrate to the reader the appearance of contacts of equipment, as they should look under ideal service conditions. It must, at the same time be clearly understood that contacts used mainly for making duty look different from those working chiefly under breaking duty. For contactors controlling heavily inductive circuits, the breaking operation represents the higher stress if the starting current remains below the contact welding value or as long as it is not essentially higher than the breaking current. In nearly all induction free or capacitive circuits, the making stress is generally greater than the breaking stress. Moreover, if the starting current is considerably higher than the breaking current, as is the case for example with contactors for condenser control without damping devices, the result will be a pure making stress effect on the contact surfaces.

The second group of examples is representative of contactors working under conditions outside the permissible range without causing definite failures. Conditions of this kind are very undesirable since they are the cause of considerable reduction of the service life of the apparatus. This will jeopardize one of the most valuable properties of our contactors and this is why it is important that these cases be rapidly recognized and remedied.

The third group illustrates those cases where excessive stress on the contact assembly resulted in a rapid development of a defect and failure of the unit. It may be suitable at this stage to review the chief causes of overstress on contactors and to examine their origin and effects.

(a) Exceeding the switching capacity of a contactor.

Exceeding the making capacity of a contactor will produce welded contacts, while exceeding the breaking capacity means — in addition to welded contacts — prolonged arcing. The most common causes for exceeding the breaking capacity of a contactor are:

1. Motors with abnormally high current peak.
2. Transformers with an extremely high flux density.
3. Short time voltage failures with running motor.
4. High proportion of harmonic waves in the mains or connection on opposed phases with condensor contactors.

Under the above specified conditions the breaking capacity is normally indirectly exceeded by exceedingly heavy inching or reversing duty, or through short circuits with a relatively high resistance in the load circuit.

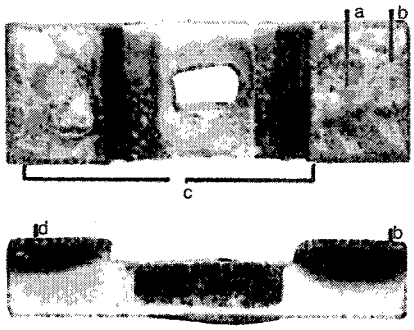
(b) Exceeding the continuous rating of a contactor.

This type of overstress will entail excessive temperature rise of the current path and of the contacts. If this overstress is extremely severe, it may cause direct harm to the contacts as well as indirect injury to other parts of the apparatus. This includes all cases where the allowable ambient temperature is considerably surpassed. The effects of an unduly high ambient are, naturally, similar to those of excessively heated contacts as a consequence of a high current rise with an ambient temperature within permissible limits. The continuous current rating is often impaired by accumulation of dirt on the contact surfaces. Suitable enclosures are therefore of utmost importance.

(c) Variations in control voltage.

Too low a control voltage is of frequent occurrence and of special importance in tracing the causes of defects. It is not sufficient in this case to check as to whether the voltage on the contactor coil is within the permissible range. Often only a temporary drop of the control voltage can be observed, due to the starting current, especially with motors of large outputs. If the control voltage is permanently too low, the result will be a lower making capacity.

An increased control voltage may considerably interfere with the behaviour of the contactor regarding rebound. Contact burning may increase and there is danger of the service life of the contactor being shortened. In extreme cases which occur where a contactor coil for a lower voltage is installed, this may lead to broken parts in the contactor.

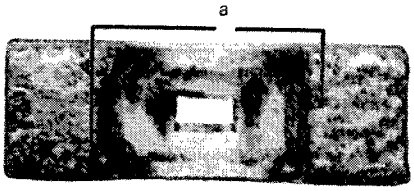


The cause for too low a control voltage may in most cases be looked for in excessive resistance of the circuit. The voltage drop in power-and-control transformers, circuits including the control circuits, must not exceed 10 per cent of the rated voltage. It must be considered that the voltage drop in the main and control circuits depends, during the starting of the motor, on its starting current; and during the making response of the contactor, on the latter's inrush current. Neglecting this fact has often been the cause of failures. Unstable control voltage may furthermore be the result of failures in the control circuit as a consequence of accumulated dirt or vibrating control devices.

The fourth group is composed of two examples showing the contacts of two units which carried a short circuit current. This extreme load forcibly produces a considerable deformation of the contact surfaces. Welded contacts will normally result. Up to this day, however, we have not heard of one single case where a flash-over occurred in one of our contactors due to a short-circuit. Neither have we experienced one single flash-over during the tests in our laboratories where our contactors were subjected to short-circuits with and without fuses.
It is, however, advisable to replace a contactor through which a short-circuit current has passed.

First Group: Normal Load

Common Characteristics: Maintained Contours



Photos Nos. 1 and 2
Breaking stress, beginning of service life

Characteristics:

(*a*) Blue colouring, uniform contact surface
(*b*) Preserved geometrical shape
(*c*) Smooth corners and edges
(*d*) Only tiny silver beads

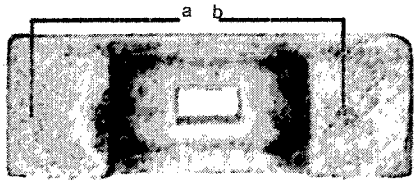


Photo No. 3
Breaking duty, end of service life

Characteristics:

(*a*) Dark brown colouring

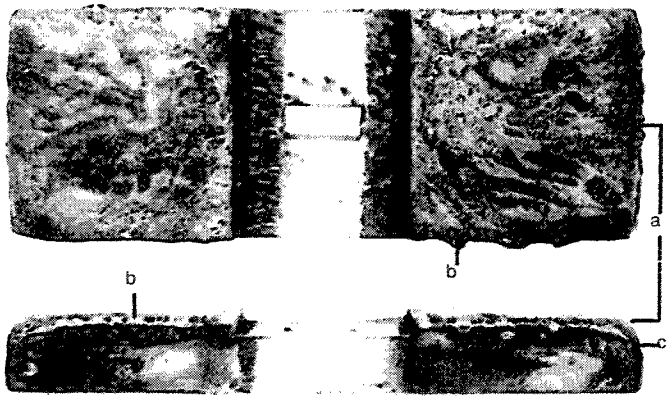
Photo No. 4
Making stress

Characteristics:

(*a*) Silvery colouring
(*b*) Surface shows chiselled effect.

Photographs Nos. 1 and 2
show the contacts of a DIL 4 which has interrupted a current corresponding to the maximum normal rating.
The contactor is at the beginning of its service life. The contact surfaces, consequently, show the typical blue colouring resulting from breaking duty. The surface is smooth and uniform in shape. The geometrical form of the contacts has remained practically unchanged, except that the outer corners are slightly rounded and very small silver beads which hardly project over the outer edges of the contacts have formed on the sides.
This picture is typical of silver contacts showing the effects of normal breaking duty.
No harmful effect from this coloured film due to starting could be ascertained in spite of many careful tests. It was, on the other hand, established beyond doubt that the formation of the contact surfaces resulting from the effects of the arc-base being exposed to the outer atmosphere, has an advantageous influence on the welding limit of the contacts.

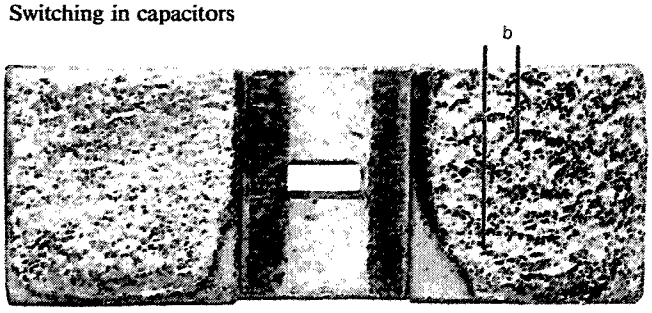
Photograph No. 3
shows a contact of a DIL 4 at the end of its useful life. This picture clearly shows that the blue colouring of the contact surface vanished gradually toward the end of the service life and that the silver hue has clearly changed to brown or dark brown.
It becomes apparent from the picture that the geometrical shape remains unchanged, provided that the load is kept within admissible limits with regard to intensity, voltage and frequency of operation — this applies particularly to the outer edges of the contact. This brown colouring which may vary to a very dark brown hue has also in this case no harmful effect on the properties of the contact. All required qualities remain fully effective up to the end of the useful life of the contact.



Photograph No. 4
shows the contact of a DIL 4 contactor having undergone making tests with the maximum allowable current at unity power factor.
By comparison with the preceding photos it becomes quite evident that the appearance of the contacts of a contactor used exclusively for making duty is fundamentally different from that of contactors working under making and breaking duty, or solely under breaking duty. The blue colouring of the contact surface typical for breaking duty is not apparent in this instance. The surface, on the contrary, has a silvery white appearance as of pure metal and gives the effect of a finely chiselled surface with a pattern as if applied by light blows. This pattern is produced by a gradual material transfer taking place at every contact making at the first point of contact, causing tiny rough spots on the contact surface. Due to the fact that the first point of contact varies at each switching operation, the tiny rough spots are distributed

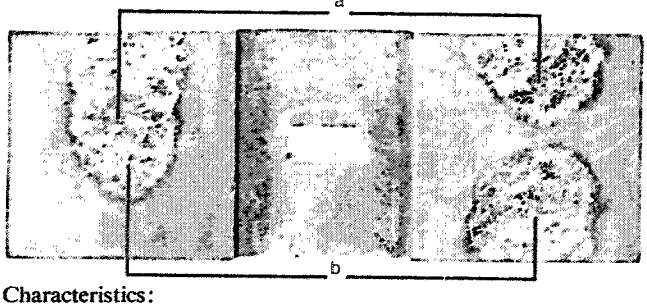
over the entire contact surface, producing this chiselled effect.
It is surprising to observe that this metallic surface does not corrode in spite of the marked affinity of silver for the hydrogen sulfide gas in the air. This form of surface shows also no trace of corrosion nor change of colouring even after a prolonged idle period without switching operations. The contacts will retain their geometrical form under exclusive making duty, provided the breaking capacity is not exceeded. The original form maintained during the service period, is evidence of normal load within permissible limits; with proof to the contrary, if the shape shows marked deformation.

Photographs 5 and 6
show the contacts of a DIL 8 contactor. The load has remained within permissible limits. The contactor is in the first half of its service life.
Here, too, the typical blue colouring of breaking duty, the formation of a smooth and uniform film on the surface, and the preservation of the original form, especially of the outer edges, are clearly visible. The silver beads on the edges are somewhat larger than those observed in the case of the DIL 4, since the magnitude of the current is correspondingly greater. The corners and edges are more rounded off than those of the DIL 4 contact. The lateral view of the contact shows that no spikes have formed and that the beads developed only directly along the edges of the contact. The contact wear allowance is therefore fully maintained for the switching operations. The contacts will thus attain the promised service life. These pictures also show clearly the characteristic appearance of contacts working within permissible load limits.



Photographs Nos. 7 and 8
These two photos of DIL 8 contacts show a comparison of contacts from two different contactors used for condenser control.
The upper picture illustrates the surface of the contacts from a contactor used for condenser control, working under making duty only. Here again we observe the typical appearance of a contact surface exclusively under making duty.
The lower picture shows a contact from a contactor used for condenser control, after a switching capacity test, consisting of making as well as breaking operations. The light brown tinge is a sign of breaking duty. The large proportion of light spots with a metallic gleam is explained by the fact that with a condenser contactor the making duty is considerably more severe than the breaking duty. Upon closer scrutiny, a great number of minute welded spots will be observed, spreading over the area where contact making occurred. These, however, were broken up again.
For this reason the photo of a contact after a test of 100 making operations was chosen because the fine welding spots will be covered by subsequent contact blows in prolonged switching duty, as can be seen by comparison with the upper photo.

Photos Nos. 5 and 6

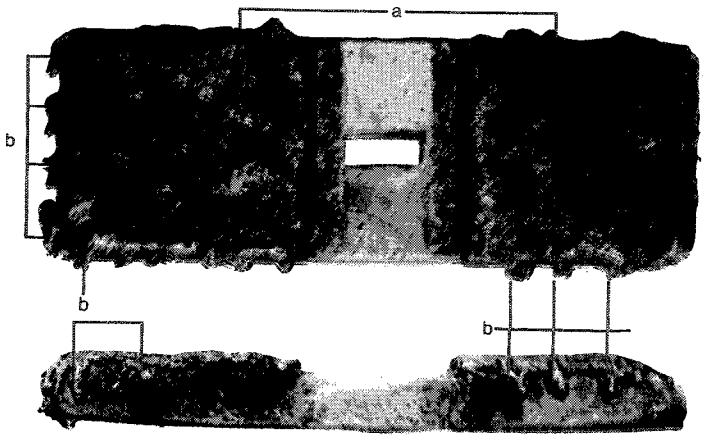


Characteristics:
(*a*) Blue colouring
(*b*) Maintained geometrical shape
(*c*) Only beads, no spikes
(*d*) Only slightly rounded off edges

Photo No. 7
Switching in capacitors

Characteristics:
(*a*) Silvery colouring
(*b*) Precisely chiselled surface

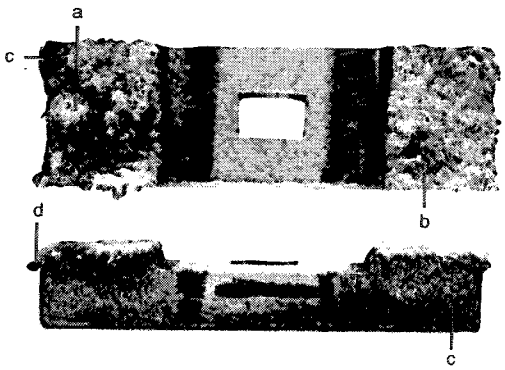
Photo No. 8
Switching in and out of capacitors



Characteristics:
(*a*) Light brown colouring
(*b*) Torn up welded spots

Second Group: Duty under excessive Load

Common Characteristics: Changed Contours



Photos Nos. 9 and 10
Excessively high breaking current together with unduly high load

Characteristics:

(*a*) Blue up to dark brown colouring
(*b*) Large silver beads and spikes

Photos Nos. 11 and 12
Exceeded continuous rating together with high frequency of operation

Characteristics:

(*a*) Welded spots
(*b*) Light brown colouring
(*c*) Extended surface
(*d*) Silver beads, no spilkes

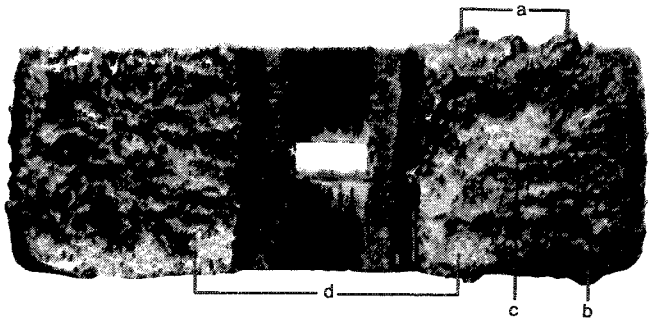
Second Group: Service under Overload. Common Characteristic: deformed contours.

Photographs Nos. 9 and 10
Contrary to the photos shown so far, these pictures of contacts of a DIL 8 contactor show marked deformations of the geometrical form. Very large silver beads and spikes have formed on the edges of the contacts which have partly bent downward. The contact surface remained smooth and has the typical blue colouring of breaking duty. No white metallic spots can be found on the contact surface. The contacts were taken from a DIL 8 contactor which was subjected to a heavy test of 160 per cent rated load. The switching capacity of the contactor was not exceeded by this test, so that no immediate disturbances occurred. This excessive load leads, however, to undue wear of the contacts, for the silver material accumulating in the form of beads and spikes can no longer be used for further contact making. This, and the increased burning of the material will considerably decrease the life of the contacts.
This kind of excessive load is, as can be seen, very easily recognized and the specified features of the contact shape are reliable indications that the rated load of the contactor has been exceeded by an unduly high breaking current.

Photographs Nos. 11 and 12
These two photos of a DIL 4 contact show positive indications of excessive thermal stress.
This example shows the effects of exceeding the continuous current rating, bringing about an undue temperature rise at the contact gap. Although the temperature did not rise to the point of fusion, a temperature near softening point was reached. In conjunction with a high frequency of operation, the impact energy of the contacts was strong enough to produce permanent deformation of the contact surface.
The load remained within tolerable limits, which becomes evident by the silver beads formed along the edges and corners of the contacts, but the spikes, the characteristic sign of too high a current, are absent.
Overstress of this nature on the contacts will ultimately produce contact welding.
On the left side of the contact small welded spots are clearly visible as well as the large welded area near the left edge, which finally led to the failure of the contactor.

Photograph No. 13
This contact also shows uneven outlines as well as an irregular surface. The colouring is also unequal, showing positive blue areas alternating with silvery bright spots with a chipped surface.
The deformation of the geometrical shape and the formation of spikes, pits and furrows on the surface suggest an excessive current. The formation of silver beads on the surface as well as the irregular colouring indicate special load conditions.

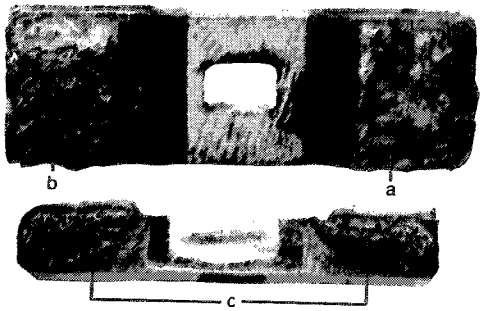
Second Group: Duty under excessive Load



Common Characteristics: Changed Contours

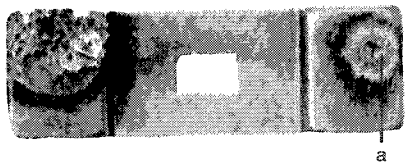
The contact is, in fact, the result of the same heavy load test applied to the contacts shown in photos Nos. 9 and 10. A condenser was, however, connected in parallel in this instance for individual power compensation. The apparent power decreased correspondingly, the spikes and points are no longer as marked as in photos Nos. 9 and 10. The blue tinge indicative of a severe breaking stress, while the silvery, chipped areas clearly indicate heavy making stresses, customary in condenser control. This contact is a good example of how the nature of the load is clearly reflected in the appearance of the contact surface.
Although the amount of burnt contact material is reduced by connecting the capacitor in parallel, the load on the contact is still unduly high.

Photographs Nos. 14 and 15
These two photos of a DIL 4 contact are again typical of a very specific case. It is obvious at first sight that the controlled current remained within permissible limits, for the edges are free from silver beads and spikes. The surface shows the typical blue colouring (however of a considerably darker hue) indicating breaking duty. The contours have undergone a change of a nature which justifies the conclusion that small silver particles have been continuously transferred to the edge of the contact in a very liquid state, from which they have flowed down. These features develop if the motor power controlled by the contactor remains in the lower half of the permissible current range and, at the same time, the frequency of operations is unduly high.
Although no welding nor excessive temperature rise of the contact surface in produced, the spots where the arc stands for a longer period are severely heated up, if the liquid silver material in this place has not sufficiently cooled down before the formation of the next arc. It may happen that the silver material, pushed by the base of the arc toward the edge of the contact in a liquid state, remains in this state, flowing down the sides. This interpretation is supported by the intensive colouring.
It is obvious that this kind of load will also reduce the contact wear allowance since part of the contact material is transferred to unsuitable places.



Photograph No. 16
This contact of a DIL 4 contactor was taken from a contactor used for making a current for above the rated capacity.
This excessive load will inevitably cause welded contacts and as a consequence immediate failure of the contactor. This example was intentionally chosen to illustrate the characteristic appearance of a genuinely welded area.
In the centre we see the core of liquefied silver, smooth and shining, enclosed by the roughened halo, which is caused partly by the breaking apart of the contact. If the rated value is only slightly exceeded, the welded spot is so small that it can only be observed if considerably magnified.

Photo No. 13
Rated breaking current exceeded. Capacitor connected in parallel.

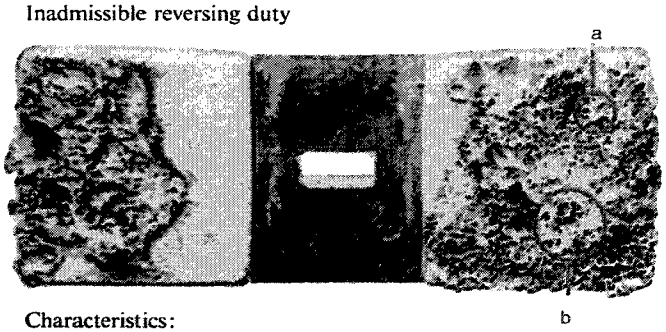


Characteristics:
- (*a*) Large spikes
- (*b*) Blue colouring
- (*c*) Furrows and beads on the surface
- (*d*) Silvery spots

Photos Nos. 14 and 15
Unduly high frequency of operations

Characteristics:
- (*a*) Deep blue colouring
- (*b*) Smooth surface
- (*c*) Flow of silver material at the edges

Photo No. 16
Excessively high making current



Characteristics:
- (*a*) Welded spot

Third and Fourth Group: Inadmissible Service Conditions

Common Characteristics: Considerably Deformed Contact Surface

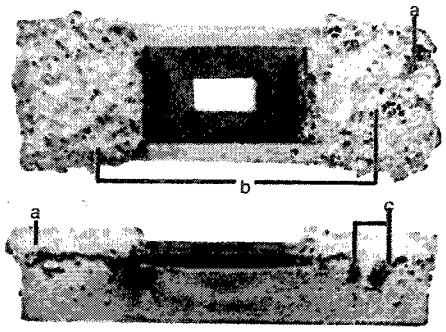


Photo No. 17
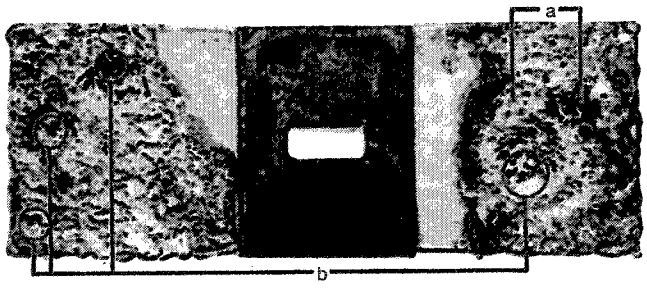
Inadmissible reversing duty

Characteristics:

(*a*) Blue-brown colouring
(*b*) Many welded spots
(*c*) Nor spikes nor prongs



Photos Nos. 18 and 19
Inadmissible Inching (jogging) duty

Characteristics:

(*a*) Strongly deformed contact surface
(*b*) Mostly silvery colouring, more rarely brown
(*c*) Spikes and prongs on the edges, in most cases not welded, only sticking contacts

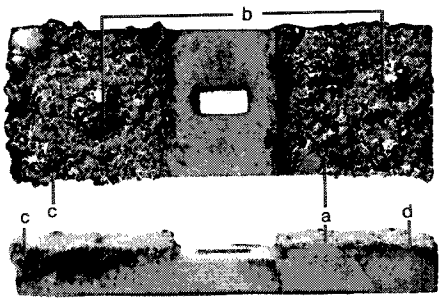
Photo No. 20
Collapsing control voltage in the moment of making

Characteristics:

(*a*) Silvery colouring with dark spots
(*b*) Very extended welded spots with pronounced liquification of silver

Photograph No. 17
This contact of a DIL 8a2 contactor shows the characteristic blue-brown colouring of breaking duty. No spikes have formed, a proof that the breaking current was not too high. Many welded spots can be observed, which are spread over the entire contact face. Although somewhat levelled out by the arcs of subsequent breaking operations they have entirely changed the smooth appearance of the surface under normal conditions. In two spots the silver became liquefied to a greater depth.
This contact shows evidence of the effects of unduly heavy reversing duty. The severe starting load was too heavy and caused the formation of a chipped contact surface by a large number of torn apart welded spots. These conditions continued until full liquefication of the contact surface occurred in two places which almost caused the welding of this contactor.
Contacts which are submitted to repeated short-time failures of the control voltage show the same features.

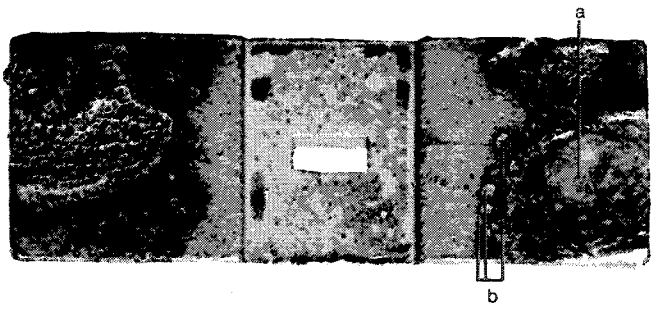
Photographs Nos. 18 and 19
As opposed to the contacts shown in photo No. 17, these contacts of DIL 4a2 contactor shows strongly developed spikes as well as an entirely white, silvery appearance of the contact surface. The contact surface proper is flattened out by pressure, changing the original form, and is probably more intensely chipped than the surface of the contact shown in picture No. 17.
The formation of points and spikes suggests above all an excessive breaking current which the white silvery appearance of the contact surface seems to contradict. When we take into consideration the exceedingly high temperature over the entire surface, existing during the process of deformation of the contact during which the silver turned viscous, suppressing the thin blue coloured layer, this seeming contradiction is explained.
This contact was taken from a contactor used for inching duty for which it was not designed. The high making and breaking currents — due to the very short intervals customary in inching duty — heated up the contact surface to an excessive degree beyond the fusion temperature of the silver. It is only natural that this fusing of the entire contact surface will inevitably produce sticking contacts.
It must be observed that the contact surface does not show any welded spots, a sign that although the switching capacity of the contactor was not exceeded, the inching duty was beyond the rated performance of the unit.
These extreme service conditions are, unfortunately, very frequent. For this reason the proper evaluation of the signs in order to eliminate the causes of possible faults is of the utmost importance.



Photograph No. 20
This contact shows no spikes and only a very slight brown colouring. The silvery spots, predominant

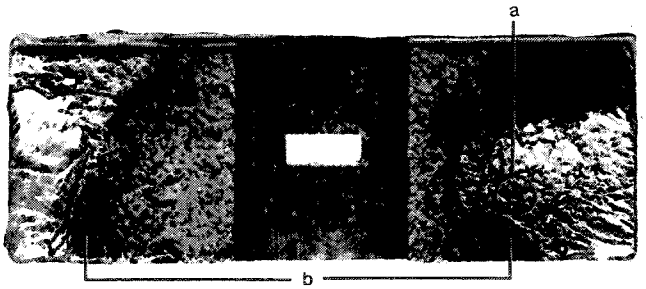
over the entire surface, are an indication that no excessive breaking stress is involved here, but that the trouble is due to failure of the unit in making. A very extensive welded area has formed on the right half of the contact, indicative of the contactor working with undervoltage.
These marks occur relatively frequently if motors with high output are controlled. In this particular case the control voltage broke down under the effects of the high starting current, producing first a chipped contact surface and finally completely welded contacts.

Photographs Nos. 21 and 22
These contacts also operated under insufficient control voltage. As opposed to the contact shown in Photo No. 20, the control voltage was permanently too low. Thus not only many and extended welded areas were produced, but also excessive heating of the entire contact surface and, consequently, complete deformation.
It might be advisable to underline at this stage that the nature of the colouring of the contact surfaces is essentially influenced by the relation between making and breaking currents and the ratio of undervoltage. All gradations of colouring between photos Nos. 17 and 21 may develop in cases of this kind.
A distinction between the cases of inadmissible inching duty, reversing service and undervoltage is not always easy to make and is only possible after minute examination of these photos.



Photographs Nos. 23 and 24
These photos of two DIL 8 contacts are a particularly clear illustration of the effects of a very high current (short circuit current) which passed through them. It can be observed in photo No. 23 that a large part of the right hand section of the contact surface was heated to a state of slight plasticity. The upper left hand section was liquefied to a state where the dynamic forces of the current succeeded in blowing the silver outwards. The contact material was carried away in this case over the middle of the silver coat. It is therefore discernible that the contactor was in the closed position when the surge current developed and remained thus, for the surface of the crescent shaped shallow crater is smooth and looks polished. Moreover, small welded spots are clearly visible on the left half of the contact. In this case three welded spots can be clearly located.
On the right half of the contact shown in photo No. 24, it may be observed that the surface of the shallow crater is no longer smooth but chipped. These marks develop when the contactor opens a short-circuit current and an arc base moves across the liquefied silver layer. This is produced by the control voltage breaking down under the effects of the short circuit current, so that the contactor drops out.
These marks constitute an absolute proof that the short-circuit current passed through the contactor has reached a multiple of the permissible continuous current rating.

Photos Nos. 21 and 22
Control voltage too low

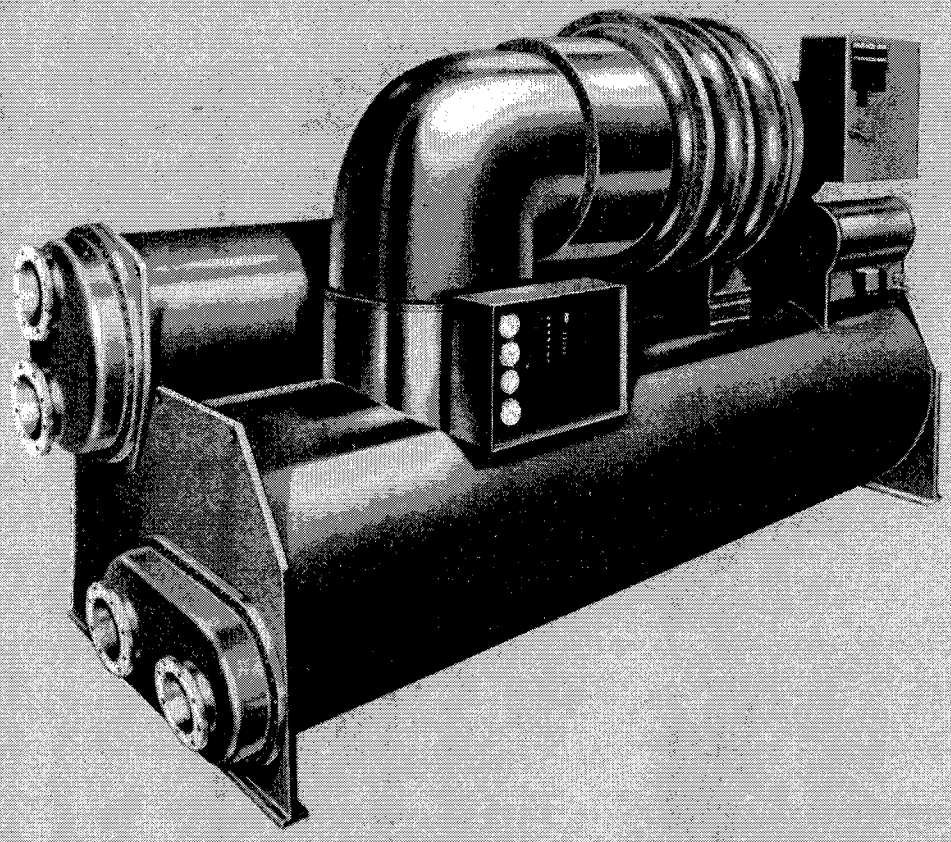


Characteristics:
(*a*) Silvery up to brown colouring
(*b*) Pronounced welded spots
(*c*) Strongly deformed contact surface
(*d*) Silver beads, but no spikes nor prongs

Photo No. 23
Short circuit in closed position

Characteristics:
(*a*) Crescent shaped shallow smooth bright craters
(*b*) Welded spots

Photo No. 24
Short-circuit with interruption



Characteristics:
(*a*) Craters as shown in Photo No. 23, yet grooved
(*b*) Pronounced accumulation of soot

Applications Engineering Manual

Control Of Model CVHE CenTraVacs

Control Of Model CVHE CenTraVacs

©The Trane Company, 1985

Purpose

This manual describes the control and application of Model CVHE CenTraVacs in single and multiple chiller installations. Overall system descriptions provide the fundamentals. In addition, functions of major control elements are detailed. Primarily, the intent is to provide adequate information to apply Model CVHE CenTraVacs to conventional chilled water systems.

The CenTraVac System

The Model CVHE CenTraVac is a state-of-the-art, water cooled hermetic centrifugal water chiller. Cooling capacities nominally range from 140 to 1250 tons of refrigeration. Three stages of centrifugal compression are used to meet the thermodynamic requirement of a conventional Refrigerant-11 vapor compression cycle. Two economizers (interstage flash cooling chambers) are used to provide maximum thermodynamic cycle efficiency.

The CVHE CenTraVac is driven directly by a hermetic, 2-pole, low slip 3600 rpm AC induction motor. Because R-11 is a low pressure refrigerant, operating pressures are below 15 psig for conventional air conditioning applications.

Chilled water is produced in a shell-and-tube evaporator of the flooded design. Refrigerant evaporates on the outside surface of the tubes, chilling water as it passes through the tubes. Water surfaces (tube internal diameter) can be cleaned mechanically or chemically by accessing the tubes at either end.

All heat is rejected through a shell-and-tube condenser. Like the evaporator, condenser water is circulated internally through the tubes. Therefore, they too may be mechanically or chemically cleaned.

The Model CVHE CenTraVac is a one-piece, completely factory assembled package. Field connections to the machine are made to four elements:

1. Main compressor power
2. Control system interlocking
3. Chilled water piping
4. Condenser water piping

Main compressor power is taken from standard 3 phase, 60 Hz utility grids. Voltages may vary from 200 to 4160, depending on the specific electrical service provided.

Proper application of the CenTraVac requires an understanding of the functions of the complete system and its components.

First, control system interlocking ties capacity control functions and CenTraVac safety devices to the chilled water system.

Chilled water is circulated by one or more pumps through a piping system to air conditioning terminals. Ordinarily, these terminals employ an extended surface heat transfer coil. One of two basic concepts can be used to control the air conditioning effect.

Modulated Flow	Constant Flow
2-way valve	3-way valve

Traditionally, water chillers are rated as constant flow devices. The reasons for this are beyond this brief overview and are discussed in Trane Engineer's Newsletter Vol. 9, No. 1. Some form of interlocking must be provided to prove chilled water flow before the chiller is permitted to operate. Operation of the CenTraVac without adequate chilled water flow has serious consequences and must be avoided.

The CenTraVac control system maintains a constant temperature, chilled water supply. The assumption is that a constant supply water temperature will satisfy the continuous cooling needs of the terminal units. In this way, chiller capacity is matched with the system's demand for cooling.

Condenser water is usually pumped from a cooling water source. Several sources re commonly available:

- Open cooling tower
- Closed circuit cooling tower (evaporative cooler)
- Cooling pond
- River or lake water (with or without heat exchanger)
- City water

Condenser water interlocking is also required. However, the physical consequences of an interrupted supply of condenser water, while important, are not as damaging as the loss of chilled water flow.

Condenser water also requires temperature control. If the water is too warm, the CenTraVac may not be able to meet the cooling load. If it is too cool, other operational problems can occur. This control system is completely separate and usually not interlocked with the CenTraVac itself.

Control Panel

Figure 1

(Figure 1) All safety and operating controls are housed in the CenTraVac control panel. The panel functions are divided into four categories, as indicated by the external panel layout:

1. Pressure indicating gauges have no operating function. They are used only to provide condenser, evaporator, lubricating oil and purge drum pressures.

2. System sequence status lights perform an important diagnostic function. A series of seven lights shows the progress of the CenTraVac starting sequence. As each of the seven circuit interlocks is verified, its individual pilot light comes on. Therefore, the reason for an aborted start can be determined by observing the pilot lights and determining the point at which the sequence was breached.

3. Five fault trip indicators display the status of each safety cutout control. Circuit interrupters are used to open the circuit instead of relays because they will hold their position in the event of power interruption. Therefore, power failure does not require the manual resetting of all safeties. Additional alarm contacts on each of the fault trip indicators are brought to a terminal strip for external connection.

4. The electronic capacity control system consists of three elements:

- Chilled water temperature control
- Demand limiter
- Manual inlet vane control

Chilled Water Temperature Control

The chilled water temperature control module uses a transistorized sensing element to measure the supply water temperature. The controller has an adjustable dead band that spans the plus and minus sides of the setpoint temperature. The dead band adjustments are ±.25, ±.50, ±1.0 and ±1.5 F. Within this dead band no control action is taken.

The control module loads and unloads the chiller using variable duration control pulses. The time lapse between each successive load/unload pulse is adjustable between 10 and 310 seconds. This, coupled with the dead band adjustment, provides the latitude of control sensitivity needed to produce stable system performance over a broad range of application conditions.

Loading...When loading, the control pulse duration is a function of the chilled water temperature deviation from the plus side of the dead band versus the motor current, as a percentage of the "% Current" setting of the demand limiter.

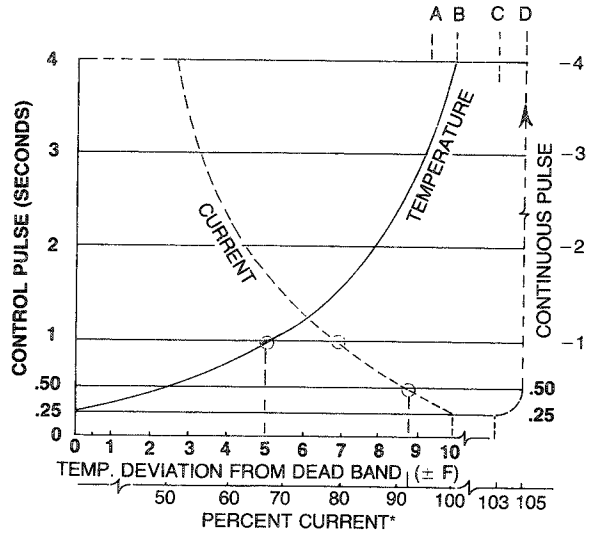

Figure 2

(Figure 2) For example, assume the supply water temperature is 5 F above the plus, or upper, dead band limit and the overload is generating a signal that is proportional to 93 percent of its "% Current" setting.

Since the module recognizes the more critical of the two conditions, instead of the one second, the lesser .5 second load pulse is used. In this example, current limiting takes precedence over temperature control. Had the current been 80 percent, or less, of the "% Current" setting, the temperature related 1 second pulse would have been used. In other words, in this example, to maintain stability, the module selects the lesser of the two pulse signals. Again, the selected 10 to 310 second time lapse is observed between successive load pulses.

Unloading...Unlike loading, the unloading mode is solely a temperature related function. Since chiller unloading provides motor current relief, motor current is not a consideration. Therefore, the unloading pulse duration is a function of the chilled water temperature deviation from the minus side of the dead band.

Demand Limiter

The demand limiter control setting is continuously variable from 40 to 100 percent of the motor full load current. Any particular setting pre-loads the device, as required, to limit the motor current to that value.

Motor current is sensed by three current transformers and is processed into a proportional DC voltage by the CenTraVac electronic overload. This output voltage is monitored by the demand limiter which transforms it into a signal that is related to its "% Current" setting.

As discussed, throughout the temperature controller modulating range, the chilled water temperature deviation from the dead band and the "% Current" signals are compared. And, the "% Current" signal is used to establish the load pulse duration when current limiting becomes the critical condition.

When in the current limiting mode, the load pulse duration is reduced until 100 percent of the demand limiter "% Current" setting is reached (point B). At this point, the control pulse duration drops from .25 seconds to zero—vane movement stops.

At 103 percent of the load limiter setting (point C), an unload sequence is initiated. This sequence consists of .25 second unloading pulses, each followed by the 10 to 310 second null period. This sequence is repeated in an attempt to return the chiller to 100 percent of the "% Current" setting.

Finally, should the current exceed 105 percent of its setting (point D), a continuous unloading pulse is established. This pulse is terminated when the motor current is reduced to 95 percent of the limiter setting (point A). At this point, the chiller is free to again accept load.

Manual Inlet Vane Control

A four-position switch provides manual override of the automatic capacity control system. In addition to "automatic" control, the inlet vanes can be made to "load", "hold" or "unload". This permits the operator to check vane motor and linkage operation.

Note: While the chilled water temperature control system is overridden, the demand limiter and low refrigerant temperature systems remain in control to limit vane travel.

Sequence Of Operation

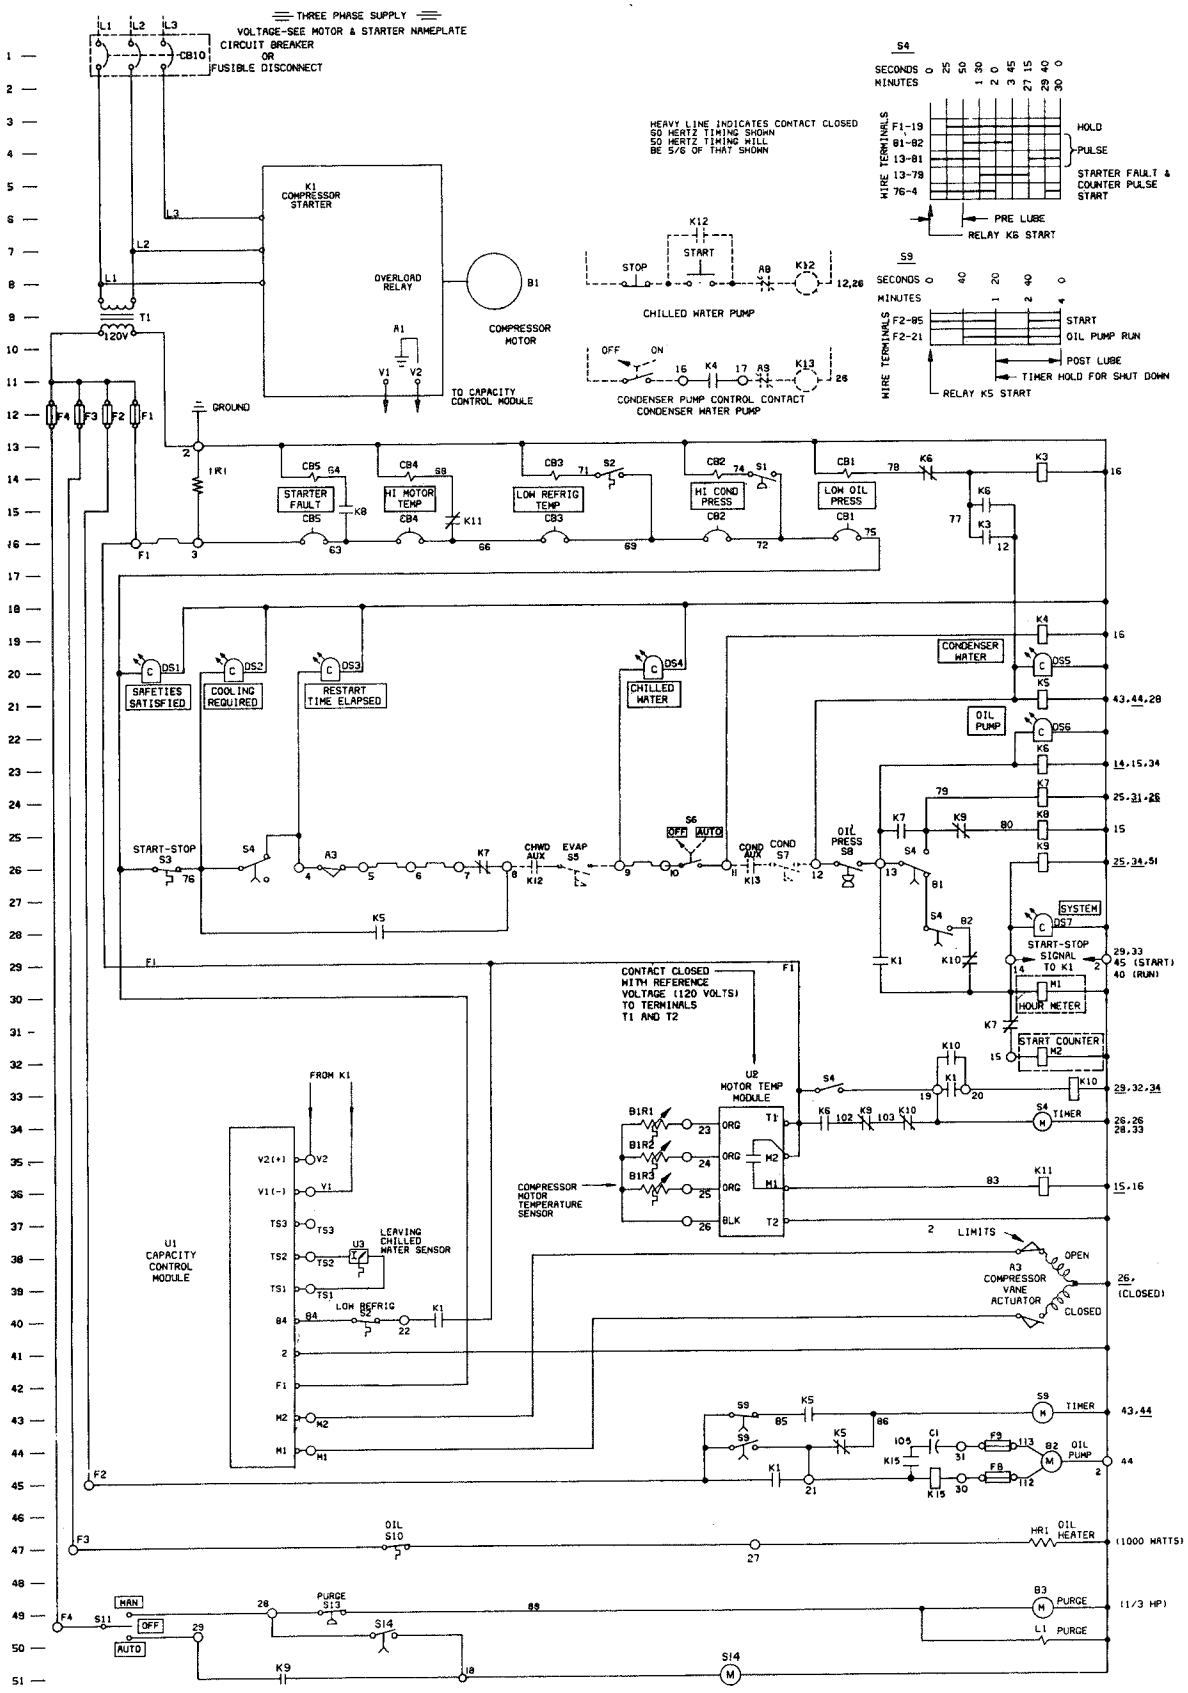

Figure 3

(Figure 3) The sequence of operation can be described using this schematic line diagram.

A start is initiated by performing three manual operations:

1. Energize the chilled water pump starter, K12 (line 8).
2. Close the main circuit breaker, CB10 (1).

Immediately, the motor temperature module, U2 (34), closes its contacts, energizing relay K11 (36). In turn, the K11 contacts (15) open, preventing circuit interrupter CB4 (16), "Hi Motor Temp.", from opening.

Note: The action of the circuit interrupters is delayed approximately 1 second. This avoids nuisance trip-out at initial start-up, when the relay logic needed to arm the interrupters is being established.

3. Set the "Off-Auto." switch, S6 (26), to "Auto.".

Once these procedures have been performed, control power is conducted through the safety control interrupter contacts (16). If all interrupter contacts are closed, Pilot light DS1 (20), "Safeties Satisfied", will light and power will be fed to the F1 terminal of the capacity control module, U1 (42). This drives the vane actuator, A3 (39), to the closed position.

Next, when the return water temperature indicates that a load exists, the cooling demand switch, S3 (26), closes. This lights DS2 (20), "Cooling Required", and conducts control power to timer contact S4 (26). Provided 30 minutes have elapsed since the previous start, S4 is closed, lighting DS3 (20), "Restart Time Elapsed".

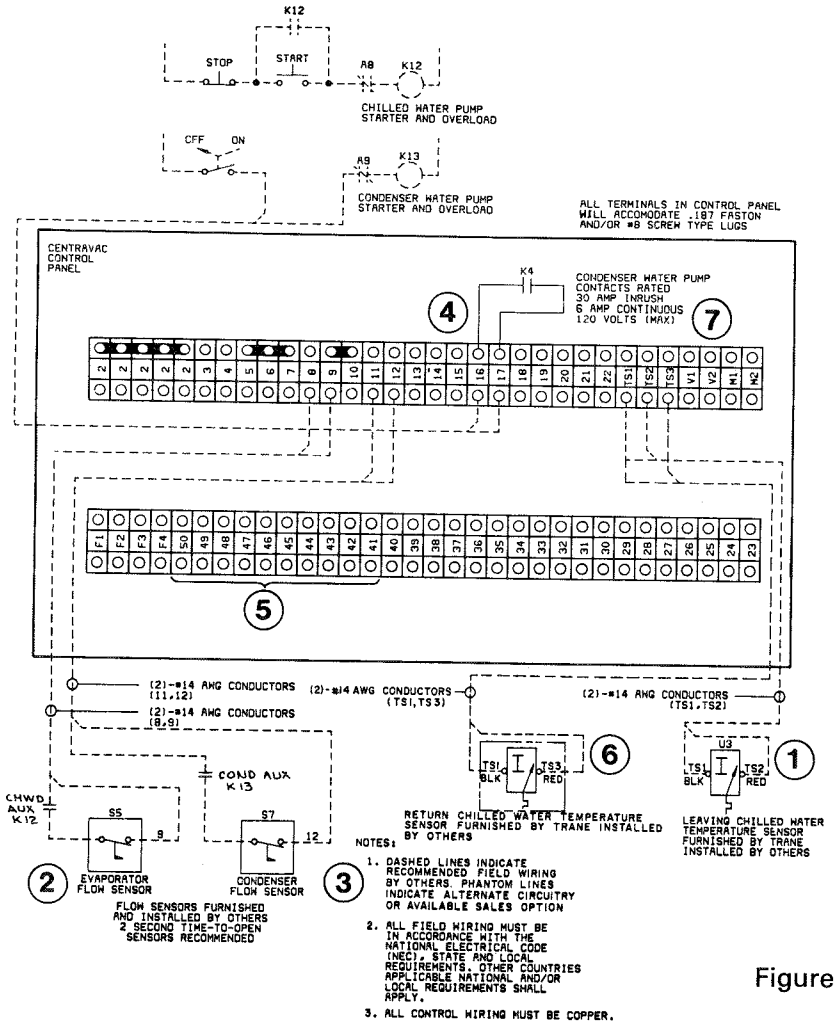
Assuming the compressor is not running and its inlet vanes have been driven to the closed position, the inlet vane actuator end switch, A3 (26), is closed. This conducts control power through the normally closed contacts of K7 (26) to the auxiliary contacts, "CHWD AUX." (26), of the chilled water pump starter, K12 (8). Once the starter is engaged and chilled water flow is established, the contacts and the flow sensor, S5 (26) close, lighting DS4 (20), "Chilled Water". Proceeding through switch S6 (26), relay K4 (19) is energized. The normally open contacts of K4 (11) close, energizing the condenser water pump starter, K13. This closes both the starter auxiliary contacts, "COND. AUX." (26), and, once flow is established, the flow sensor S7 (26). In turn, pilot light DS5 (20), "Condenser Water", lights and relay K5 (21) is energized. Contacts K5 (43 and 44) reverse positions, energizing the oil pump timer, S9. Approximately 40 seconds later, the S9 contacts (44) close, energizing the oil pump motor, B2, through a current sensing relay, K15. Relay K15, in turn, closes, placing the start capacitor, C1, into the circuit. Once the motor assumes running load current, K15 drops-out, de-energizing C1. Another set of K5 contacts (28) close to maintain the control circuit by forming a parallel path with the start inhibitor functions.

When oil pressure is established, oil pressure switch S8 (26) closes, lighting DS6 (22), "Oil Pump", and energizing relay K6 (23). Contacts K6 (14, 15) reverse positions, energizing relay K3 (14). In turn, the K3 contacts (16) close, arming the low oil pressure circuit interrupter, CB1 (14). A third K6 contact (34) closes, energizing timer motor S4 (34). Twenty-five seconds later, contacts S4 (33) close, keeping the S4 timer motor energized throughout its timing cycle. After another 25 seconds have elapsed, S4 contacts (28) close, lighting DS7 (28), "System", and energizing compressor motor starter K1 (29). The closing of the K1 contacts (29) holds power on the motor starter. A second set of K1 contacts (33) energizes relay K10 (33).

One set of K10 contacts (32) closes forming a holding circuit for relay K10. A second set (29) opens, removing the start signal from the K1 starter circuit. Consequently, the start pulse lasts only long enough to energize the starter. A third K1 contact (45) maintains power to the oil pump motor as long as the main compressor starter remains energized.

When the compressor motor starter reaches the "run" configuration, the K1 interlock (40) feeds control power to terminal 84 of the capacity control module, U1 (40), through the low refrigerant temperature switch, S2. Once energized, U1 transmits variable duration load/unload pulses to the inlet vane actuator, A3 (39). As discussed, the pulse duration is established by processing the signals from the chilled water temperature sensor, U3 (38) and the demand limiter, which is an integral part of U1. Since U1 is not powered until the compressor comes to speed, the chiller starts unloaded.

Note that relay S2, "Low Refrig. Temp.", has normally closed (40) and normally open (14) contacts. In the event a low refrigerant temperature develops, contacts S2 (40) open, causing U1 (38) to transmit a constant "unload" signal to the compressor vane actuator, A3 (39). If an additional temperature drop equal to the differential of S2 occurs, contacts S2 (14) close, tripping circuit interrupter CB3 (16), "Low Refrig. Temp.".



The arming of the "Starter Fault" circuit interrupter is initiated when relay K9 (26) is energized, opening its contacts (25). The arming is completed 40 seconds after the initial pulse is sent K1, when timer contact S4 (26) switches from 13-81 to 13-79, energizing relay K7 (24). In turn, the K7 contacts (25) close, locking relay K7 into the circuit. With this circuit arrangement, if some fault causes K1 to open, relay K9 (26) de-energizes, closing contacts K9 (25). This energizes relay K8 (25), closing contacts K8 (15), opening the "Starter Fault" circuit interrupter, CB5 (16).

Sequence Of Operation

When the CenTraVac is stopped normally by the cooling demand switch, S3 (26), or abnormally by a safety trip-out, the relays (K1 and K5) within the oil pump control circuit de-energize. To provide bearing oil pressure during compressor coast-down, a contact of timer S9 (44) remains closed for 2 minutes 40 seconds to operate both the oil pump and timer motors.

Loss of oil pressure while the compressor is running causes the oil pressure switch, S8 (26), to open. This interrupts control power at terminal 13, de-energizing the compressor and, in particular, relay K6 (23). With K6 de-energized, power feeds from terminal 12 (26) through contacts K3 (16) and the normally closed K6 contacts (14) to trip circuit interrupter CB1, "Low Oil Pressure", de-energizing the control circuit.

Finally, the purge unit may be operated continuously by placing the "Man.-Off-Auto." switch, S11 (49) in the "Man." position. When placed in the "Auto" position, purge operation is cycled by timer contacts S14 (50) as long as the compressor is operating and relay contacts K9 (51) remain closed. The timer, S14 (51), is adjustable from 0 to 60 minutes. The typical adjustment produces 5 minutes of purging per hour of unit operation.

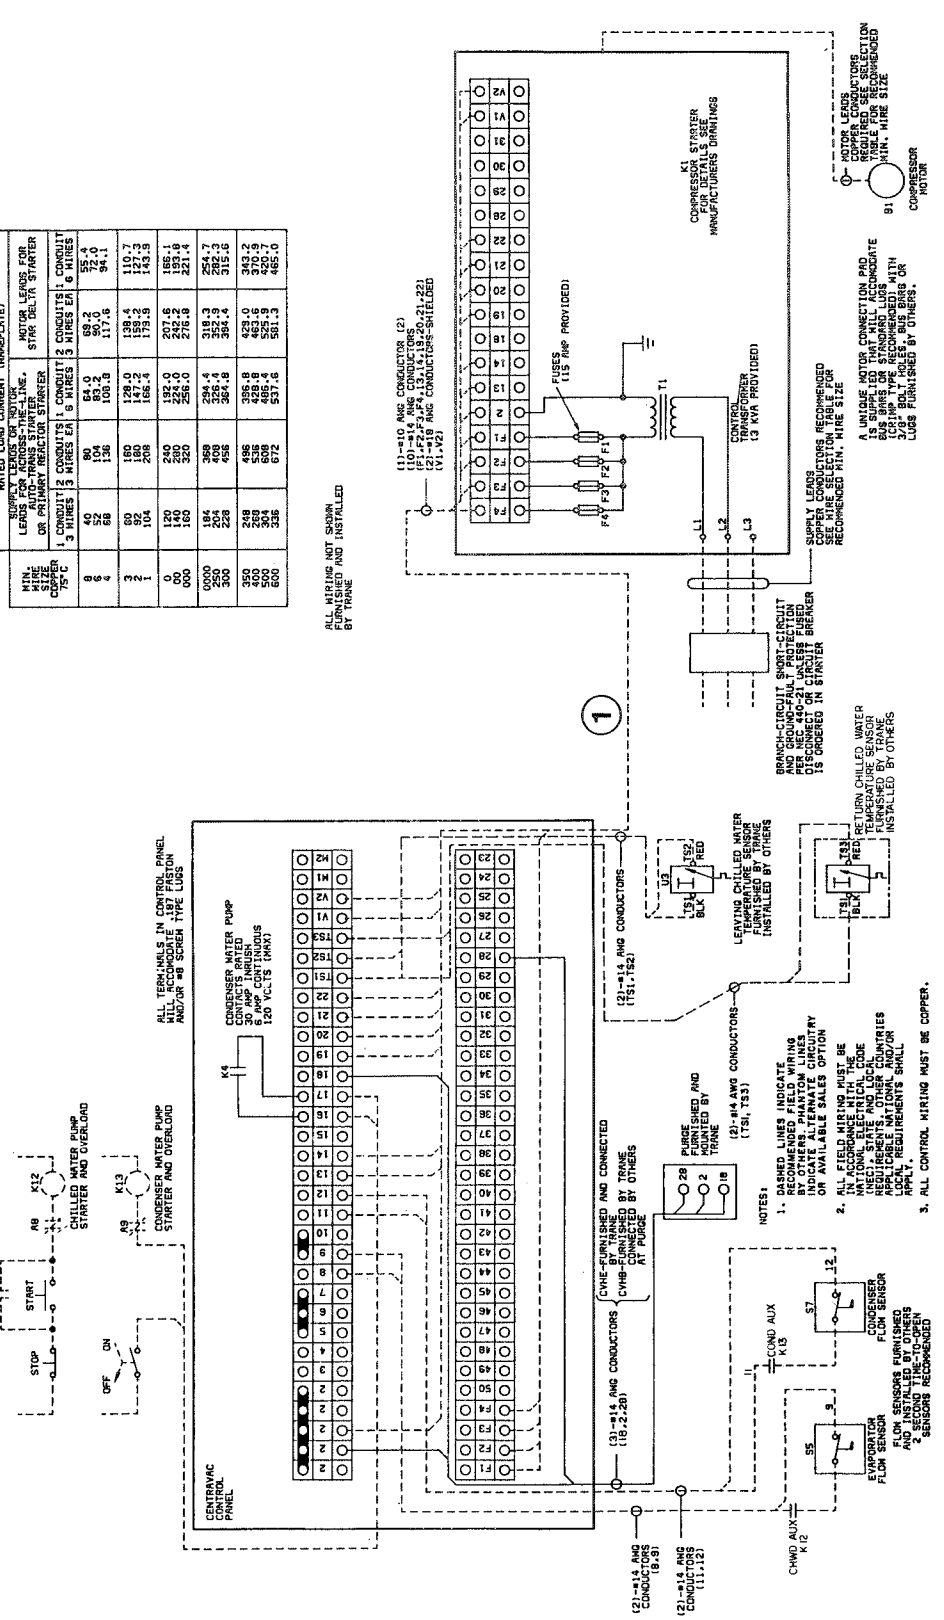
Figure 4

(Figure 4) The wiring and corresponding terminal points used to interconnect the panel with the various external control functions are:

1. Chilled water temperature sensor...Terminals TS1 and TS2 accept wiring from the chilled water temperature sensor (U3), located in the supply water piping.

2. Evaporator flow sensor (S5)...Terminals 8 and 9.



3. Condenser flow sensor (S7)...Terminals 11 and 12.

4. Condenser water pump relay (K4)...Wiring from relay K4 exits at terminals 16 and 17. In addition, terminal points are provided for optional connections:

5. External alarm...Terminals 41 through 50 can be used as N.O. or N.C. contacts for connection to external alarms.

6. Return chilled water temperature sensor...-Terminals TS1 and TS3 accept input from this sensor. In turn, the capacity control module (U1) processes the signal to provide chilled water temperature reset.

7. Remote demand limiter control...Terminals V1 and V2 (connected to the electronic overload relay A1) will accept additional input from a 0 to 8.25 VDC source. This additional signal can be used to provide separate demand limiting capability.

Figure 5

(Figure 5) In addition to the required and optional wiring discussed and illustrated in Figure 4, the wiring needed to interconnect the panel with a remotely mounted starter is:

1. Starter (K1)...Thirteen wires interconnecting the motor starter and panel.

Fused control power, start-stop relay signals and starter interlocks use eleven wires. The remaining two, connecting V1 and V2, conduct a VDC signal from the overload relay (A1) to the load limiting function of the capacity control module (U1).

Factory-Mounted Starter Panel

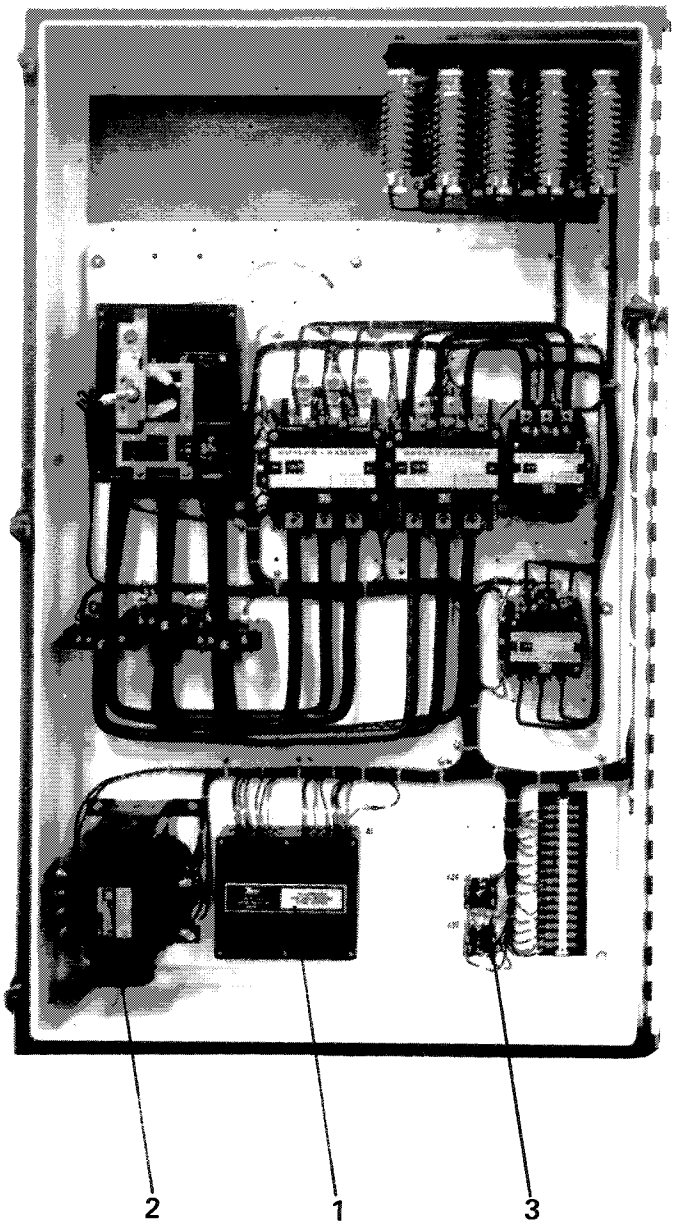

Figure 6

(Figure 6) As a standard option, factory-mounted starter panels are available for all low voltage (200 to 575 volts) Model CVHE CenTraVacs. They contain conventional star-delta, closed transition starters. Factory mounting eliminates field placement of the starter plus all wiring interconnecting the panel and starter and the starter and the CenTraVac.

The starter panels have these advanced features:

1. Solid state electronic overload relay and distribution fault protector.

2. 3 KVA control power transformer.

3. Two (redundant) pilot relays, plus run and start interlocks and a low loss, non-threaded motor connection system.

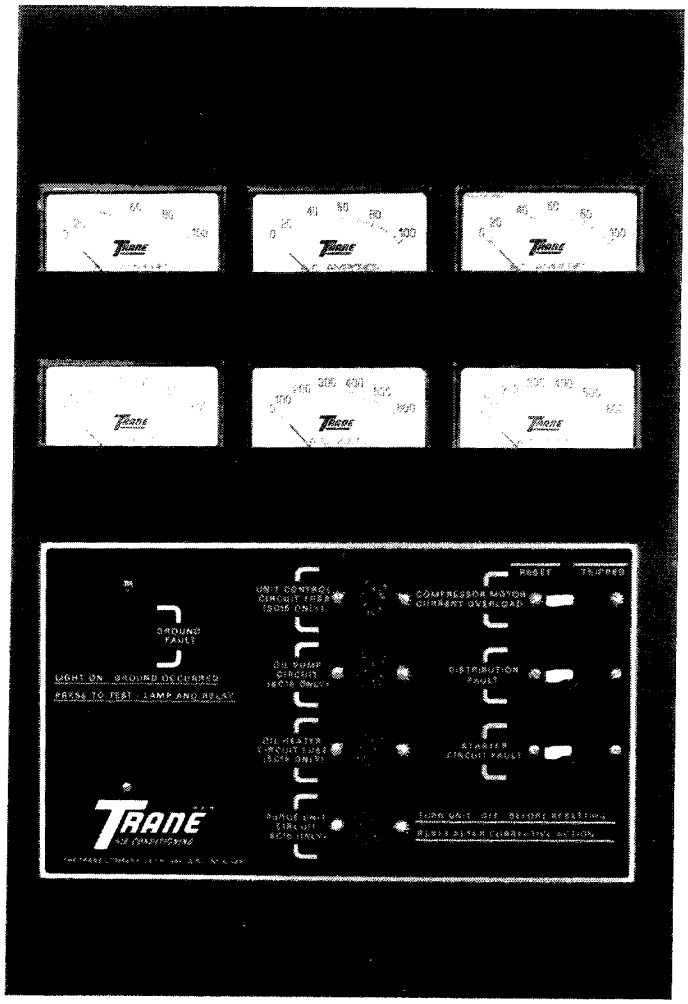

Figure 7

(Figure 7) In addition, the occurrence of a starter fault, overload or distribution fault is displayed by fault trip indicators located in the panel door. Optionally, a ground fault indicator and voltage and amperage meters, for each of the phases, are available.

The CenTraVac motor is started in the star, or wye, configuration and accelerates to the normal operating speed (3575 ± 0.7 percent). Starting current is monitored by the electronic overload module (A1) and, as soon as the current falls to approximately 85 percent of motor RLA, transition to full voltage (delta) is initiated.

When transition is complete, motor current is monitored against a value of 107 percent of RLA. If the current should reach this value, the overload will trip, disconnecting the motor.

Motor Overload Protection

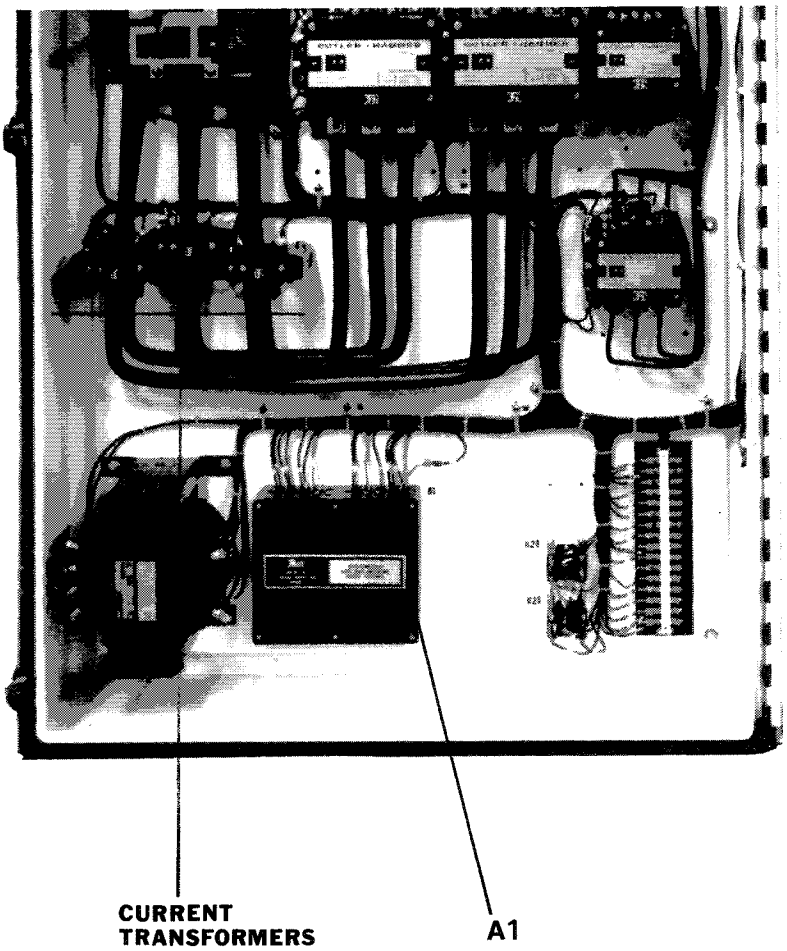

Figure 8

(Figure 8) Three-phase current is monitored by three polarized current transformers located in the primary motor power feeders. The outputs of these current transformers allow the electronic overload A1 to perform its functions. Further, the outputs are used to signal the load limiting function of the capacity control module U1.

The degree of protection afforded by the solid state electronic overload is significantly better than any electro-mechanical device available. The motor is protected throughout its starting and running cycles. Should the current fall outside specific bounds, electronic circuitry will trip the motor starter instantly.

The overload will stop the compressor if any of a variety of system abberations (low voltage, phase failure, phase unbalance or phase reversal) cause high motor current. If specific lockouts are required to cope with these problems, starters may be fitted with such standard options as low voltage protectors and phase failure — phase reversal relays.

Complete description of the CenTraVac motor overload system appears in Installation, Operation and Maintenance MPCA-IOM-1.

Distribution System Fault Protector

Modern electrical distribution systems employ state-of-the-art circuit switching equipment. This allows the utility to supply "uninterrupted" power to its customers during electrical storms and periods of high circuit usage. A definition of "uninterrupted", however, reveals a potential problem. The utility overlooks short duration interruptions. Certain types of loads are adversely affected by short duration power interruptions.

Obviously, electronic loads such as computers and medical monitoring equipment can be severely affected. In addition, high inertia centrifugal equipment can experience trauma when subjected to short duration power interruptions.

The mechanics of this problem are based on the fact that an induction motor, rotating near its synchronous speed, generates a "back e.m.f." that is nearly as large as the driving voltage. When the driving voltage is removed, the back e.m.f. remains, allowing control circuits to remain active for about 60 cycles (1 second).

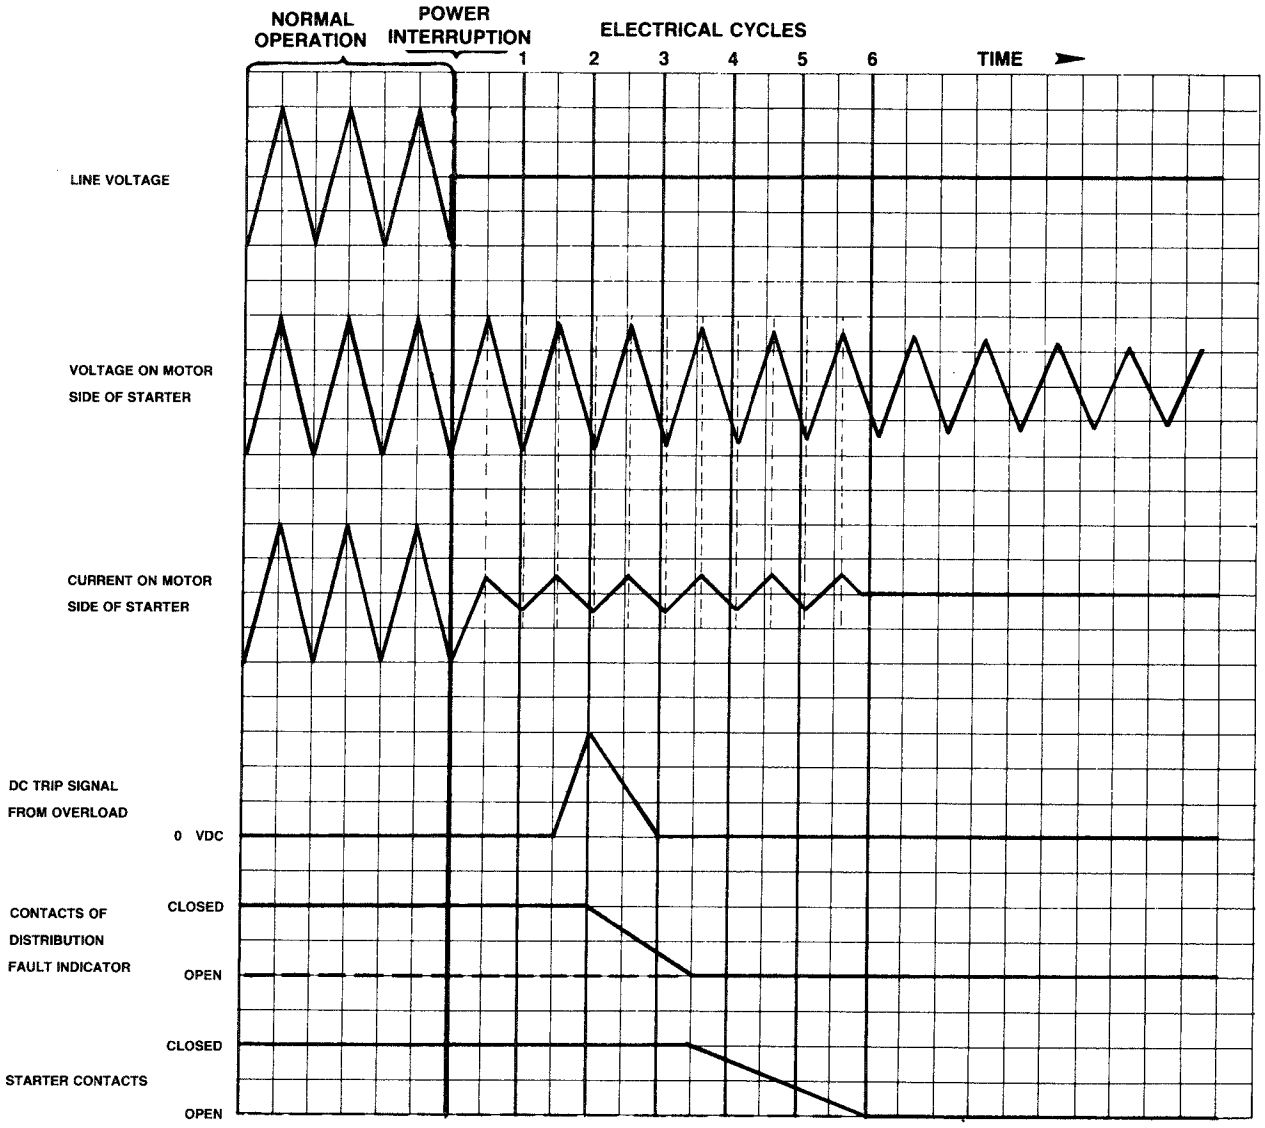

Figure 9

(Figure 9) The frequency of the remaining back e.m.f. follows the decelerating motor, as shown in this brush recording. Therefore, when utility voltage is restored, the motor and power frequencies are "out of synch". The result is extremely high mechanical torques attempting to put the motor and compressor back into synchronization.

Distribution System Fault Protector

(Figure 10) These high torques are potentially damaging to motor windings, shafts, bearings and, as shown, compressor keyways and impellers can also be severely damaged. Therefore, high torque conditions must be avoided at all cost.

The CenTraVac distribution system fault protector can detect short duration interruptions and take the motor off the line within six electrical cycles (1/10 second). It accomplishes this by sensing motor current decline (instead of voltage loss). When motor current decreases to a value less than 20 percent RLA and the starter (K1) contacts remain closed, this module sends a signal to the starter to disengage immediately.

A power interruption of 2 cycles duration (1/30 second) initiates a starter trip with the starter becoming fully disengaged at approximately 6 cycles (1/10 second).

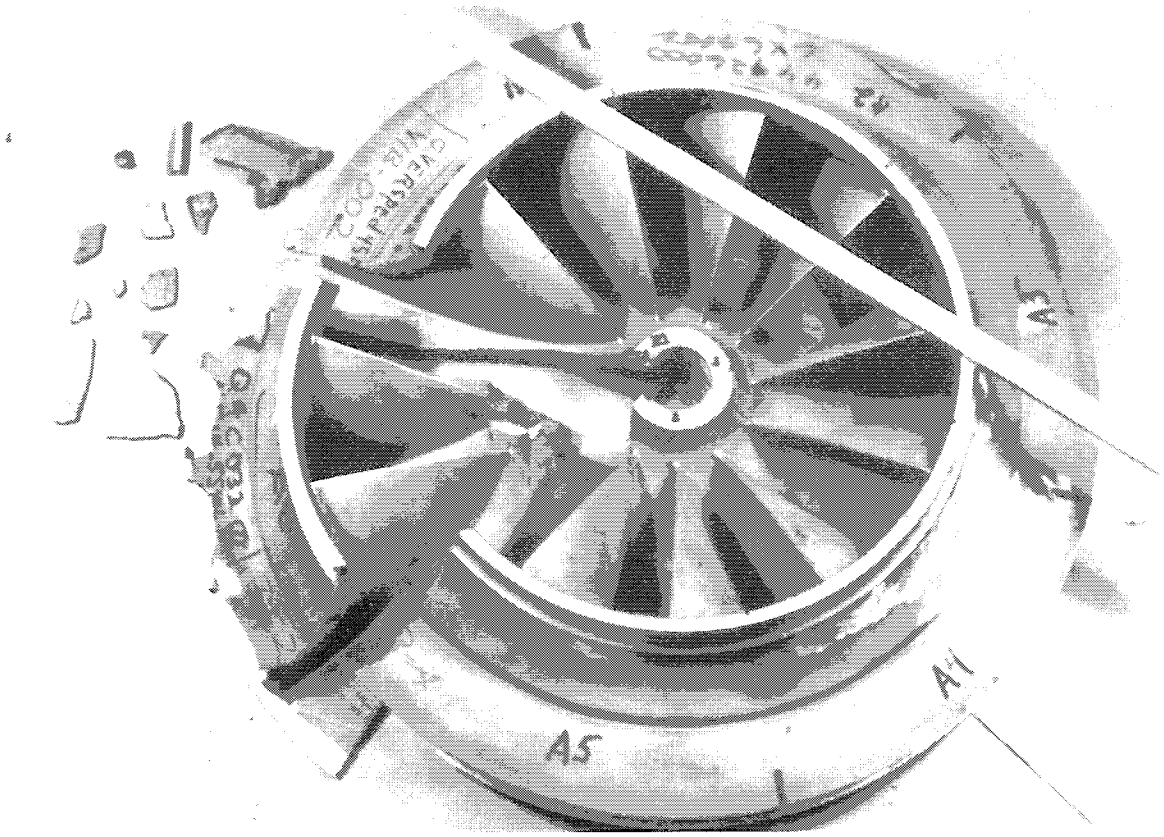

Figure 10

Water Piping And Control

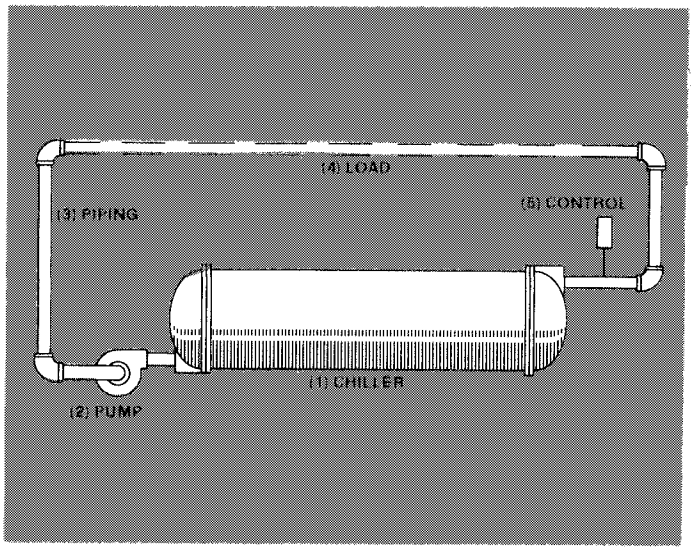

Figure 11

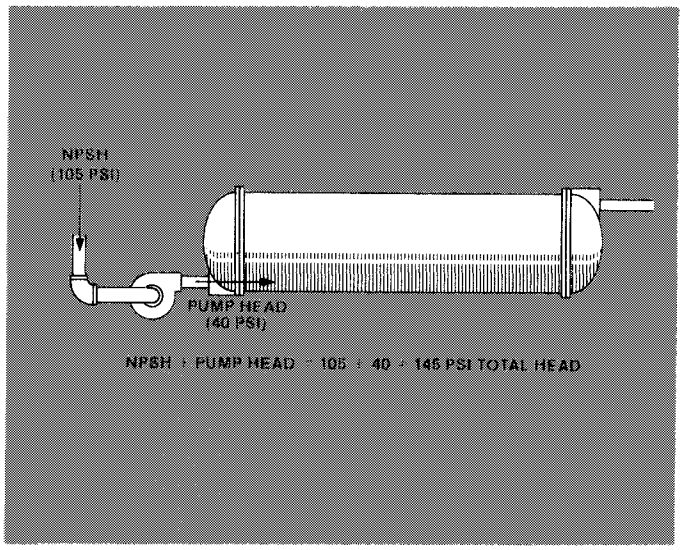

Figure 12

(Figure 11) The basic closed loop chilled water system consists of five elements:

1. Chiller
2. Pump
3. Piping
4. Load
5. Control

Pump location...Should the chilled water pump "pull" or "push" through the chiller? The answer lies in the system's ability to deliver an adequate net positive suction head (NPSH) to the pump. Therefore, in general, pumps are placed upstream of chillers. Exceptions to this generalization occur when the NPSH of a system is very high. This causes the dynamic pressure in the chiller itself to be even higher. And, it may force chiller construction into a higher cost pressure range.

(Figure 12) For example, a system may develop a pump NPSH of 105 psi (243 ft. of water). The pump might be sized to produce 40 psi (92 ft.). The total is 5 psi below the chiller rating of 150 psi. However, the "zero flow" pressure capability of the pump can be well over 45 psi, pushing the pressure at the chiller beyond its rating. In this circumstance, the pump would be better placed downstream from the chiller.

Chilled water flow range...(Figure 13) By changing evaporator pass arrangements, a wide range of chilled water flow rates can be accommodated. Catalog DS-CTV1 shows the various pass arrangements that are available. Two generalizations can be made:

1. Higher flow rates require lower numbers of evaporator passes.

2. CenTraVac capacity increases with higher numbers of evaporator passes.

Therefore, it can be said that high system temperature rise (low flow rate) generally promotes increased chiller efficiency and capacity when the number of passes is optimized.

Flow variations...Once a system flow rate is established, it is usually not changed. While variable flow is sometimes a desirable concept from an energy standpoint, it presents several operating difficulties. First, flow variations can fall

Evaporator Flow Limits and Connection Sizes

Figure 13

outside the allowable tube flow ranges (DS-CTV1). Second, flow variations appear to the control system as a change in "system size". Consequently, the control system must be able to cope with "system size" changes without manual attention. Few existing chiller control systems have this capability. Application of chillers to variable flow systems should be done only with great care.

Control...The Model CVHE CenTraVac chilled water temperature control system is based on the concept of providing a constant supply water temperature. However, the system embodies sufficient flexibility to allow a variety of control strategies.

The basic system is described on page 5. It is a proportional control system in the sense that the inlet vane actuator movement rate is changed depending on the amount of temperature offset (error). The system also employs floating point control. Corrective action is taken whenever the actual temperature varies from the setpoint. Consequently, the CenTraVac control system is a hybrid system that employs the best features of proportional and floating point control. Additional features are optionally available.

Remote reset of chilled water temperature...The addition of a separate remote manual resetting control accomplishes remotely the same thing that can be done at the panel by adjusting the chilled water temperature setpoint control.

Automatic reset of chilled water temperature...Some control strategies call for higher supply chilled water temperature at reduced system load. Generally, reduced system load is evidenced by a decreasing return water temperature. A separate sensor is placed in the return water stream and its output is plugged into terminals TS1 and TS3 of the control panel. The "command module" uses this input to automatically reset the setpoint. The reset "authority" can be adjusted between zero and 2.0 degrees per degree.

Remote demand limiting...Energy management systems are used commonly to shed electrical loads during times of high demand. CenTraVac systems should never by cycled in response to energy managers. Duty cycling is not useful in controlling large motors such as those used in large centrifugal chillers. Instead, it is possible to shed electrical load by injecting a DC voltage in series with the signal between the electronic overload and the command module.

Application of alternative controls...The basic CVHE CenTraVac control system and hardware are fixed. Alternative devices to perform similar functions cannot be used to replace individual components in the CenTraVac control system.

Modifications to the temperature control system can only be made outside the physical property boundaries of the CenTraVac.

Condenser water...Several suitable condenser water supplies are potentially available. The most common heat sink is an open circuit cooling tower. Heat is rejected to the atmosphere by evaporating a portion of the circulating condenser water. About 1000 Btu's are rejected for each pound of water that is evaporated. Consequently, contaminants are concentrated as more and more water is evaporated.

Cooling towers require chemical treatment, maintenance and control. Temperature control is usually based on fan control, water bypass, or both. The basic concept of tower water control is to maintain a minimum temperature to the CenTraVac condenser. If the temperature is too high, the CenTraVac may not be able to meet the cooling load. Or, it may cause unnecessarily high power consumption. If the temperature is too low, the CenTraVac may not be able to maintain enough pressure differential between the evaporator and condenser to keep all lubrication and refrigerant flow systems functioning properly.

Other heat sinks may be used. "Once through" systems can use water from lakes, rivers or wells. Sea water can be used when it is separated from condenser water by a heat exchanger. Since the temperature of these "infinite heat sinks" cannot be controlled, the flow is controlled. The simplest way to execute condenser pressure control is to use a proportional pressure controller to regulate a simple V-port (linear action) condenser water valve. A typical arrangement is shown in Figure 14.

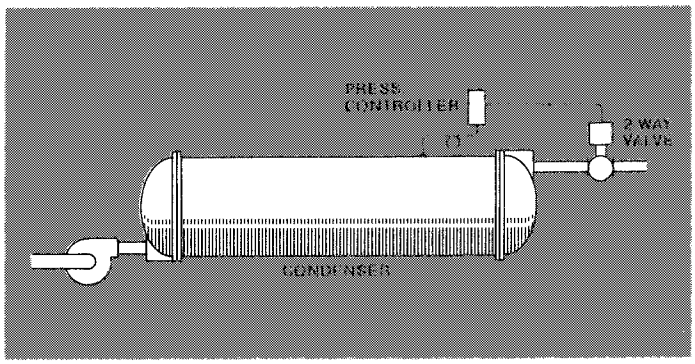

Figure 14

Electrical Interlocking

The Model CVHE CenTraVac requires a modest amount of system interlocking. Using the factory mounted starter option, interlocking is limited to six devices, per figure 4:

1. Chilled water flow switch (S5)

2. Condenser water flow switch (S7)

3. Condenser water pump pilot relay (K4)

4. Leaving chilled water temperature sensor (U3)

5. Chilled water pump interlocking contacts (K12).

6. Condenser water pump interlocking contacts (K13).

Separately mounted starters require additional control and power wiring. Figure 5 shows the specific terminals and wires that are needed to complete this interlocking.

Pneumatic Control

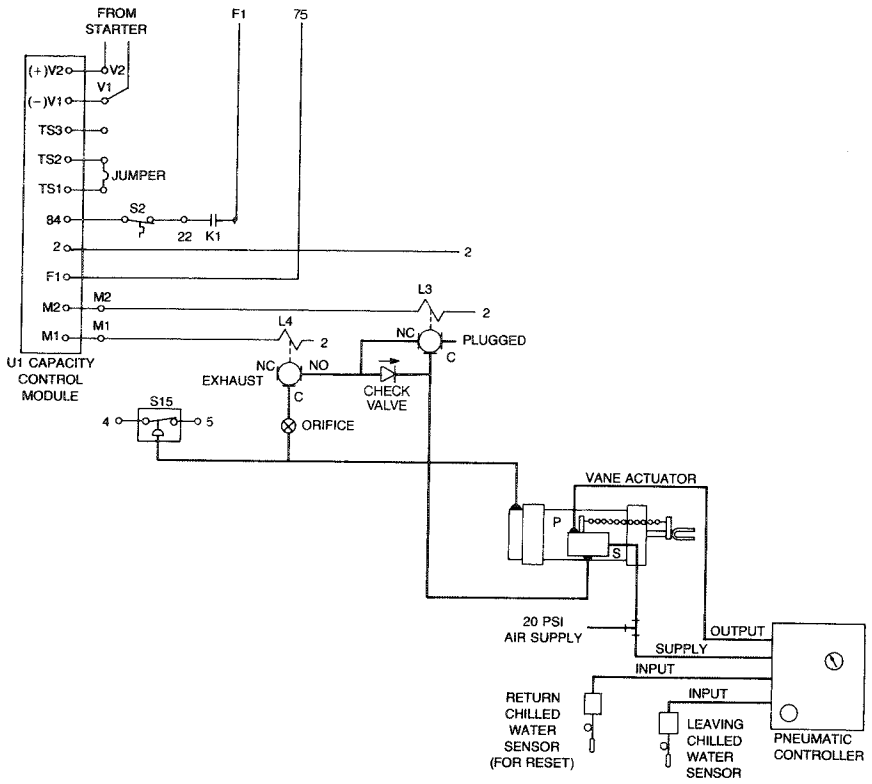

Figure 15

Clearly, the CVHE CenTraVac temperature control system is not pneumatic. However, for those designers that prefer to accomplish their control objectives pneumatically, an interface scheme is provided.

(Figure 15) In this scheme, an analog (proportional) signal from a conventional pneumatic temperature controller is fed into the pilot port (P) of the pilot positioner of a pneumatic inlet vane actuator. In addition, a jumper between terminals TS1 and TS2 of capacity control module U1 is substituted for the electronic leaving chilled water sensor U3, used in the previous scheme.

When the compressor motor starter assumes the "run" configuration, closing interlocking contacts K1, the continuous circuit between TS1 and TS2 causes the module to transmit a repeated, pulsed loading signal to solenoid valve L3. Unlike the previous scheme, the duration of this pulse is solely the function of motor current, in terms of its relationship to the "% Current" setting of the demand limiter. As before, the selected 10 to 310 second time lapse is observed between successive load pulses.

During the load pulse, the normally closed (NC) port of valve L3 is opened, permitting the output air pressure from the pilot positioner to be trans-

mitted through the normally open (NO) and common (C) ports to L4 to the vane actuator. Within the time interval of the load pulse, the pneumatic temperature controller has the authority to open the vanes or to hold the current vane position. However, its unloading authority is continuous. A reduction in chilled water temperature, resulting in a reduced output pressure from the pilot positioner, causes air to bleed back through the check valve. This equalizes the pressure within the vane actuator with that output by the pilot positioner, repositioning the vanes to balance the lesser load.

When the system is shutdown, opening K1, or a low refrigerant temperature condition opens S2, control module U1 transmits a continuous unloading signal. This signal closes the normally open (NO) and opens the normally closed (NC) ports of valve L4, exhausting control air pressure from the actuator, closing the vanes.

Load limiting is handled as it is in the previous scheme. As motor current rises, the duration of the loading pulse decreases. At 100 percent of the "% Current" setting of the demand limiter, the pulse duration drops from .25 second to zero. At 103 percent, a .25 second unloading pulse is initiated, followed by a 10 to 310 second null period, in an attempt to return the current to 100 percent of the demand limiter setting. Finally, at 105 percent, a continuous unloading pulse is established. It is terminated when the motor current is reduced to 95 percent of the setting.

While the loading function is curtailed during load limiting, the unloading function is not. As discussed, any load reduction is handled by the bleed-off of actuator pressure through the check valve. This enables the pneumatic temperature controller to retain uninterrupted unloading authority throughout the load limiting function.

Notice that control air is supplied to and exhausted from the vane actuator through an orifice. This orifice is factory adjusted to produce the same vane movement rate as that produced by the actuator used in the electric control system.

Finally, the pneumatic-electric switch (S15) replaces and performs the same function as the end switch (A3) of the electric inlet vane actuator, Figure 3, line 26.

The remaining circuitry of the pneumatic system is the same as that used by electric control.

Multiple Chiller Systems

Varying control strategies give rise to a great number of multiple chiller piping nd control concepts. Most CenTraVac installations involve more than one chiller. Therefore, it is important to describe a variety of common arrangements.

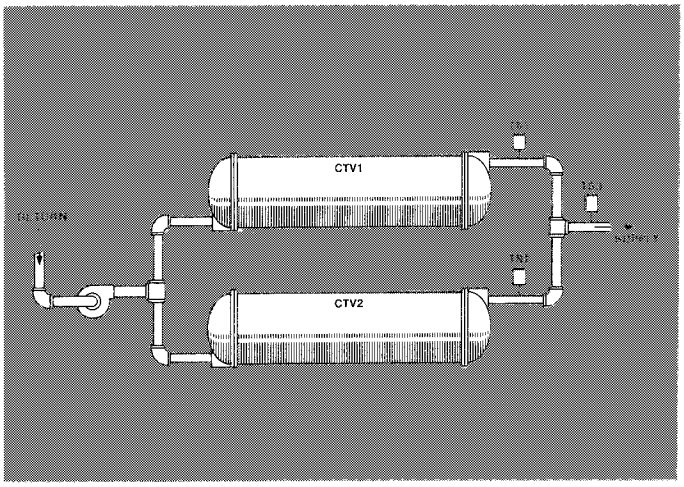

Figure 16

Two chillers, one pump...(Figure 16) A constant flow of chilled water is circulated through both chillers whether they are running or not. Obviously, this scheme allows water streams of possibly different temperatures to mix. The system return water temperature is common to both chillers. If one chiller is off, return water from CTV 1 mixes with supply water from CTV 2 to become the system supply temperature. This causes the common supply temperature to be higher than that of the water leaving the operating machine. It is an unavoidable consequence of this arrangement.

To obtain a controlled system supply temperature, the sensors of each chiller must be located in the common supply. The danger is that either operating chiller could "over chill" in an attempt to reach the correct common temperature. Each CVHE CenTraVac is equipped with a "low refrigerant" limit and cut out control. Used as a limiter, it will monitor refrigerant temperature and prevent it from becoming too low. This allows placement of the active water temperature sensor in the common supply line.

The next function to control is machine sequencing. The concept is to monitor CenTraVac motor current as it is processed into a 0 to 8.25 V. DC signal by A1. As the current exceeds a specific value for a duration of time, a second, or 'lag", chiller is allowed to start and accept load.

Sequencing is changed by simply reversing the position of a single pole double throw switch located in the sequence control panel.

The panel also contains two microprocessor based current monitors. One monitor module is dedicated to the "lead" chiller and the other to the "lag" chiller. In addition, several multi-pole relays are included in the panel.

The sequence of operation begins with a manual setting of the "lead-lag" switch. The lead chiller is now under the control of sensor TS3 located in the common chilled water supply. When the second chiller is directed to start, control of each CenTraVac is transferred to sensors TS1 and TS2 located in their respective supply water lines.

The reverse occurs when current in the "lag" chiller falls below the set current threshold, again, for an established duration of time. The "current and time to load" can each be set independently from the "current and time to unload". This provides a wide variety of loading strategies to be executed. Overlapping can be designed to obtain optimized performance from two machines. Lag chiller startup can be automatically delayed to accommodate a "real" need for two-machine operation.

In application, it is not necessary for the two CenTraVacs to be equally sized. Chillers are always operating on their own temperature controllers. Thus, the temperature control systems can be discretely set to operate as single chillers. The sequence control panel will not interfere with sensitivities or "ramp rates" originally dialed into the individual control panels. Separate flow switches are required for normal interlocking with each chiller.

Two chillers, two pumps...Figures 17 and 18 show two schemes. In the case of Figure 17, two pumps simply take the place of one. Thus, control is identical to the first arrangement.

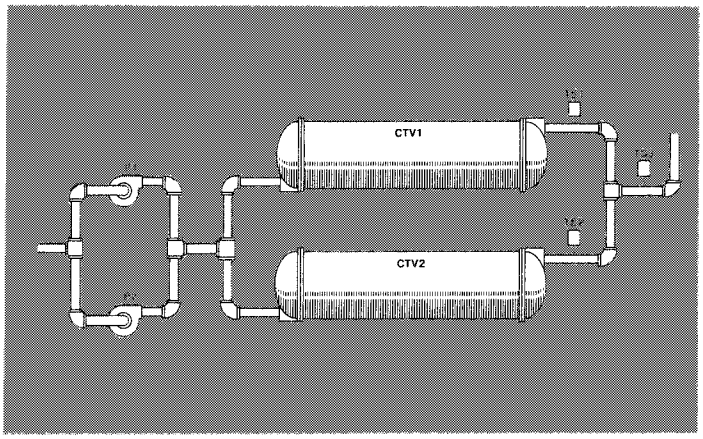

Figure 17

Multiple Chiller Systems

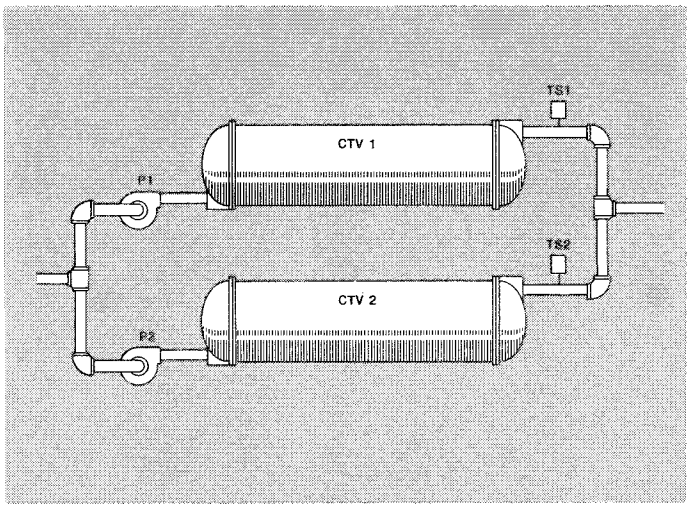

Figure 18

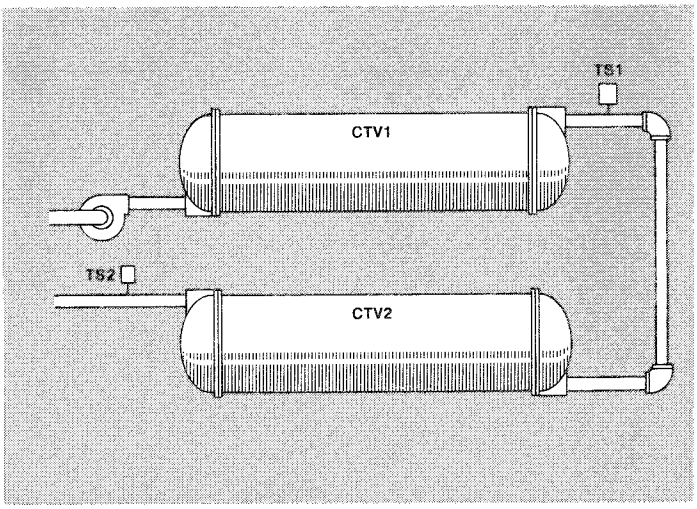

Figure 19

When pumps are to be sequenced in response to system demand, it can be accomplished as shown in Figure 18. In this case, a third temperature sensor is not needed because there is no mixing of dissimilar supply water temperatures.

Clearly, system flow changes as the number of pumps changes. This disruption in system dynamics introduces a measure of complication. Assume a condition of increasing load. As the "lead" chiller reaches its maximum capacity, the second pump is turned on. System water flow will nearly double even though the return water temperature will not fall immediately. The second CenTraVac will accept load as it responds to sensor TS2. Next, the return water temperature will fall rapidly as more system water is bypassed by the 3-way valves at the terminal coils. As long as the "drop out" current and time settings are below the reduced values that occur, the "lag" chiller will stay on the line. The required time setting can be expected to be longer than with the single pump system because of the time needed to restore system stability. However, the basic sequence control panel remains unchanged. The signal to start and stop the "lag" chiller also operates the "lag pump".

The two systems do not respond identically. In this case, the system is subjected to two different flow rates; one about 60 percent of the other. As long as all air conditioning terminals are satisfied with 60 percent flow (until the second chiller starts), loads will be met. But, if any loads cannot be met with low flow, they will simply suffer until the entire system loads the "lead" chiller to its "call" current. At that point, the "lag" pump and chiller are called to start. Again, this is a system characteristic and cannot be altered by control tactics or hardware.

Two chillers in series...(Figure 19) The sequence of control is identical to "two chillers, one pump", except that two sensors (TS1 and TS2) are used. Sensors are located just downstream from each chiller. Both chillers are set to control at the design supply temperature, so that either one can act as the "lead" machine. When both chillers are operating, they do not share the load equally. Instead, the upstream machine will take the greater load until both chillers are at full capacity.

Dual chiller control...The optional Sequence Panel (Figure 20) provides the type of control described previously for each of the dual CenTraVac arrangements (Figures 16 through 19).

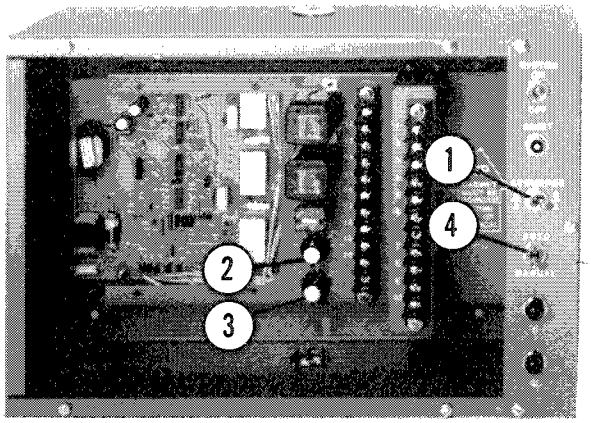

Figure 20

The "Sequence" switch (1) enables the operator to select the lead chiller. Once started, the panel monitors the current draw of the active machine. When the current equals, or exceeds, the adjustable "Load" threshold value (2) for a continuous 15 minutes, the lag chiller is started. The chillers then share the load.

When the current draw of both chillers equals, or falls below, the adjustable "Unload" threshold (3) for a continuous 15 minutes, the panel turns off the lag machine. The lead machine then loads, as necessary, to balance the remaining chilled water load requirement.

Placing the "Auto-Manual" switch (4) in the "Manual" position, bypasses the sequence panel. This arms both chillers, enabling them to respond to their individual control systems.

Multiple (3 or more) chiller control...Problems associated with temperature mixing, cross-connected pumps, flow variations and chiller redundancy create considerable design confusion for multiple chiller applications. The number of permutations and combinations of design schemes is well beyond the scope of this manual. In fact, most designers cannot afford the time to investigate all possible arrangements.

A simplifying technique has been applied successfully to a great number of multiple chiller systems. It involves separating the distribution pumping system from the production pumping system. Thus, the system hydraulics are "decoupled".

Figure 21 shows this basic arrangement. The variable flow distribution system can employ single or multiple pumps. Or, it can be a number of secondary pumping systems. The common element is a length of bypass piping that connects the return and supply headers.

Taken separately, the distribution and production pumping functions form complete hydraulic systems. Thus, events in one system do not affect pressures or flows in the other. The systems are hydraulically "decoupled".

From a control standpoint, the entire system is greatly simplified. Each pump-chiller combination operates as an individual and is independent from the remaining chillers. Capacity control is exactly as if each chiller were alone. Therefore, the conventional single chiller control system is perfectly suited for this arrangement.

Decisions on the number of chillers to operate are also simplified. Instead of using temperature as an indicator of system demand, flow is used. More accurately, relative flow is the indicator. If the distribution system demands greater flow than is being supplied by the number of chiller-pump combinations, return water is forced through the bypass into the supply header (left to right in the illustration). This will eventually cause the supply water temperature to rise and the system flow rate to increase further. This is a clear indication of the need for additional chiller capacity. Therefore, bypass flow in that direction is a signal to start another chiller-pump set. The additional flow will cause a reversal of the bypass line flow. Flow in this direction satisfies the needs of the distribution system.

Over capacity is also detected by bypass flow—but in the opposite direction (right to left in the illustration). When the flow in that direction exceeds the flow capacity of a chiller-pump, that pump (and its chiller) can be turned off without causing a flow reversal. Thus, bypass flow is used to indicate the need for more or fewer chiller-pump combinations.

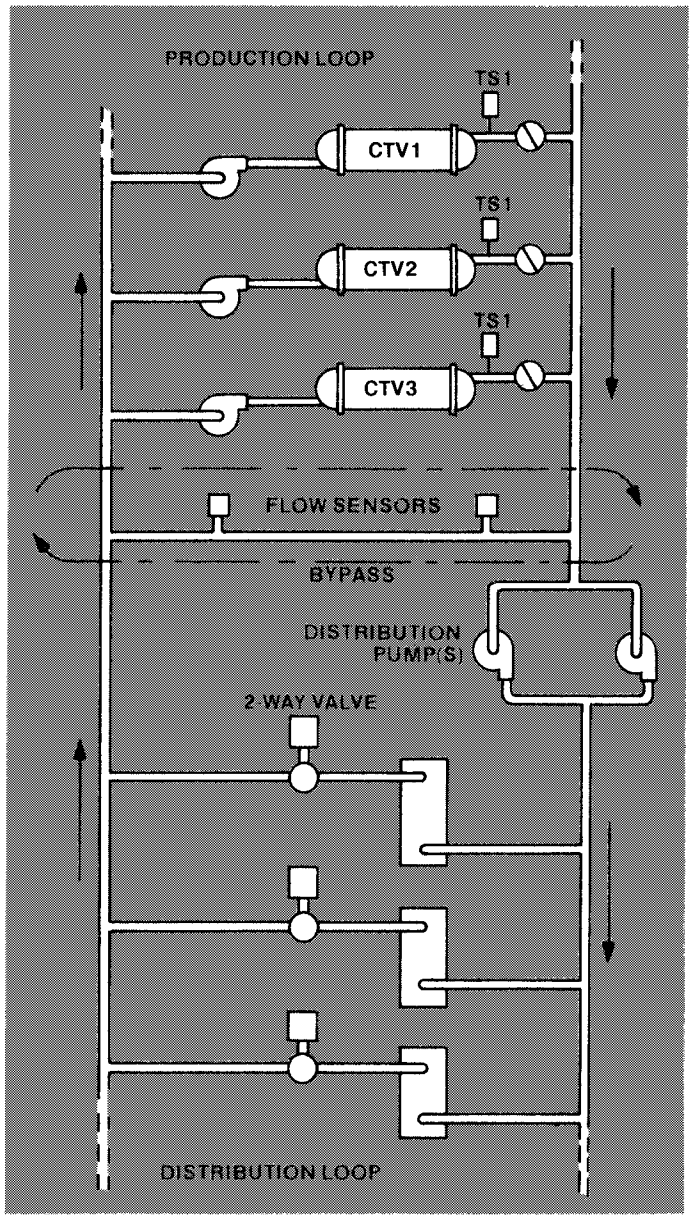

Figure 21

Integrating this concept with the Model CVHE CenTraVac control system is straightforward. The signal that requests additional flow accomplishes two things:

1. Starts an additional chilled water pump

2. Closes a pair of contacts bridging terminals F1 and 3 in the control panel of the associated CenTraVac. (Figure 3, line 16).

This initiating signal can be manual or automatic, depending on the control philosophy of the designer. Both arrangements use a simple impact type flow sensor signal. Figure 22 shows the manual scheme. Signals from electrical switches on the flow sensor (similar to "Annubar type 75") simply energize annunciator lights. The system operator can then start or stop chiller-pump combinations at his discretion.

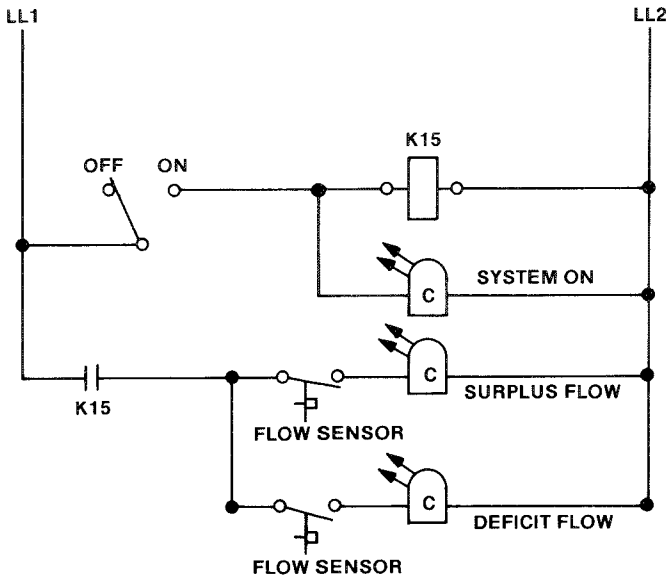

Figure 22

The automatic scheme shown in Figure 23 employs a Honeywell S684 step controller to actuate chiller-pump combinations. Signals from the flow sensors run the step controller in opposite directions to operate more or fewer chillers. Flow switches continue to be used as interlocks in each CenTraVac control panel (terminals 8 and 9).

Once this interlocking is completed, the CenTraVac capacity control system performs in the usual single chiller mode. An important benefit of this scheme is its energy optimization capabilities.

1. Chilled water is not produced unless it is required by the loads.

2. Chilled water is not allowed to circulate in the distribution system without experiencing a temperature rise.

3. Variable chilled water flow rate minimizes distribution system pumping power.

4. Chiller pumping is minimized (low pressure head; minimum chillers in operation).

5. Chillers run at their most efficient operating point.

Additionally, the decoupler system can be easily applied with thermal storage, heat recovery and on expansion projects. Chiller size, type and age are not critical. Thus, this system is extremely versatile and has wide application.

Applications Engineering Manual

Model CVHE CenTraVacs With Microprocessor Based Control

CON-AM-20 (389)

©American Standard Inc. 1987

Model CVHE CenTraVacs With Microprocessor Based Control

The Trane Company, La Crosse, Wisconsin 54601

Purpose

This manual has three purposes:

- To provide a hardware description of the standard single-unit control system and components,
- To provide an explanation of the control system's operation and function,
- To provide information regarding the application of the standard control system to various CenTraVac configurations.

Note: The descriptions in this manual apply specifically to design sequence K CenTraVacs (the tenth digit in the CenTraVac model number is "K"). Other models may vary in detail.

Hardware

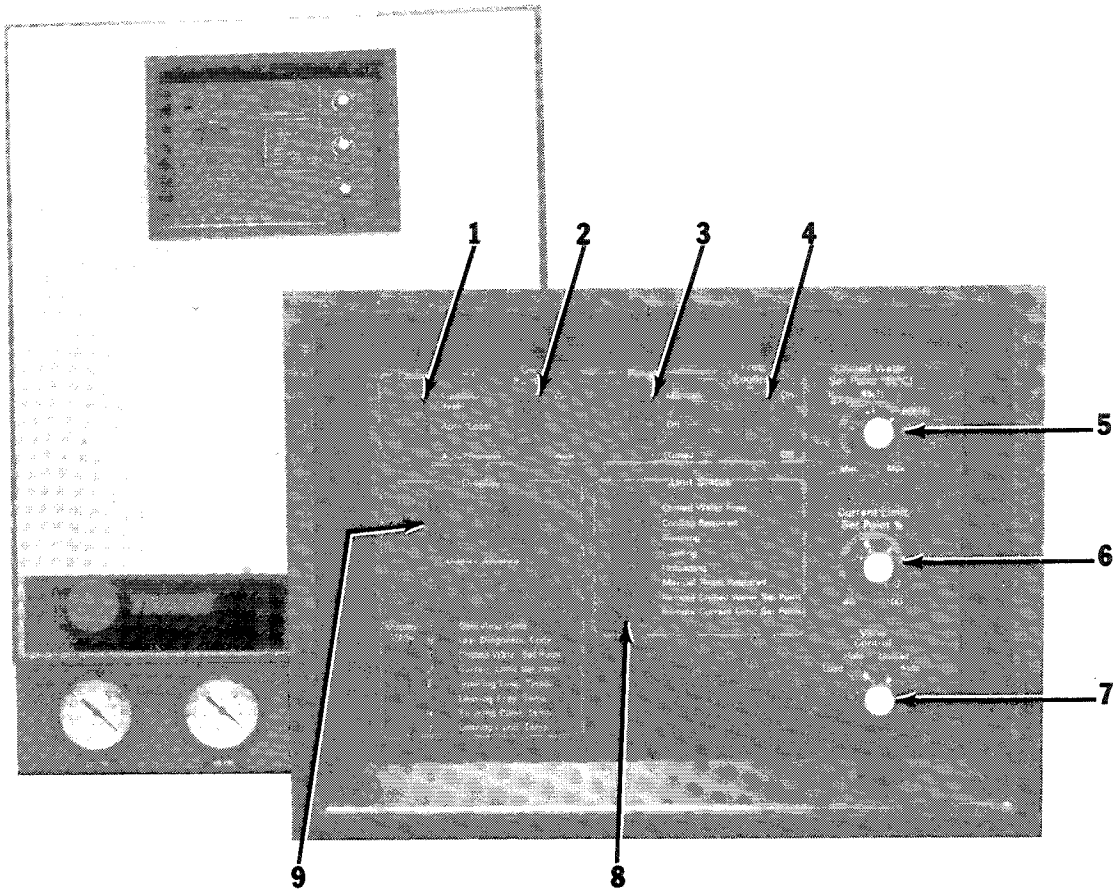

Figure 1

Figure 1 shows the CenTraVac, microprocessor-based, unit control panel (UCP 695), highlighting the man-machine communication adjustments and displays. The communication capabilities are divided into "inputs" and "outputs".

(Note: It may be helpful to refer to the complete electrical line diagram, Figure 5, page 10, when specific component references are made.)

Inputs

1. Chiller Switch. . . This 3-position switch determines CenTraVac operating mode:

Standby/Reset. With power applied and the switch in this position, the control system is armed, but unit operation is prevented. The operating code "A 0" appears on the display. This position is used by the operator to clear a latching diagnostic (a fault requiring manual reset).

Auto/Local. In this position, the CenTraVac is allowed to run automatically in response to the panel control settings.

Auto/Remote. In this position, the CenTraVac runs automatically in response to setpoints established at a remote device and communicated to the panel via the optional "Serial Communications Interface" (SCI). If no SCI link exists, or there are no remote setpoints established, control reverts to the local settings.

2. Oil Pump Switch. . . This 2-position switch determines the operating mode for the lubricating oil pump motor.

On. In this position, the oil pump motor runs continuously. The CenTraVac cannot start when this switch is on. This switch position should only be used by a competent service engineer since a latching diagnostic will occur, requiring manual reset.

Auto. This is the normal position. Operation of the lubrication system is supervised by the Unit Control Module (UCM).

3. Purge Switch. . . Any of three operating modes can be selected:

Manual. The purge unit will run continuously in this position. Refer to "Operation-Maintenance CVHE-M-3" to properly operate the purge system in this mode.

Off. When this switch is in this position, the purge system will not operate UNLESS it is already running in the "timed" mode. WARNING: The purge unit can operate, under certain conditions, with the switch in the "off" position.

Timed. This is the normal position. The purge unit operates in response to a timer and a purge pressure switch. The purge compressor will be run five minutes out of every two hour period of chilled water system demand. Operation is extended automatically by four minutes whenever the pressure switch indicates noncondensibles remain in the CenTraVac. The run time is again extended so long as the pressure switch remains unsatistfied.

4. Free-Cooling (Optional)...Operation of the "Free-Cooling Option" requires this switch to be turned "on" manually. A set of free-cooling valves are opened and the compressor is prevented from running. When this switch is turned "off", the compressor will not be allowed to restart until the free-cooling valves have repositioned closed.

When the CenTraVac is equipped with the (remote) SCI option, free-cooling can be turned on or off remotely, regardless of the position of this (local) free-cooling switch.

5. Chilled Water Setpoint....This manually adjustable potentiometer is used to establish the setpoint for the leaving chilled water (supply) temperature. Remember, this is the SETPOINT (an input value), and not the actual supply chilled water temperature.

6. Current Limit Setpoint....This manually adjustable potentiometer is used to establish the load limiting (current) setpoint. Continuously variable dial settings between 40 and 100 percent of motor "rated load amps" (RLA) are available. This, also, is an input value and does not reflect the actual motor current.

7. Vane Control Switch....This 4-position switch determines what signals are sent to the compressor inlet vane operator.

Load. As long as the vane control switch remains in this position, the "vanes open" relay (1U1Q7) is continuously energized. Normal automatic vane control is suspended. However, three limiting actions take precedence over manual loading...1) motor current limit, 2) condenser pressure limit, and 3) evaporator temperature limit. Approach to any of these three limits supercedes manual loading.

Hold. With the vane switch in this position, both the "vanes open" relay (1U1Q7) and the "vanes close" relay (1U1Q8) are de-energized. Inlet vanes will remain in their present position, unless one of the three limits (motor current, condenser pressure, or evaporator temperature) is approached. The "hold" position also redefines the menu of codes appearing in the "condition display window". A further explanation of this is found under "Display", page 4.

Unload. This switch position energizes the "vanes close" relay (1U1Q8). Automatic inlet vane control is suspended.

Auto. This is the switch's normal position. Inlet vanes are controlled automatically by the controller microprocessor, or "unit control module" (UCM). Details of this controller's action are found under "Capacity Control", page 14.

Outputs...Status Lights (Figure 1)
A series of eight status indicator lights (8) are located directly below the purge switch. These blue lights provide the operator with specific CenTraVac system information. The first four lights are sequential. That is, they will only light in sequence. The remaining four can light out of sequence.

- Chilled Water Flow...Illumination of this light occurs when the chilled water flow switch (5S2) is closed, indicating water flow in this circuit.
- Cooling Required...This light illuminates only when chilled water flow is established and the controller (UCM) detects a demand for cooling. A requirement for cooling is found when the leaving chilled water temperature exceeds the chilled water setpoint by a value greater than the "differential-to-start" criteria (a variable input to the UCM, as described on page 9).
- Running...This light will illuminate when the chiller is running in either of the two "Auto" (chiller switch) modes, and the starting sequence is complete. It will also remain lit when the unit is in its post-lube cycle, even though the compressor has been shut down.
- Loading...This light glows when the inlet vane operator is opening the vanes. It is normal for signals to the inlet vane operator to occur in short pulses.
- Unloading...Likewise, this light glows when the inlet vanes are being moved toward the closed position.
- Manual Reset Required...This light indicates that a latching diagnostic has occurred and the chiller is shut down. Unit operation cannot resume until the chiller switch is manually placed in "Standby/Reset" and returned to one of the "Auto" positions.
- Remote Chilled Water Setpoint...This light indicates that a remote device (through the SCI) has established the setpoint. The local setpoint is ignored unless the SCI link is broken. It will also light when either of the chilled water reset options is active.

Hardware

- Remote Current Limit Setpoint. . . Similar to the action of "Remote Chilled Water Setpoint", above, this light indicates that a remote device has established the current limit setpoint.

Outputs. . . Display (Figure 1)
A blue, 4-digit, vacuum fluorescent display and a "Display Advance" push-button (9) provide access to four specific types of operator's information:

1) Operating Mode, 2) Diagnostic Code,
3) Setpoints, 4) Measured Temperatures

The "Display Advance" push-button simply scrolls through each entry of the operator's display menu sequentially as the button is pressed. A blank display signifies the end of the menu. To go to the top of the menu, press the push-button once.

Operating Mode. . . The first of the three digits is a code prefix, telling which of the eight operating mode menu items is indicated. Table 1 shows the eight code prefixes and their meanings.

Table 1

Code Prefix	Description
A	Operating Mode
b	Last Diagnostic
C	Chilled Water Setpoint
d	Current Limit Setpoint
E	Entering Chilled Water Temp
F	Leaving Chilled Water Temp
H	Entering Condenser Water Temp
J	Leaving Condenser Water Temp

The last two digits of the display indicate which specific operating mode, diagnostic, setpoint or temperature exists, as defined by the prefix. Table 2 shows the menu of operating modes (Prefix "A").

Table 2

Last 2 Digits	Description of Operating Mode
Blank	Power Off
0	Standby/Reset
1	Auto (Local Or Remote)
9	Free Cooling
70	Restart Inhibit
71	Establish Cond Water Flow
72	Start
74	Run: Normal
[1]75	Run: Current Limit
[2]76	Run: Condenser Limit
[3]77	Run: Evaporator Limit
[4]78	Run: Surge Condition
79	Posts-Lube
88	Reset

For example:

[1]As the current limit setpoint is approached, the UCM restricts further inlet guide vane opening.

[2](Optional) As the condenser pressure limit setpoint is reached, the UCM restricts additional compressor loading to avoid high condenser pressure shut down. In this operating mode, a "head relief request" (optional relay) is initiated.

[3]Further opening of the inlet vanes is restricted to avoid a unit shutdown on low evaporator refrigerant temperature.

[4](Optional) Compressor loading is suspended and a "head relief request" (optional relay) is initiated. An automatic CenTraVac shutdown will occur if the unit remains in surge for a 15 minute period.

Diagnostic Codes. . . The "Last Diagnostic" codes (Prefix b) are listed in the Appendix. Diagnostics occur only when an abnormal CenTraVac shutdown occurs. If the UCM detects a diagnostic condition, the display alternately flashes between the diagnostic code and the operating code. The "Last Diagnostic" code is erased when the "chiller switch" is placed in the "Standby/Reset" position and then in one of the "Auto" modes. Advancing past the "Last Diagnostic Code" entry in the menu automatically clears the code registered there from memory.

Codes prefixed by a "C" or "d" are followed by the corresponding setpoint value, local or remote, as applicable.

"E", "F", "H" and "J" code prefixes are followed by an actual measurement of the specific system parameter. If the particular sensor is not installed and connected to the control panel, the display will show "----".

Note: The display is redefined to a "Serviceman's Menu" by placing the vane control switch in the "hold" position. Refer to "Operation-Maintenance CVHE-M-3" for instructions on the use of this menu.

Outputs. . . Gages And Meters (Figure 2)

1. Low Oil Pressure. . . This gage monitors the oil pressure inside the oil tank reservoir. Since this reservoir is vented to compressor suction, the Low Oil Pressure should be very close to evaporator pressure.

2. High Oil Pressure. . . This gage measures the pressure in the oil supply line to the compressor bearings. The differential between this pressure and the "Low Oil Pressure" is the net oil pressure.

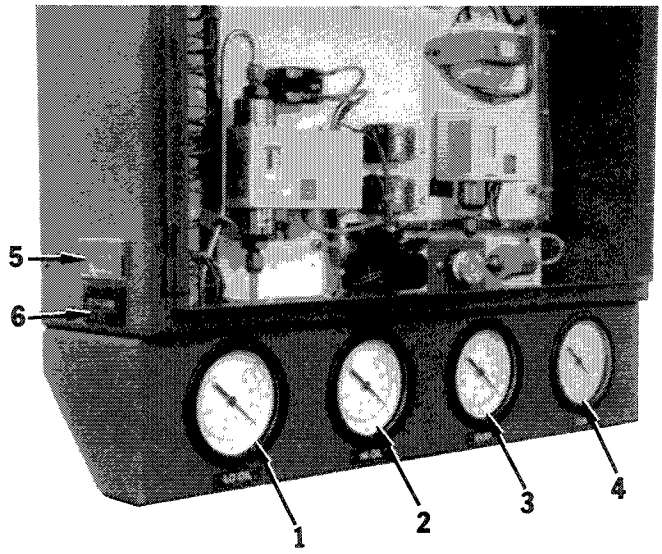

Figure 2

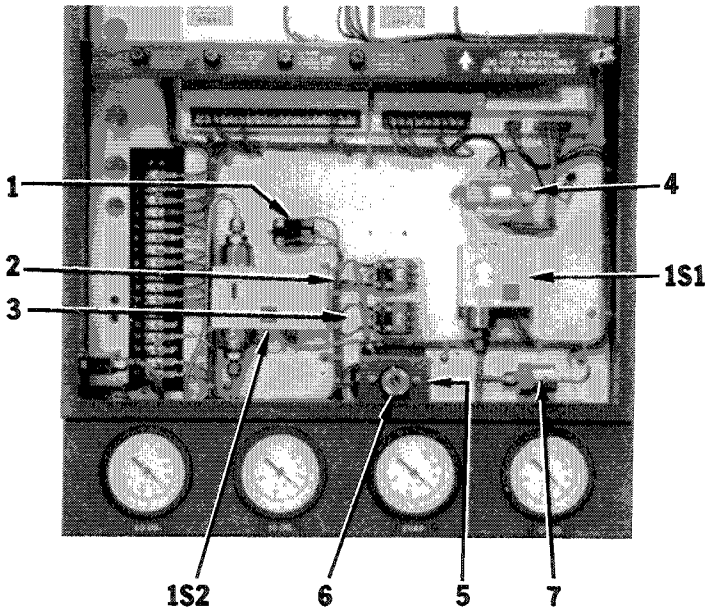

Figure 3

3. Evaporator Pressure . . . This gage indicates the refrigerant pressure in the evaporator.

4. Condenser Pressure . . . This gage indicates the refrigerant pressure in the condenser.

5. Hour Meter . . . This meter indicates the accumulated hours of chiller operation. It will record a maximum of 99,999.9 hours, at which point it restarts at zero hours. It is not resettable.

6. Start Meter . . . This meter displays the accumulated number of compressor starts that have been attempted. It will record 99,999 starts before restarting at zero. It, too, is not resettable.

This completes a description of the operator-machine interface portion of the CenTraVac control panel. Normal chiller operation does not require the panel door to be opened. However, there are a number of important control elements inside the panel.

CVHE safety and operating controls are partitioned into 2 major sections: the Unit Control Module (UCM) and the "non-UCM" devices described below.

Non-UCM Devices (Figure 3)

Condenser High Pressure Switch (1S1). . . . This safety control opens when it detects a condenser refrigerant pressure that exceeds its setting. A chiller shutdown caused by this control produces a latching diagnostic (code "b F5") requiring manual reset. The cutout pressure setting of this control is not automatically coordinated with the setting of the optional "Condenser Limit Control", page 15.

Differential (oil) Pressure Switch (1S2) . . . This operating control senses the "high" and "low" oil pressures. See table 3 for control values.

Output Relays . . .

1. 1K8. Oil pump starter.

2. 1K16. Chilled water pump relay.

3. 1K17. Condenser water pump relay.

K15. (Optional) Hot gas bypass relay.

Other Electrical Components . . .

4. Control Power Transformer (1T1).

5. Oil Pump Capacitor (1C1).

6. Oil Pump Fuse (1F1).

7. (Optional) Condenser pressure transducer.

Table 3

Safety Control Unit Cutouts		Control Trip Point	Diagnostic Code
Motor Winding Temperature Run Inhibit		265 ± 15 F	b E7
High Oil Temperature Run Inhibit		180 ± 2 F	b F4
High Bearing Temperature Run Inhibit (Optional)		180 ± 2 F	b EA b Eb
Differential Oil Pressure Switch	Opens Closes	9 psig diff. 11.5 to 15 psig diff.*	b E8 or b F2
High Condenser Pressure Cutout Switch	Std. units ASME units	15 ± 1 psig 25 ± 1 psig	bF5
Low Water Temperature Cutout, Lvg. Chilled Water		35 ± 1 F	None . . . auto reset

*Switch has non-adjustable 2.5 to 6 psi differential range.

Hardware

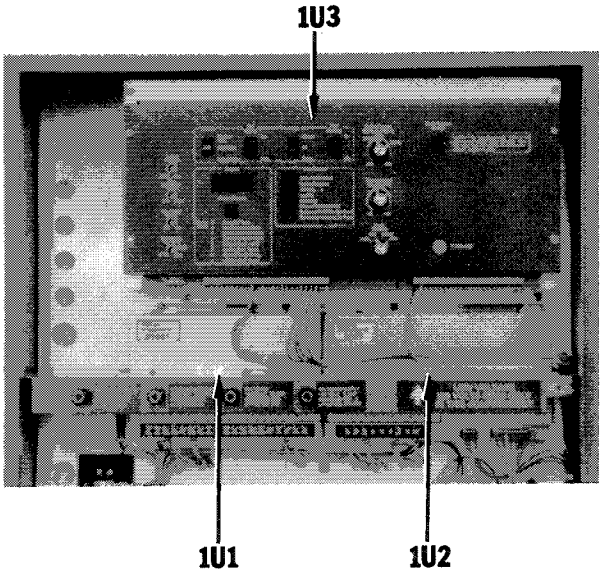

Figure 4

UCM (Figure 4)
The Unit Control Module is actually a series of microprocessor based sub-assemblies that handle most of the safety and control functions. Sub-assembly sections are:

Relay/Output Module (1U1)...This module contains the relays that interface panel microelectronics with specific electrical devices outside the panel. Its terminal strip identification is (1TB1).

- Compressor Inlet Vane Operator (4B2): Open (1U1Q7), Close (1U1Q8).
- Condenser Water Pump Relay (1U1K6).
- Purge Unit Relay (1U1K9).
- (Optional) Head Relief Request Relay (1U1K3).
- (Optional) Alarm Relay (1U1K4).
- (Optional) Free Cooling and Auxiliary Free Cooling Relays (1U1K1 and 1U1K2).

Power Supply/Output Module (1U2)...This module contains the power supply for microelectronic circuits and relays. Further, it provides relay contact closures to interface with specific devices outside the panel. Its terminal strip identification is (1TB2).

- Reset Relay (1U2K1).
- Stop Relay (1U2K2).
- Overload Relay (1U2K3).
- Compressor Start Relay (1U2K4).
- Starter Transition Relay (1U2K5).
- Oil Heater Relay (1U2K6).
- Oil Pump Relay (1U2K7).

Micro Module (1U3)...This module houses the microprocessor that contains all control algorithms for the CenTraVac control system. It accepts a variety of sensor inputs through terminal strips (1TB3, 1TB4 and 1TB6).

- Leaving Chilled Water Temperature (4RT1).
- (Optional) Entering Chilled Water Temperature (4RT2).
- (Optional) Entering Condenser Water Temperature (4RT3).
- (Optional) Leaving Condenser Water Temperature (4RT4).
- Evaporator Refrigerant Temperature (4RT5).
- (Optional) Ambient (air) Temperature (4RT6).
- Chilled Water Flow (1K16).
- Condenser Water Flow (1K17).
- Inlet Vanes Closed (4B2).
- Differential Oil Pressure Switch (1S2).
- (Optional) Running External Interlock (5S4).
- Transition Complete (2K2).
- Oil Temperature (4RT7).
- Motor Winding Temperature (4B1R2, 4B1R3 and 4B1R4).
- (Optional) Bearing Temperature #1 (4RT8).
- (Optional) Bearing Temperature #2 (4RT9).
- Motor Current (from current transformer 2T5).
- Motor Current (from current transformer 2T6).
- Motor Current (from current transformer 2T7).

Chilled Water Reset Interface Module (1U4)...This optional module is mounted in the control panel when the Chilled Water Reset Interface option is installed. It accepts one input (4 to 20 ma or 0 to 10 vdc reset signal) and is connected to the 1U3 module. Its terminal strip designation is TS1.

Based on these inputs, this module performs four basic functions:

1. It controls the leaving chilled water temperature in response to the setpoint by repositioning the compressor inlet guide vanes.

4. It executes start and stop sequences.

In addition, this module can (optionally) perform either of two mutually exclusive control options:

- System Controller Interface (SCI)... This option provides a proprietary interface with a higher level control authority "Trane System Control Panel". This system is described more fully, beginning on page 23.
- Chilled Water Reset (CWR)... This option enables the UCM to reset the chilled water temperature setpoint based on load (entering chilled water temperature) or ambient air temperature.

System Operation

The control logic that governs the CenTraVac chiller system takes the form of algorithms that reside in UCM memory. Two references embellish the written explanations. They are Figures 6 (a time-line of sequential events) and 5 (a line wiring diagram).

Power Supply. . . With the power supply disconnect switch or circuit breaker (2CB1) closed, 120 volt power is provided through control power transformer (2T4) and a 30-amp starter panel fuse (2F4) to terminal 1TB5-1. From this point, control voltage is available through:

Fuse (1F2), supplying power to the micro module (1U3), starter control, oil heater, and secondary transformer 1T1 circuits.

Fuse (1F3), supplying power to the oil pump and inlet vane operator circuits.

Fuse (1F4), supplying power to the purge control system.

The 1F2 branch circuit directs power to five separate subcircuits:

1. The micro module (1U3). The relay output module (1U2) and the power supply module (1U1) all receive power through another fuse (1F5) and the power supply transformer (1T1).

2. The oil sump heater (4HR1) is energized through the normally- open K6 contacts of the power supply output module (1U2). Temperature sensor (4RT7), located in the oil sump, controls K6 to keep the oil temperature between 140F and 145F.

3. Chilled water flow switch (5S2) circuit. . . Closure of this switch and the chilled water pump electrical interlock (5K1) energizes relay 1K16, giving the micro module an indication that chilled water flow does exist.

4. Condenser water flow interlock (5S3) circuit. . . Closure of this switch and the condenser water pump electrical interlock (5K2) energizes relay 1K17, giving the micro module an indication that condenser water flow does exist.

5. Starter Control circuit. . . The state of relay contacts K1 (reset), K2 (stop) and K3 (overload) are determined by logic executed in the micro (1U3). When they appear "closed", control voltage passes to the compressor "start" relay (K4). If all preconditions for start-up are met, the micro sends a signal to the power supply output module (1U2) to close the K4 contacts. A "start" signal is passed along to the compressor motor starter relay (2K5). Simultaneously, control voltage flows to the start counter (1M2) and the hour meter (1M1).

Starting Sequence. . . The following paragraphs describe the starting sequence for a conventional wye-delta, closed transition type starter, commonly used on CenTraVac compressor motors.

Relay 2K5 has two sets of N.O. contacts. The first set (Line 18) closes to lock the starter relay into the control circuit around the K4 contacts. The second (Line 19) enables control voltage to flow through the N.C. contacts of 2K2 (starter start, 1M) and 2K4 (starter transition, 1A) to the coil of starter contactor 2K3 (starter star, S).

When star contactor (2K3) energizes, its N.O. auxiliary contacts (Line 21) close, allowing control voltage to pass to the coil of starter contactor 2K1 (starter start, 1M). Auxiliary contacts lock 2K1 in, around the auxiliary 2K3 contacts. Power is now supplied to the compressor motor (4B1) in the Wye, or Star, configuration through the 2K3 and 2K1 contactors.

As the compressor accelerates, compressor motor current decreases. When motor current falls to 85% of the motor RLA setting, the micro sends a signal to (1U2) to close the N.O. contacts of transition relay K5. This energizes the coil of transition contactor (2K4) and causes its N.C. set of auxiliary contacts (Line 19) to open.

With the star contactor (2K3) now open, 2K3 drops out and its N.C. auxiliary contacts (Line 22) reclose, allowing control power to reach the coil of starter contactor (2K2) (starter run, 2M). Contactor 2K2 is locked in by a set of auxiliary contacts (Line 23) around auxiliary contacts on 2K3 and 2K1 (Lines 21 and 22). Further, an auxiliary set of N.C. 2K2 contacts open (Line 19) to interrupt control voltage to the transition contactor 2K4.

Within the starter itself, contactors "S" and "2M" are physically prevented from closing simultaneously. This is in addition to the foregoing electrical interlocks.

The compressor is now operating in the normal "run" mode. It will continue to operate this way until the "net state" of the K1, K2 and K3 contacts in (1U2) "open". At this point, voltage to the starter relay (2K5) disappears and starter relays are de-energized.

Stopping The Compressor. . . Any of the following conditions will cause the "net state" of the K1, K2 and K3 string of contacts in module 1U2 to be open, stopping the compressor:

1. Chiller switch is placed in "Standby/Reset",

2. A latching or non-latching diagnostic is detected by the UCM, or

3. Chilled water load (by virtue of a decrease in return water temperature) is insufficient to keep the chiller operating. The setpoint for this control is determined by adjusting the "differential to start" (a serviceman's control setting on the control panel). Table 4 shows recommended "differential to start" settings.

Table 4 — Recommended Differential to Start Settings

Chiller Delta T Degrees F	Setting Deg. F	Degrees Below Setpoint Where Chiller Shutdown Occurs (Exit CHW Temp)
4 or less	2.0	2.0
5 or 6	3.0	2.0
7 or 8	4.0	2.0
9 or 10	5.0	2.0
11 or 12	6.0	2.0
13 or 14	7.0	2.0
15 or 16	8.0	2.4
17 or 18	9.0	3.2
19 or more	10.0	4.0

As an example, consider a chilled water system designed for a full load delta-T of 12 F and a supply water temperature of 44F. By setting the temperature controller at 44F and the "differential to start" at 6F, the chiller will start when the supply and return temperatures rise to 50F. While this may seem to represent a 50% chiller load, it probably does not. The 50F return temperature occurs only because the chiller is not running. As soon as the supply temperature is decreased to 44F, the return will also decrease. The chiller will continue to run, controlling the supply water to 44F, until its minimum capacity exceeds the real system load. At this point, both the supply and return temperatures will steadily fall, until the return temperature drops 2.0F below the setpoint of 44F. At 42F the chiller will automatically stop and remain stopped until the system water again warms to 50F.

Fuse 1F3 Branch Circuit.

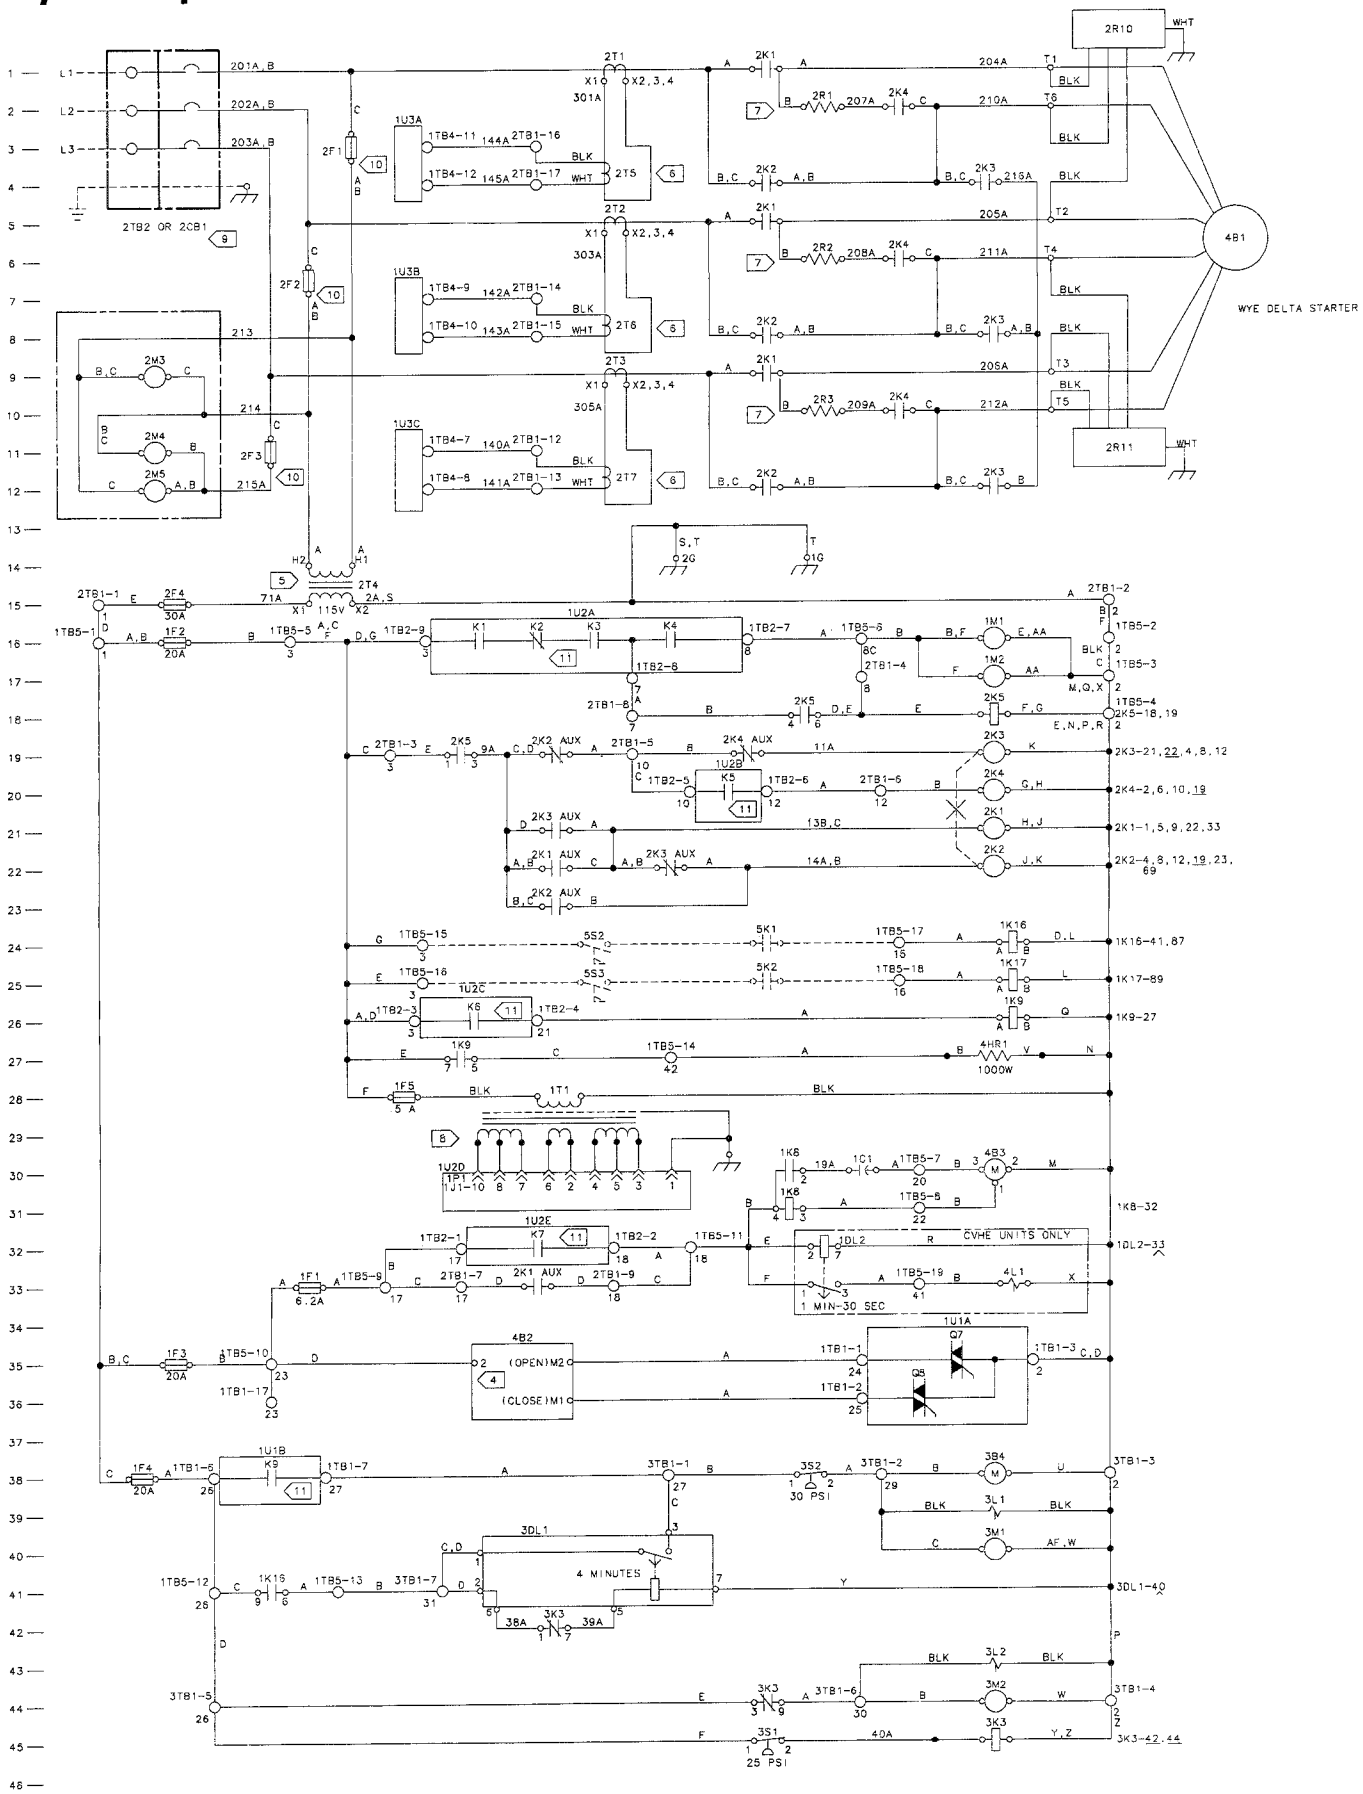
Oil Pump Circuit. . . The 1F3 branch circuit sends 120 volt control power through fuse 1F1 to the oil pump motor (4B3). Fuse 1F1 protects the oil pump motor from overcurrent conditions. Parallel contacts of the compressor motor starter interlock (2K1) and the oil pump relay (K7 in 1U2) keep oil pump motor starter (4B3) energized. While the location of K7 is 1U2, its status is controlled by the micro (1U3).

The oil pump motor is a single-phase capacitor start motor. The capacitor is engaged when its high starting current flows through current sensing relay (1K8). The "start" winding provides additional starting torque. As the motor accelerates, its lower current drops out the starting relay (1K8), and the motor runs on its "run" windings only.

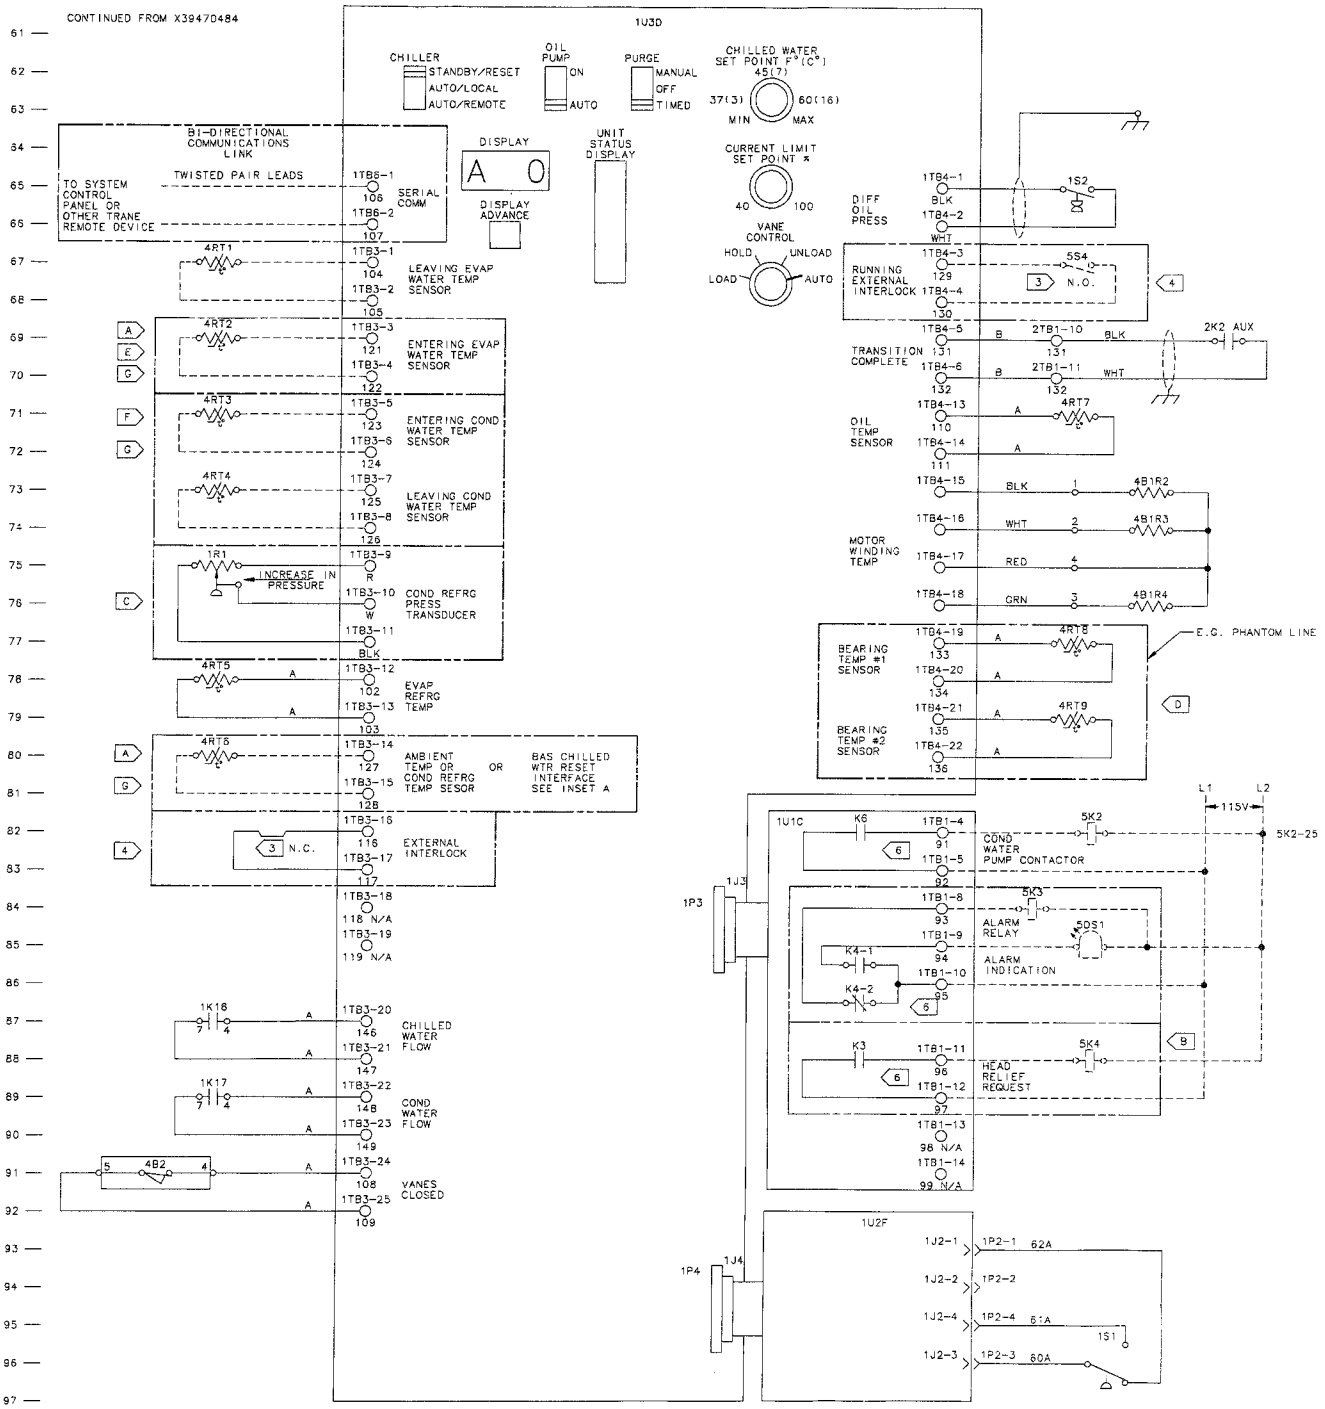
As long as the micro calls for oil pump operation, it will run. Further, parallel contacts from the compressor motor starter (2K1) will keep the oil pump operating any time the compressor motor is running, whatever the cause. Oil pump operation ceases only when both K7 and 2K1 open.

Inlet Vane Actuator Circuit. . . 120 volt power enters the inlet vane actuator motor (4B2) at terminal 2. This motor is highly accurate in positioning the inlet vanes. It runs either to the "open" or "closed" position. Therefore, small, precision movements are accomplished by "pulsing" the motor.

Pulsing signals are generated by Triac switches (Q7 and Q8) located in the relay output module (1U1). Appearing like relays, Q7 and Q8 are controlled by the micro (1U3).



Fuse 1F4 Branch Circuit.



Purge System Circuit. . . The purge system automatically rejects impurities that may leak into the CenTraVac. This includes both condensible (mainly water) and non-condensible (mainly air) impurities. Since one is usually not present without the other, the need for purging is signalled by an increase in purge drum pressure, after a brief period of purge compressor (3B4) operation.

Automatic purge operation involves periodic timed purge compressor running. If no impurities are found, the purge compressor will run for 5 minutes out of every 2 hour period that chilled water flow is available and the chiller is in one of the two "auto" positions. The presence of impurities elevates the purge drum pressure and extends running time through the action of timer (3DL1) and pressure switch (3S1).

A more complete explanation of manual and automatic purge unit operation is found in "Operation/Maintenance CVHE-M-3".

Figure 5 (cont.)

Sequence Of Operation

Figure 6 displays a "Time-Line" sequence of operation. Description of Figure 6:

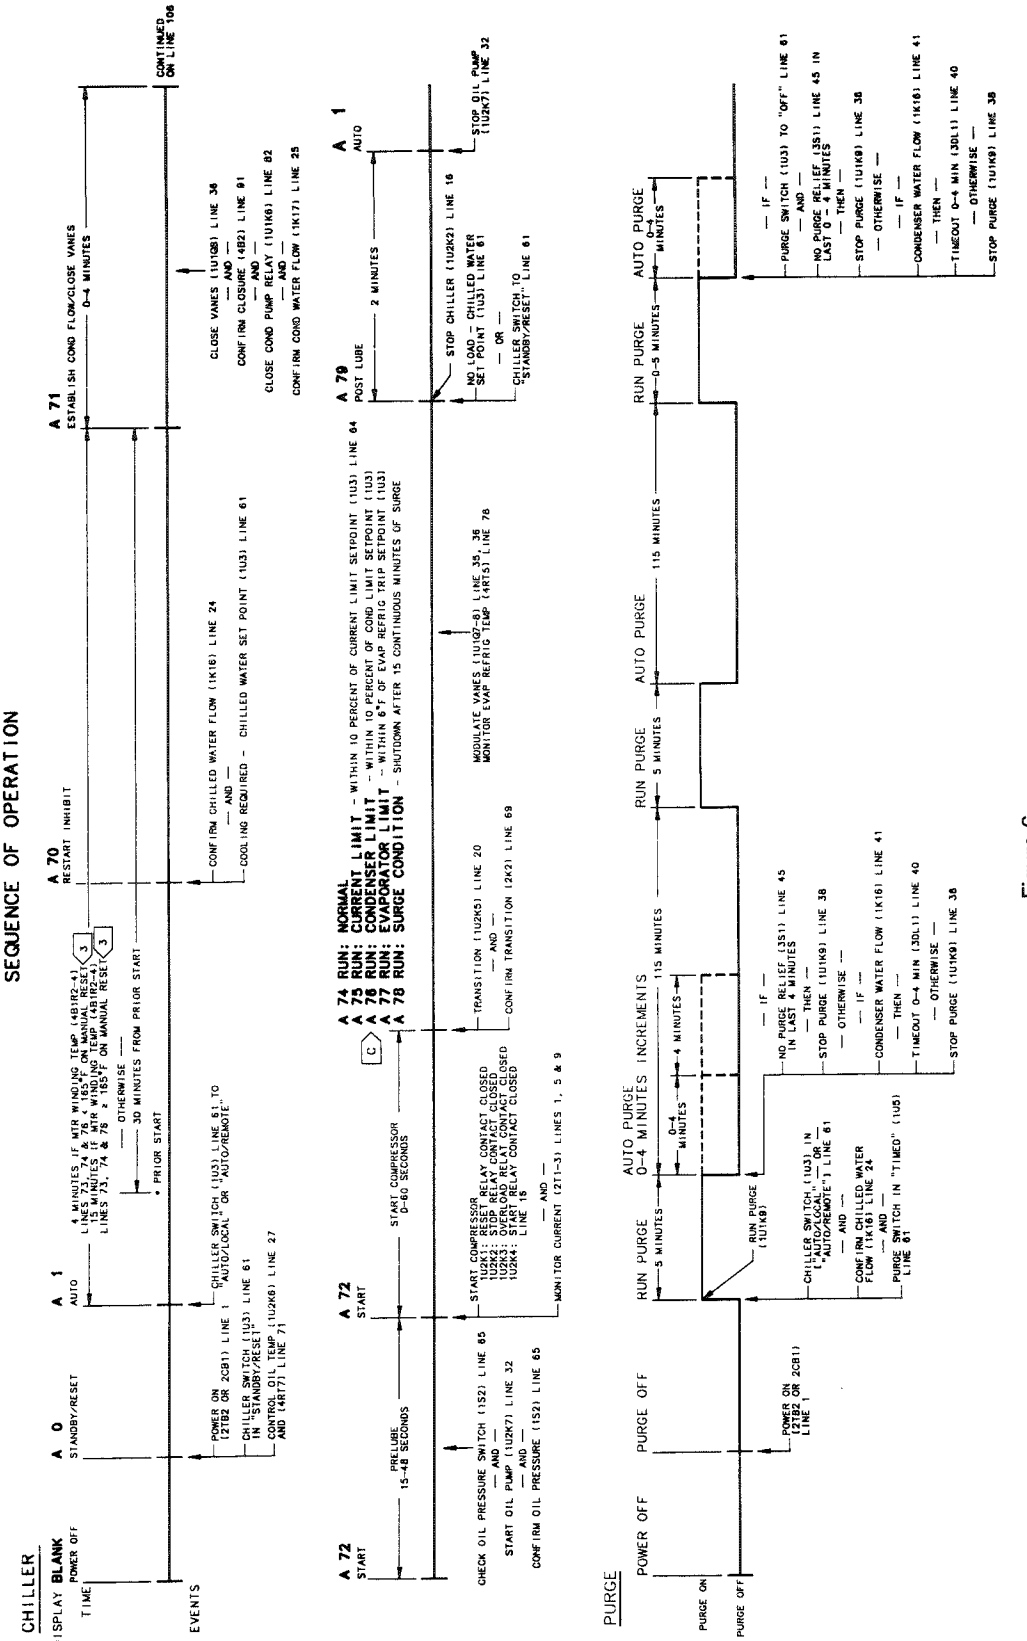

Figure 6

DISPLAY	DIAGNOSTIC	INTERPRETATION	TIME
BLANK	POWER OFF		
00	STANDBY/RESET	Power on. System is reset.	
01	AUTO	Chiller switch in auto/local or auto/remote. System is armed but cooling not required.	
70	RESTART INHIBIT	CVHE held off. Confirm chilled water flow.	Delay is: 4 min. if WT < 165F, 15 min. if WT > 165F, or 30 min. from prior start.*
71	ESTAB COND WTR FLOW	Output signal to run condenser water pump and to close inlet vanes. Confirm CDW flow and closure of inlet vanes.	Wait up to 4 min. for confirmations.
72	START	Prelube. Start oil pump motor. Confirm oil pressure.	Wait from 15 to 48 sec. to establish oil pressure.
72	START	Start compressor motor. Relays closed: (1U2K1) Reset (1U2K2) Stop (1U2K3) Overload (1U2K4) Start Monitor motor current.	Wait up to 60 sec. to accelerate motor.
74	RUN: NORMAL	Initiate compressor motor starter transition to "run". Confirm transition. Modulate inlet vanes.	
75	RUN: CURRENT LIMIT	Same as 74, plus inlet vane position limited by motor current.	
76	RUN: COND LIMIT	Same as 74, plus inlet vane position limited by approach to condenser pressure cutout setting.	
77	RUN: EVAP LIMIT	Same as 74, plus inlet vane position limited by approach to evaporator temperature cutout setting.	
78	RUN: SURGE CONDITION	Same as 74, plus head pressure relief relay energized by compressor surge condition.	
79	POST LUBE	Compressor stopped by: no load; chiller switch set to "reset" position; or (optional) free-cooling switch set to "on".	Oil pump is run 2 min. in post lube.
01	AUTO	Stop oil pump. Chiller is armed. Chiller shutdown on loss of cooling required.	

*After chiller switch is toggled to AUTO, the 70 display is skipped if the machine has been in the 01 condition, without cooling required, long enough to satisfy the timers.

CenTraVac System Control

Capacity Control

CenTraVac capacity is controlled to match chilled water system demand through repositioning the compressor inlet guide vanes. A variation in leaving chilled water temperature indicates a mismatch between chiller capacity and system load. Therefore, leaving chilled water temperature is the sensed variable for the capacity control system.

Control algorithms reside in the micro module (1U3). Any deviation from chilled water temperature set point creates a response via the condition of Triacs (1U1Q7 and 1U1Q8). The exact control response is calculated in the micro. Proportional, integral and derivative characteristics are incorporated in this controller. Consequently, the CenTraVac can be applied in a wide variety of comfort and process chilled water systems.

Control Accuracy.
Control accuracy depends, to some extent, on the "control gain" setting. This serviceman's setting (under the covered portion of the front panel) increases the speed of response as well as its sensitivity. The purpose of providing a "control gain" adjustment is to allow the chiller's response dynamics to be matched to the dynamic characteristics of the system.

Systems consisting of extremely short water loops respond quickly. They require fast response from the temperature control system. However, fast responding controls are usually more sensitive and prone to instability. There is no advantage in applying fast response controls to a system with slow dynamics. With the proper control gain setting, the CenTraVac temperature control system is designed to hold the leaving chilled water temperature within 1F of the setpoint, if the system delta-T is 15F or less. Accuracy is within 2F if the system delta-T is above 15F.

Load Limiting.
Compressor loads are determined by chilled water system conditions. Yet, compressor motor capacity is finite. Somehow, the control system must be able to limit compressor loads so as not to overload the compressor motor.

Compressor load limiting is accomplished by repositioning the inlet vanes whenever a pre-determined motor load is reached. Motor load is sensed by three current transformers located in the motor starter. If the micro senses that motor current is approaching the current limit, it will direct the inlet vanes to "hold" or "close", depending on how imminent the approach is.

The load limiting setpoint is adjusted in two ways. The primary setting (100%) is set by the service engineer. It is based on the RLA of the CenTraVac motor. The "Current Limit Setpoint %" (see "Inputs", item 6, page 3) cannot exceed 100%, but can be set to any lesser percentage, down to 40%. Since the measured variable is motor current, the percentage value refers to current. . . not motor or chiller load. (Motor current is not linearly proportional to either motor or chiller load).

Other Variables That Alter Inlet Vane Position.
Algorithms in the micro recognize other operating and safety conditions that have a bearing on vane position.

Motor Overload Current Trip. . . Separate calculations are made in the micro to evaluate the proximity to the motor overload current trip setting. As this setting is approached, inlet vane opening is inhibited. Further approach causes an "unload" command. Failing to arrest approach to the trip setting, the micro will initiate a latching diagnostic, overload trip (b Ec).

Evaporator Refrigerant Temperature. . . A temperature sensor (4RT5) in the evaporator provides information to the micro that allows it to determine an approach to the cutout temperature setting. When such an approach is discovered, inlet vanes are given a "hold" or "close" command, depending on the speed and magnitude of the approach.

Condenser Refrigerant Pressure (Optional). . . Similarly, an approach to the refrigerant pressure (as sensed by the optional pressure sensor) limit setting, will result in micro outputs that override inlet vane repositioning instructions.

Motor Protection

The compressor motor represents the costliest part of a CenTraVac. Its protection is of primary concern. Algorithms in the micro guard against the effects of the abberations listed below. Table 4 shows the diagnostic, its code and its reset mode.

Table 4

Diagnostic Description	Reset Mode	Code
Motor current overload	Manual	b Ec
Momentary power loss	Automatic	b E2
Extended power loss	Automatic	b d9
Low voltage	Automatic	b d9
Phase imbalance	Manual	b E3
Phase loss	Manual	b E4
Phase reversal	Manual	b E5
High motor temperature	Manual	b E7
Max. accelerating time	Manual	b EE
Transition	Manual	b F0

Motor Current Overload. . . 3-phase motor current is monitored continuously. An explanation of the algorithm used during motor starting appears on page 8. Shortly after the micro receives confirmation of a "compressor run" signal, running current is monitored. Any current over 107% of the setting for motor RLA will result in an overload trip. The "inverse-time" relationship above 107% RLA integrates current and time such that a steady 107% current will trip in 20 seconds. Any current exceeding 140% RLA will result in an overload trip in 1 second.

Momentary Power Loss. . . The damage potential of momentary power loss (6 to 30 cycles) is well documented. When the micro contacts 1U2K1 (reset), 1U2K2 (stop) and 1U2K3 (overload), Figure 5, are closed and the motor current falls to 15 percent of RLA, this simultaneous event can only occur when line voltage is interrupted.

Interruptions of less than 30 cycles causes an E2 diagnostic (momentary power loss), greater than 30 cycles a d9 (extended power loss). Both are non-latching (automatic reset) diagnostics.

Low voltage. . . Motors can be damaged by continuous low line voltage when the combination of motor load and low voltage results in higher than RLA current. CenTraVac motors are protected from overcurrent by the load limiting system and the overload trip.

Additionally, low voltage can produce unexpected and unpredictable operation of relay coils. The micro, by sensing control power voltage, detects this condition and issues the non-latching diagnostic (b d9), which is the same as an extended power loss.

Phase Loss or Imbalance. . . The loss or imbalance of any of the three electrical phases causes the remaining motor current to increase. Since the three phases are monitored independently, unbalanced phase currents, or zero phase currents, produce a latching diagnostic.

Phase Reversal. . . While the CenTraVac is not mechanically harmed by operation in the reverse direction, its cooling performance is grossly effected. Phase reversal is detected by the micro and results in a separate latching diagnostic.

High Motor Temperature. . . Motor stator winding resistance temperature detectors provide the micro with this information. It is used in two ways. First, a winding temperature under 165F allows a normal "start inhibit" time of 4 minutes after the chiller switch is placed in either of the "auto" positions. A winding temperature of 165F or above causes a "start inhibit" time of 15 minutes.

Second, a latching diagnostic indicating high motor temperature occurs if the detectors encounter a winding temperature of 265F.

Maximum Acceleration Time. . . Should motor starting torque not overcome accelerating torque in a specified time, the micro will issue a trip command and a latching diagnostic. This is detected by measuring the time interval between the signal to start and a reduction in motor current to less than 85% of RLA.

Transition. . . If transition from "start" to "run" is not completed within two seconds of its initiation, a trip signal and diagnostic are generated by the micro.

Control Options

The standard CenTraVac control system can be equipped with a variety of optional controls that perform specific "value-added" functions.

1. Relay Package. . . This option consists of two relays. . . an "alarm" relay and a "head relief request" relay.

Dry contacts of the alarm relay are field-connected between terminals 1TB1-9 and 1TB1-10 (normally open) or 1TB1-8 and 1TB1-10 (normally closed). The "coil" for this relay is powered by the micro through module (1U1). A customer-supplied alarm can be triggered by the alarm relay.

Designed for use with the standard surge protection feature as well as the optional condenser pressure limit control, the head relief request relay is intended to provide a signal for a reduction in entering condenser water temperature. NOTE: This relay is not intended to act as condenser water temperature controller. (Its logic contains no control algorithms which would allow it to perform as a controller). The normally-open relay is field connected between terminals 1TB1-11 and 1TB1-12.

2. Condenser Limit Control. . . This option is designed to prevent "nuisance" trip-outs of the refrigerant high pressure safety control. This option includes a manually adjustable condenser limit potentiometer (1R1), a pressure transducer and associated piping and wiring.

In an attempt to prevent a high pressure trip, this option limits inlet vane opening when the potentiometer setting is approached. If the Relay Package (above) is included, the head relief request relay may also energize to signal further corrective action (such as lowering the condenser water temperature).

3. Bearing Temperature Sensors. . . This option includes sensors 4RT8 and 4RT9 connected to 1TB4-19 & 20, and 1TB4-21 & 22, respectively. Should the motor/compressor bearing temperatures reach or exceed 180 F., the chiller is stopped with latching diagnostic bEA or bEb.

4. Chilled Water Reset. . . This option can be used on applications where design chilled water

temperature may not be needed to meet system part-load conditions. In these cases, the leaving chilled water temperature can be automatically reset upward using this option.

Reset authority tables shown in CenTraVac "Operation and Maintenance Manuals" determine the amount of temperature resetting that will occur. Two reset initiators are possible: a) return chilled water temperature, and b) ambient (outside) air temperature. (See "Generic BAS Chilled Water Reset Interface'", below.)

If return chilled water is the basis of reset, a sensor is installed in the return chilled water piping and its leads are connected to terminals 1TB3-3 & 4. The "Operation and Maintenance Manual" applicable to the specific model CenTraVac contains setup instructions to provide the appropriate amount of temperature reset for any particular application.

If ambient air temperature is used to establish the amount of chilled water temperature reset, an outside air temperature sensor is wired to terminals 1TB3-14 & 15. Care must be taken in the placement of this sensor to avoid "temperature contamination" from sunlight, radiation or atypical airstreams. Commonly, this sensor is placed in the fresh air intake to the building.

5. Generic BAS Chilled Water Reset Interface... This option is used in conjunction with the chilled water reset option. It allows the chilled water setpoint to be reset directly by an external 4-20 ma or 0-10 vdc signal. This option is most frequently used in conjunction with a generic building automation system (BAS) that has the capability of determining an appropriate chilled water setpoint by monitoring the building load requirements.

This option is provided through an additional module (1U4) that is mounted inside the control panel. Reset is only allowed upward from the front panel setpoint and the maximum amount of reset is 20 F. For additional information see the CenTraVac Operation/Maintenance manual CVHE-M-3A.

6. Serial Communications Interface... A serial communications interface option allows the microprocessor module to exchange information with a higher-level control device. A "translator", such as a Trane SCP699, must be used between the UCM and the higher-level control device, typically a TRACER automation device.

Condenser Water Control

The CVHE control system does not control condenser water temperature or flow. In application, some chillers may require some form of condenser water control. There are several to choose from, depending on the need.

Head pressure control... Chillers using an "infinite heat sink", such as a lake, river or supply of ground water, usually need this kind of control. We cannot exert much control over the temperature of natural bodies of water. Therefore, it is common to control flow in such a way as to 1) provide enough water to maintain efficient operation and, 2) limit flow so adequate condenser refrigerant pressure is provided to insure proper operation of various chiller "sub-systems", such as lubrication and motor cooling.

By sensing condenser refrigerant pressure, a simple reverse-acting proportional controller can be used to regulate the position of a water modulating valve located in the leaving condenser water line. The leaving position is used to keep the condenser "full" of water when a drain can act as a siphon. Refrigerant pressure is sensed by tapping into the

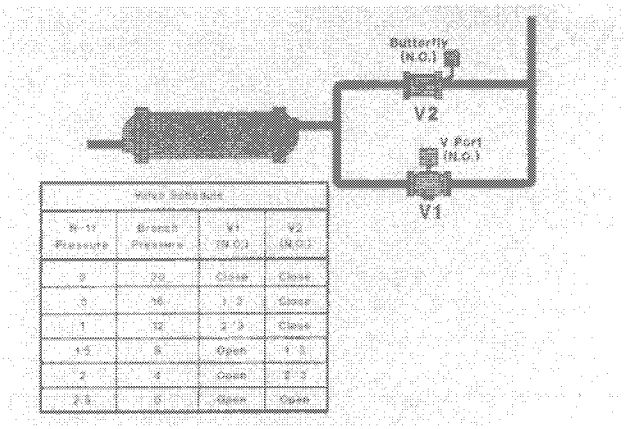

Figure 7

condenser pressure gage line, taking care to prevent the build-up of a column of liquid refrigerant that may give false pressure indications.

Modulating valve selection also depends on the application. For precision and wide flow variation, V-ported valves are best, although expensive. An alternative to a large V-ported valve can sometimes be found by using a large butterfly valve in parallel with a smaller V-ported valve, as shown in Figure 7. The total control pressure range is split sequentially between the two valves. This allows precise V-port valve control at low flows where hunting can occur, and the large capability of a butterfly valve to pass high volumes.

Application of this concept is not necessarily limited to infinte heat sinks. Head pressure control, by way of flow modulation, can also be applied

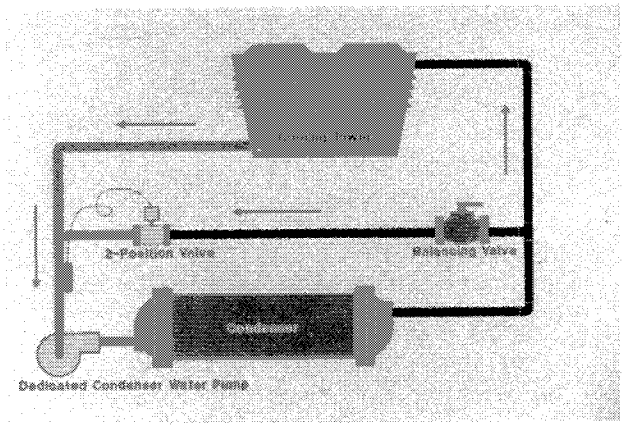

Figure 8

A simple method to assure proper condenser water temperature is shown in Figure 8. This scheme uses the "dedicated pump" concept. Water is recirculated within the condenser loop until it reaches a high limit temperature. At this point, a two-position control valve is closed, preventing recirculation. A balancing valve is used in the recirculation loop to adjust the loop pressure drop so that during recirculation, a significant amount (perhaps 50% of design flow) of tower water is drawn into the loop.

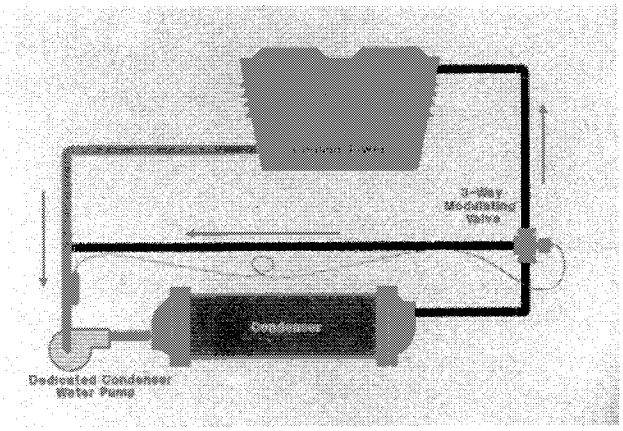

Figure 9

Figure 9 shows the next step in complication. This scheme employs a 3-way control valve to regulate the proportions of recirculated and tower water entering the condenser. The 3-way valve can take the form of two 2-way valves mechanically linked together.

When dedicated condenser water pumps are not possible, control of condenser water temperature is more complex. Depending on the size and type of cooling tower, it may be possible to control sump temperature by bypassing the entire system flow back into the sump, as shown in Figure 10.

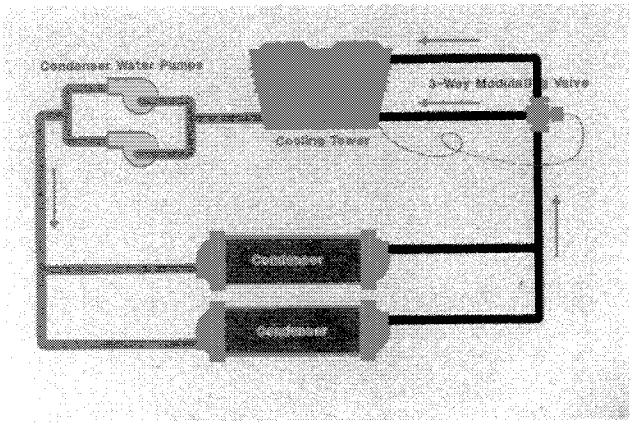

Figure 10

Some towers cannot tolerate loss of flow in cold weather. And, some systems are so large that it takes too long for such a bypass system to gain control over the water temperature.

Before adding complexity of this magnitude, the designer should evaluate the need for control. Large systems often remain active day, night, and on weekends. Heat rejected into such systems is usually sufficient to allow normal fan control to hold temperature. When a cooling tower system is very large, compared to chiller size, the condenser water system appears "infinite". The same kind of head pressure control system used for infinite sinks can be applied.

Compressor Motor Starter

The starter interlocking explanation, contained in section "System Operation", page 8, applies to star-delta, reduced voltage starters of the closed transition type. Other kinds of starters can be used, but all must be closed transition. (An open transition will be interpreted as a momentary power interruption by the micro circuitry.)

Starter types, other than star-delta, require specific internal parts and interlocking to communicate properly with the micro. In general, the following starter types can be used:

1. Star-delta, closed transition 200- 575 volts
2. Primary reactor, closed transition 2300-5000 volts
3. Primary resistor, closed transition 200- 575 volts
4. Full voltage (X-line) 200-5000 volts

Anyone contemplating the use of a starter other than star-delta, closed transition, should seek specific information about the special requirements and approval for its use.

Caution:
NEVER use shunt-trip or electrically operated circuit breakers or switch gear as replacements for CenTraVac motor starters. These devices are not inherently "fail-safe", and thus they place the compressor motor in significant and unnecessary peril.

Application

The CVHE microprocessor-based control system has been designed to serve a broad range of chilled water applications. Limitations, as applied to chilled water service are:

1. Chilled water temperature setpoint
   (min deg. F) 37 (extended range 20)
2. Chilled water temperature setpoint
   (max deg. F) 60 (extended range 70)
3. Reset — Chilled water reset cannot exceed the active setpoint range limits given in items 1 and 2 above.
   Note: Negative chilled water reset is not allowed.
4. Chilled water flow rate (min. gpm/ton) 0.8
5. Chilled water flow rate (max gpm/ton) 8.0
6. Loop water volume (min. gal./ton) 5.0
7. Loop water volume
   (max. gal./ton) infinite
8. Controller operating ambient
   (min. deg. F) 32.0
9. Controller operating ambient
   (max. deg. F) 158.0

When the chilled solution is an anti-freeze (brine) mixture, the minimum chilled water temperature setpoint is lowered to +20 deg. F.

Single Chiller Systems

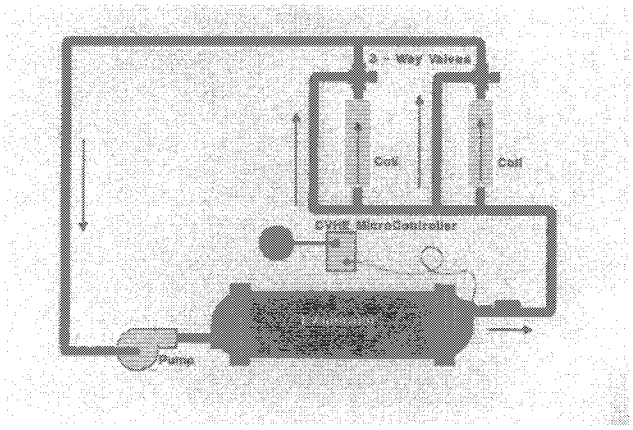

Figure 11

Basic Control. . . The basic single chiller loop is shown in Figure 11. Matching CVHE capacity with load demand is accomplished by controlling the leaving chilled water temperature at a pre-set value. When the temperature rises above this value, CVHE inlet vanes are opened past their present position. Conversely, when the observed chilled water temperature falls below the preset value, the inlet vanes are moved toward the closed position.

The only other operating signal that can influence the inlet vane position is motor current. A "load-limiting" function prevents the compressor from loading the motor beyond a preset value. This value is generally set at the maximum RLA rating of the motor. However, action of the "demand limiter" can reduce the current to any value, to a minimum of 40% of the load limit setting.

Two safety signals can limit inlet vane position, as well. They are, 1) the low refrigerant temperature limit and 2) the high condenser pressure limit. As either of these limits is approached, inlet vanes are moved toward the closed position.

Control Accuracy. . . The controller algorithms contain routines that provide an inherent accuracy of plus or minus 0.5 F. However, a combination of chilled water loop size and stability may prevent this accuracy from being achieved. In other words, loads can change so rapidly that the controller cannot sense temperature changes quickly enough, or the inlet vanes cannot move to a new position quickly enough to maintain this accuracy. Realistically, we can expect to hold the leaving chilled water temperature within 1 deg. F, if the system delta-T is 15 deg. F or less, and within 2 deg. F if the delta-T is above 15 deg. F.

System size and response characteristics vary widely. Thus, the CVHE control system is provided with a control input named "control response". This control adjusts the "response gain" to accomodate varying system characteristics. This control should be adjusted only by a qualified service engineer, since improper adjustment can lead to "hunting" or other unwelcome peculiarities.

The start/stop differential can be set manually to lengthen or shorten cycle times between starts. The "differential to start" control measures the difference between the actual chilled water temperature and the chilled water setpoint. A minimum difference turns the chiller off. This event occurs when minimum chiller capacity exceeds load demand long enough for the entire loop to fall to this value.

Likewise, when the chiller is off, a rise in the system water temperature to the other end of the differential setting will cause the chiller to restart. Cycle times are lengthened by using a large differential and vice-versa. Small chilled water loops generally require a large differential setting to limit cycling.

Variable Flow. . . Controller algorithms permit application of the CVHE CenTraVac to variable chilled water flow schemes, so long as they meet each of the following criteria:

1. Minimum and maximum flows within the cataloged limits for the specific evaporator size.

2. Changes in flow rate do not exceed a rate of 2% of design flow/minute. For example, a maximum change rate of 20 gpm/minute for a nominal 1000 gpm system.

Process Chilled Water Systems. . . In general, load changes associated with air conditioning applications occur slowly and predictably. The application of CenTraVacs to process chilled water loads opens up the possibility of:

1. Loads that come and go quickly and without warning.

2. Loads that require extremely precise temperature control.

3. Loads that return "used" chilled water to the chiller at temperatures well above the maximum safe return water temperature.

4. Loads that require a supply water temperature well above the maximum permitted.

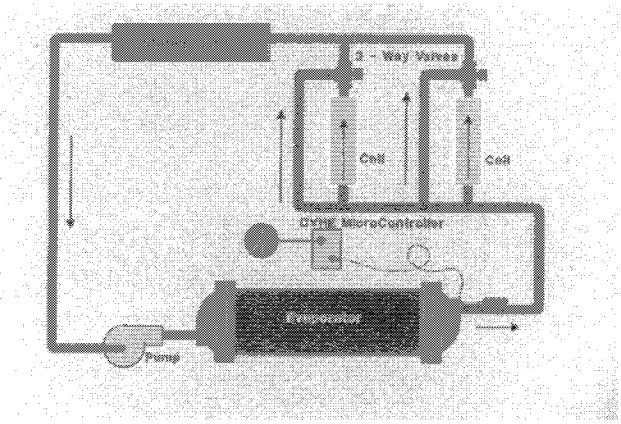

Figure 12

Figure 12. Suddenly appearing or disappearing loads, in themselves, may not be a problem. However, when temperature stability limitations accompany them, a "thermal flywheel' of some sort may be required. Many designers feel a storage tank is the answer. Possibly so. But, in many cases a storage tank does nothing but delay the problem of sudden load changes. In effect, the tank becomes a longer chilled water supply or return pipe. The magnitude of the temperature upset is not changed. Instead, it's appearance at the chiller is simply delayed.

Application

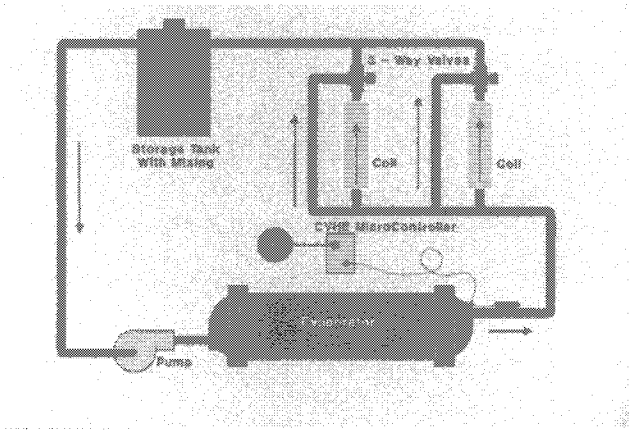

Figure 13

To achieve a flywheel effect, the tank must be a mixing chamber. In this way, water returning to the chiller is allowed to assume a "floating average" temperature before exiting the tank, Figure 13.

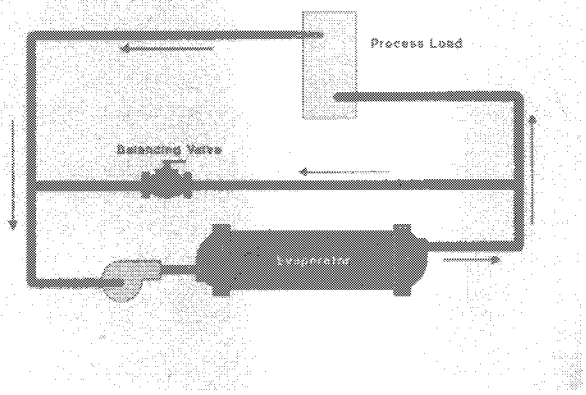

Figure 14

Figure 14. To prevent excessively warm water from returning to the chiller, a separate bypass loop must be established. A single circulating pump can be used if the chiller flow rate always exceeds the process demand. Surplus flow is sent through the bypass line into the return and mixed with return process water. If load changes are sudden, the return "tee" actually becomes a mixing tank, as shown in Figure 15.

Figure 16. When the process loads operate at supply and return temperatures above those allowed in the chiller, two circulating pumps are required. Two loops (process and chiller) are interconnected by bypass piping. Flow in the process bypass pipe is controlled by a temperature controller set at the desired process supply value.

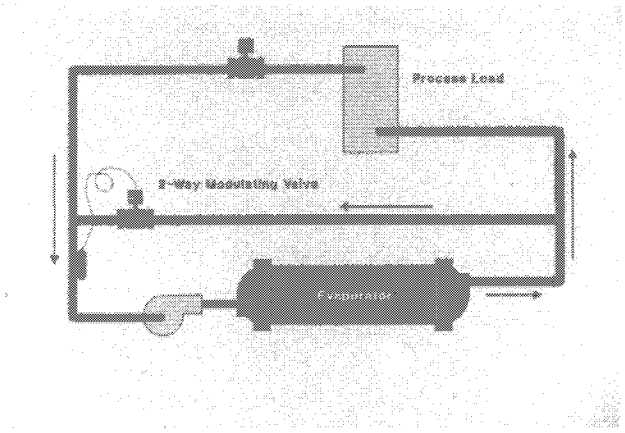

Figure 15

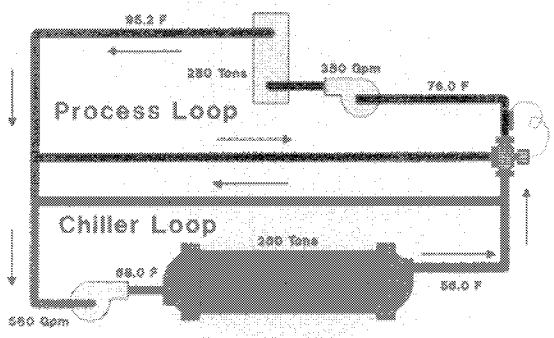

Figure 16

Flow in the chiller bypass line, then, automatically assumes the balanced rate. Temperature mixing equations are used to calculate the various design flow rates, and the controller does the rest.

Example: Assume a maximum process load demand of 280 tons, cooling 350 gpm from 95.2F to 76.0F. Also, assume a chiller is selected to provide 280 tons, cooling 560 gpm from 68.0 to 56.0F.

If "X" is the flow in the interconnecting link piping,the mixing equation is: 56.0X + 95.2(350-X) = 76.0(350), or 56.0X-95.2X = 26600-33320, or X = 171.43

Therefore, the design load flow rate in the process bypass line is 350 - 171.43, or 178.57 gpm. Likewise, the flow in the chiller bypass line is 560 - 171.43, or 388.57 gpm.

Multiple Chiller Systems

Certain kinds of multiple chiller systems involve "integrated" control strategies. That is, a higher level control authority instructs unit-level controllers in a predetermined way to act as a complete system.

Other multiple chiller systems are put together in such a way as to allow individual chillers to act independently. No higher level authority is required to coordinate the control of individual chillers. An example of one such system is shown in Figure 17.

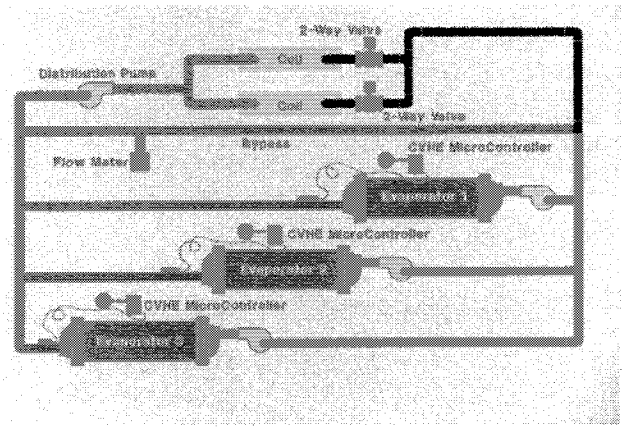

Figure 17

The primary/secondary pumping arrangement is used commonly to handle multiple chiller systems. This particular hydraulic combination decouples the distribution circulation from the production part of the system. In operation, a simple flow measuring controller decides how many chiller/pump "production units" are needed. Once this decision is made, the CVHE unit-level controller accepts all responsibility for temperature control.

Chilled water temperature control is separate from system control. Thus, any number of independent chilled water temperature controllers can operate on the same system. While it makes sense to have all such controllers set at the same setpoint, there is nothing to prevent different setpoints. However, different setpoints cause varying system supply water temperatures as different chillers are brought on line.

The common return water temperature establishes individual chiller demands for capacity. Since the return temperature is the same for all operating chillers, they share total system load in proportion to their pump's flow rate. "Preferential" loading is possible only by rearranging the hydraulics, as shown in Figure 18. When the common bypass (decoupler line) is placed "outside" a production

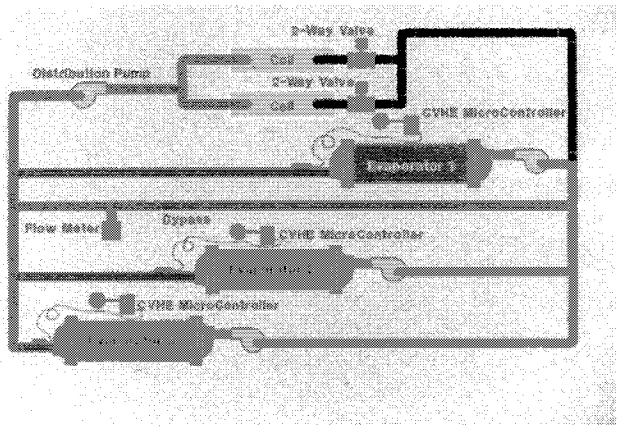

Figure 18

chiller/pump "production unit", that unit can be preferentially loaded. This occurs because its return water temperature is not diluted (decreased) by water flowing through the bypass from the supply main.

Series flow chillers. . . When evaporators are piped in series, Figure 19, it is possible to control the chillers separately and independently. The chilled water control set points are based on:

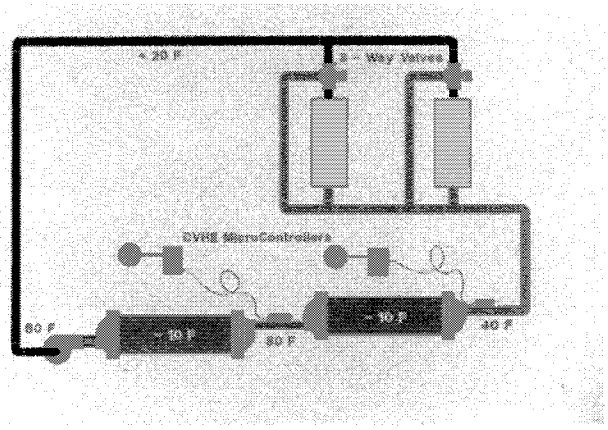

Figure 19

1. Setting both chillers to the system design water temperature. This method loads the upstream chiller first in sequence.

2. Setting only the downstream chiller at the system design water temperature. By setting the upstream chiller at the design intermediate temperature, it will be sequencially loaded last.

Application

Heat Recovery

CVHE chillers applied as heat recovery machines present unique control challenges. The basic water chiller control system does not recognize heat recovery control as being different from conventional chilled water control. To apply CVHE CenTraVacs to heat recovery service, a basic control strategy must be selected. There are several to choose from:

1. Auxiliary Heat Recovery. . . Figure 20. Control of CVHE inlet vanes remains with the leaving chilled water temperature controller. One method to establish a suitable heat recovery temperature level is to use the same kind of condenser head pressure control described in the "Condenser Water Control" section, page 16. This heat recovery system is characterized by its inability to absorb all of the heat rejected by the refrigeration system. Therefore, the main heat sink must be capable of accepting all rejected heat at any time.

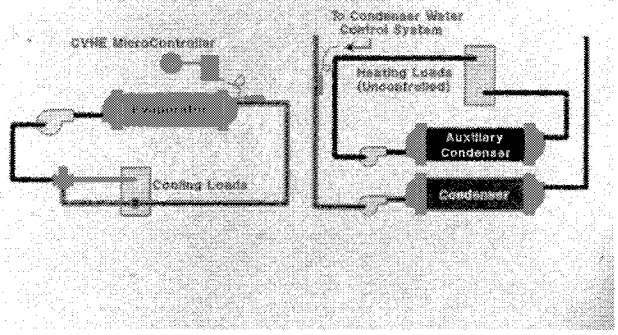

Figure 20

Head pressure control permits this while maintaining a condensing pressure (and temperature) high enough for auxiliary heat recovery.

2. Controlled Heat Recovery. . . Figure 21. When the heat recovery circuit is capable of absorbing all rejected heat during this mode of operation, the temperature of the returning hot water is used to control the amount of heat (usually by water flow) directed to the cooling tower water circuit. This also leaves inlet vane control completely under the control of the leaving chilled water controller. The basic CVHE control system is unaffected.

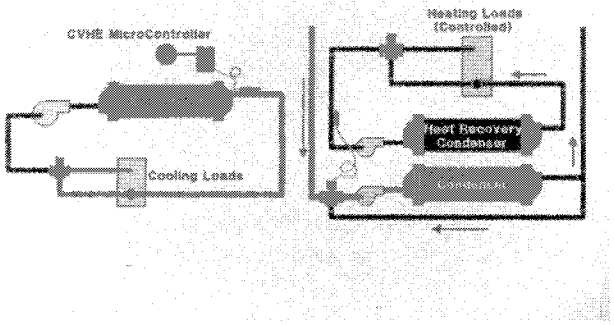

Figure 21

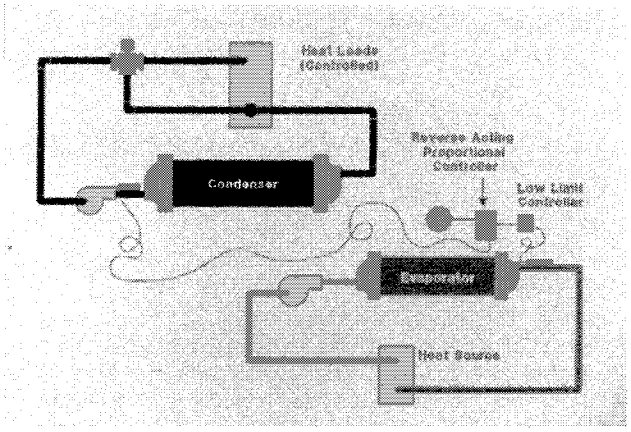

Figure 22

3. Heating As Primary Mission. . . Figure 22. In this case, the importance of heating transcends that of chilling water. The CenTraVac becomes primarily a heating device. This kind of system is used when the heat source, rather than the sink, is infinite. There is no possibility of running low on either chilled water flow or temperature. Control of the inlet vanes is taken away from the leaving chilled water controller and given to a heating water temperature controller.

For information pertaining to converting the CVHE controls for heating priority, refer to Trane Engineering Bulletin CTV-EB-91.

Interfacing With Other Control Systems

While the CVHE control system is microcomputer-based, its language and protocol are not common to control systems marketed by other control manufacturers. Therefore, it is not possible to simply tie a pair of wires into the micro with the hope of passing information and data back and forth.

Instead, a "translator" is needed. This function is filled by a system control panel, model SCP 699. In general, all remote interfaces, except the following listed ones, require an optional SCI (serial communications interface) and a Trane SCP 699 system control panel.

On-Off. . . Remote control of the on-off (start/stop) function can be executed through the optional "translator" panel SCP 699. If this is the only remote function that is desired, a less costly, but less friendly interface is possible. One way to accomplish it is to break into the chilled water interlock circuit. The circuit is identified by terminal pairs 1 TB5-15/17, Figure 5 line 24. This is less friendly because an interruption of the circuit causes a non- latching diagnostic. While the message indicates flow interruption, the operator can never be sure whether a flow failure has actually occurred or the unit is being turned off by the remote device.

Alarms. . . Remote alarm systems can be connected to the (optional) relay package (1U1, Figure 5). A customer-supplied, self powered alarm device can be activated by this pair of dry contacts, either normally closed or normally open. Any of the several CenTraVac alarm sequences will cause a signal to change contact position. Since there is a single alarm point, this circuit will not give an indication of the specific alarm condition.

A second alarm relay contact pair (head relief request relay) is included in the optional relay package. This relay is activated whenever the standard surge protection feature detects compressor surge. A request for condenser head relief can be used to remotely 1) reset existing condenser water temperature controls, 2) activate additional supplies of condenser water, or 3) signal any other remote and existing apparatus that will lower the condenser refrigerant pressure. This contact pair cannot be used as a controller output because it is not driven by control algorithms.

Hot Gas Bypass

The purpose of compressor discharge hot gas bypass is to false load the compressor with sufficient gas volume so as to maintain stability. Basic CVHE compressor stability is unusually high due to the three-stage design and the use of pre-rotation inlet vanes ahead of each stage. The inlet vanes ahead of the first and third stages are positioned by the temperature control system.

This permits the CenTraVac to be applied to systems that require aggressive turn-down ratios. Rule of thumb, CenTraVacs will operate with high stability at loads as small as 10% of the chiller's maximum capacity. In many cases, stable operation can be expected at even lower loads (sometimes on only system pipe gains).

On rare occasions hot gas bypass is necessary to false load a compressor to achieve a high pressure ratio at low "real" loads. Or, the start/stop cycling that occurs at loads below minimum loading may be unacceptable. In either event, control over hot gas bypass is executed by four devices contained in an optional hot gas bypass kit:

1. Hot gas bypass relay (1K15). Allows the inlet vanes and the hot gas bypass valve to close on chiller shutdown.

2. Inlet vane end switch (4S4). Permits adjustment of the activation point for the hot gas bypass, depending on inlet vane position.

3. Hot gas bypass valve switch (4B5). Directs "vanes close" or "vanes open" signals to the inlet vanes or to the hot gas bypass valve, depending on the relative position of each.

4. Discharge temperature switch (4S5). Shuts down the chiller if the compressor discharge temperature exceeds 210 deg. F., which may be caused by excessive no-load operation.

The hot gas bypass valve option should not be applied to a chiller indiscriminantly. It is not a cure-all for poor system design.

Free Cooling

The CenTraVac free-cooling option consists of five additional items:

1. Refrigerant gas line to bypass the compressor, including electrically actuated two-position valve.

2. Refrigerant liquid return line from condenser to evaporator, including electrically actuated two-position valve.

3. Liquid refrigerant storage vessel (actually, an extension to the existing economizer vessel).

4. Additional refrigerant charge to provide added wetted evaporator tube surface.

5. Free-cooling selector switch.

Application

When a CenTraVac operates on the free cooling cycle, temperature control is lost. The chiller simply becomes a pair of heat exchangers that permit heat from the chilled water loop to be rejected into the cooling tower circuit. The balance between the chilled water load and available condenser water temperature will produce an equilibrium condition at some leaving chilled water temperature.

This will likely not be the design system chilled water temperature. So long as it meets the needs of the system, however, free cooling is appropriate. When the derived chilled water supply temperature no longer satisfies system needs, it is time to switch the system over to "powered" cooling. This change-over is executed manually.

Since the condenser water temperature, at the time of change over, is likely to be low, some form of condenser water control is desirable (if not mandatory). The various options are listed in the "Condenser Water Control" section, page 16.

Low Temperature (Brine Chilling)

Model CVHE CenTraVacs may be applied as low temperature brine chillers.

Chiller modifications are limited to the control systems and various safety cutout settings. In other respects, the CenTraVac is essentially the same as a conventional water chiller.

Systems of this type often require two chilled water temperature control setpoints. One is used for ice-building and the other for conventional operation. To perform this change, a remote setpoint adjustment should be used. As indicated in the "Interfacing with Other Control Systems" section, page 23, the serial communications interface and the SCP 699 interface panel must be used to perform remote setpoint changes.

Appendix

The following describes the "Last Diagnostic" codes (Prefix b) displayed when an abnormal CenTraVac shutdown occurs.

Unit Diagnostics Condition

Code	*Description*
A3	Evap. Refrig. Temp. Range
A4	Motor Temp. Sensor #1
A5	Max. Accel. Time Range
A7	Motor Temp. Sensor #2
A8	Motor Temp. Sensor #3

Introduction

This applications Manual discusses an Integrated Comfort System that combines Model CVHE and CVHB CenTraVacs (using a micro-based control panel UCP695) with other parts of an air conditioning system through a Tracer Building Management controller.

The intent of this manual is to aid the designer of chilled water systems that employ CenTraVacs. It is organized to describe the system features, present system design guidelines, and outline application potentials.

This manual is partitioned into ***Part I*** and ***Part II***. Part I describes the systems and the hardware in these systems. Definitions and basic capabilities are covered. Part II focuses on applications and the techniques that can be used to achieve specific results.

PART I

System Description

Simplicity is the key word that describes the Trane Integrated Comfort System concept. In general, individual system components, such as chillers, pumps, cooling towers, fans, coils and valves are designed normally. The basic control strategy is also unchanged. The new ingredients are the control devices, their location and the algorithms that run them.

With the Trane ICS, individual controllers are part of the equipment. For example, the chilled water temperature controller is a part of the CenTraVac. (It is more than a controller, but we'll get back to that later). Alone, this controller is fully capable of executing any of several chiller control strategies. It needs no higher level of control authority in order to function properly.

This controller is built into the CenTraVac at the factory. Every CenTraVac is factory-equipped with an identical micro-based control panel. It's primary functions are to control the supply chilled water temperature and to protect the CenTraVac from conditions which might cause harm or damage to the system, equipment or people. Thus, all controls are categorized as either ***operating*** or ***safety*** controls. In general, safety controls are fixed into the hardware, while operating controls can be altered. In the language of microelectronics, safety controls are "hard-coded" into the micro-chips. Their values cannot be altered without changing the chips. Most operating controls, on the other hand, can be changed by changing software. Their values can be changed at will.

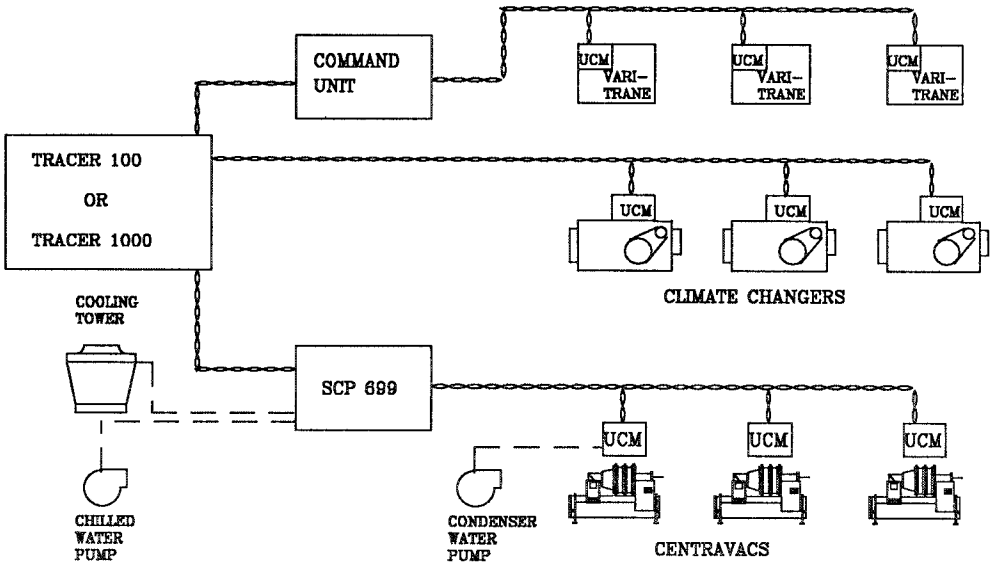

Figure 1

Changes to the various control values can be made manually (on-site) by programming, or remotely through an electronic interface. The latter is the technique used by the Trane Integrated Comfort System (Figure 1). The algorithms used to change operating values may reside in any of several places:

1. Trane Remote Chilled Water Temperature Reset Module (Figure 2).

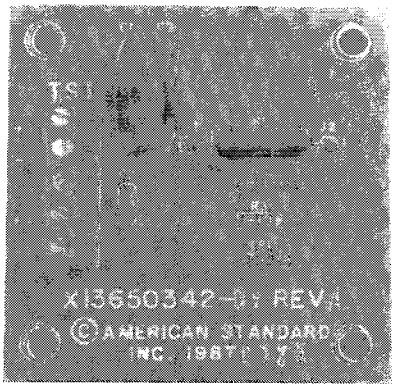

Figure 2

2. Optional "System Control Panel", Model SCP699 (Figure 3), or

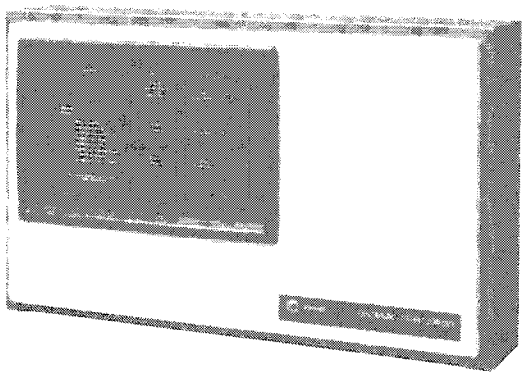

Figure 3

3. Tracer-100 (or Tracer-1000) Building Management Controller (Figure 4), or

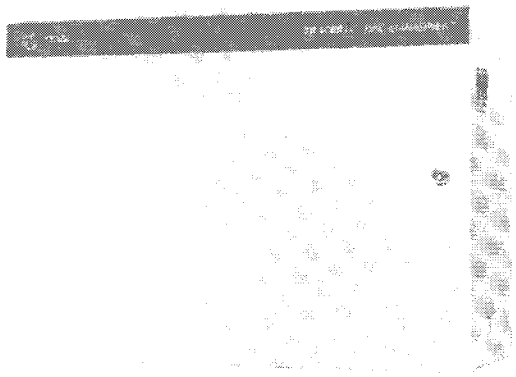

Figure 4

4. Generic BAS Interface through SCP699 (Figure 5).

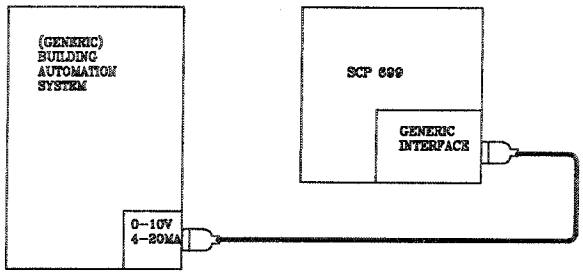

Figure 5

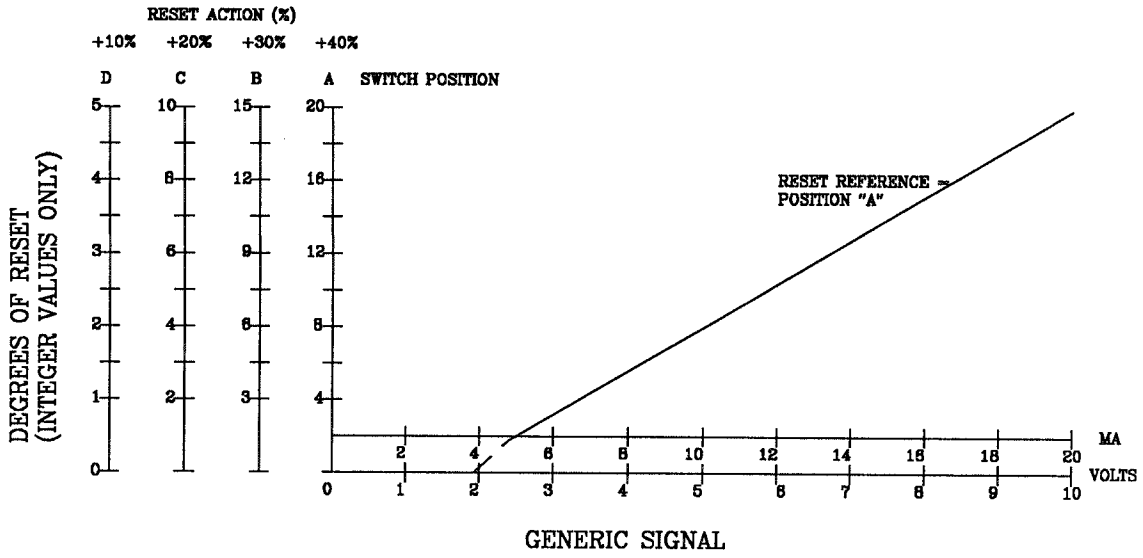
The capabilities and actions of these four "higher level of authority" devices are quite different from each other. Thus, they are described separately.



Remote Chilled Water Reset Module

The module identified as Trane part number B4533-2379-01 is a definite-purpose remote chilled water resetting interface. This device permits any remote 4-20 milliamp or 0-10 v.d.c. signal to reset the CenTraVac's supply chilled water temperature setpoint.

Connections are made directly to the CenTraVac panel, module 1U4. Communication is by way of a polarized pair of unshielded low voltage wires.

Chart 1 displays the possible reset relationships. In order to have this module perform its resetting function, four adjustments must be made to the CenTraVac panel 1U3D module:

- Set the "CHILLER" switch to "AUTO-REMOTE"
- Set "RESET TYPE" to "REMOTE TEMP."
- Set "RESET ACTION" to position "A, B, C, or D"
- Set "RESET REFERENCE" to position "A"

NEW CHILLED WATER SETPOINT =
(PANEL SETPOINT) + (DEGREES OF RESET)

Chart 1

As shown in Chart 1, there are two reset ranges. The first range, up to 2.4 v. or 4.8 ma., permits a maximum of only 1.8 F of reset action. The second range is more useful. It permits resetting the temperature up 20 F. Logic within the CenTra-Vac panel prevents negative resetting.

System Control Panel (SCP699)

Note: For further detailed information on the SCP699 panel, refer to CVMA-IN-1 (Installation), and to CVMA-OG-1 (Operator's Guide).

The Trane SCP699 system is capable of a wide variety of strategies and options. Some of these are mutually exclusive...some are not. Table 1 shows the various features and capabilities of the SCP699, when used alone, as a multiple chiller control panel.

Table 1

1. User interface.
   The "user interface" gives the operator access to data available within the chiller system. This includes all data normally available through the CenTra-Vac UCP695 panel.

2. Coordinated control.
   1, 2, or 3 CenTraVac chillers with and sequencing UCP695 control panels. Chillers can be piped either 2 or 3 in parallel chillers, or 2 in series.

3. System temperature.
   A common supply water temperature is maintained by regulating individual chiller capacities.

4. Scheduling.
   System operation is scheduled on a 7-day, 24-hour basis, plus holiday scheduling.

5. Cooldown.
   Variable rate "soft-loading;" of chillers minimizes electrical demand peaks.

6. Reset.
   System chilled water temperature reset is executed manually or automatically.

7. Demand limiting.
   System electrical demand limit control is executed based on pulsed signals received from a system electrical demand meter.

8. Centralized manual control. Specific parameters are controlled from a central location (SCP699).

9. Auxiliary components control. Control of major auxiliary chiller system components, such as chilled water pumps.

10. Condenser water temperature. Optional 2-stage *limit control* of cooling tower water temperature permits a variety of special strategies.

11. Free Cooling control. Optional temperature-initiated free-cooling control permits automatic enable/disable commands.

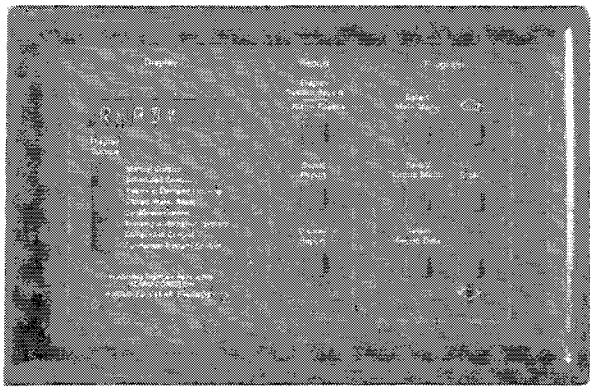


Figure 6

1. User Interface

An 8-character alpha-numeric display, 8 status indicator lights and 9 pushbutton switches comprise the interface section (Figure 6). Three primary groups make up this interface: the *display*, *report*, and *program* groups.

The *display* group indicates to the operator various messages and status information.

The *report* group enables the operator to view as many as 5 preformatted status reports (4 system reports and 1 chiller report).

Programming is performed in two areas; **SYSTEM** and **CHILLER**. Major **system** programming areas are:

- Time scheduling,
- Chilled water setpoint, reset, and control gain strategies,
- Electrical demand limiting setpoint and rate,
- Cooldown (slow-load) strategy, and
- Free-cooling enable/disable temperatures

Major individual **chiller** programming areas are:

- Leaving chilled water temperature setpoint,
- Electrical current limit setpoint,
- Order of rotation for chiller start sequence , and
- Percent chiller capacity to be used as a "trigger" to advance chiller sequence.

2. Coordinated Control and Sequencing of Multiple Chillers

Coordinated control and sequencing is accomplished through programming the "**CHILLER**" portion of the **main menu** (Figure 7). Three unit inputs and the unit sequence inputs are revealed in the **group menu**.

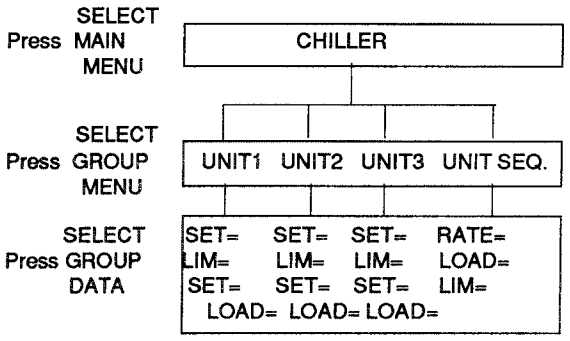

Figure 7

In general, temperature and current limit **group data** settings made in the **"CHILLER"** portion, take precedence over those made in the **"SYSTEM"** portion. The default value for "SET" and "LIM." values is "AUTO". This setting allows the settings entered in **"SYSTEM"** to assume control.[Reminder: For further detailed information on SCP699 panel programming, refer to CVMA-IN-1 (Installation), and to CVMA-OG-1 (Operator's Guide).]

Group data entries for "UNIT SEQ. SET =" determine the order of chiller sequence rotation. The entry in "RATE =" will then determine the rotation period (time). At the end of each period, the sequence order is advanced.

3. System Temperature Control

Chillers are sequenced on or off on the basis of the current drawn by operating chillers relative to a "trigger" current entered in "LOAD =" (UNIT SEQUENCE). A normal value between 90% and 95% will cause the next chiller in the sequence rotation to be started. Similarly, the "LIM. =" entry will cause the last chiller started to be turned off. A value less than 50% is recommended for this entry.

Whenever the system's common chilled water temperature strays from the setpoint, SCP699 resets the individual operating chiller setpoints. In this way, all operating chillers are persuaded to meet the system load.

4. Scheduling

SCP699 incorporates sophisticated 24-hour, 7-day time-clock and calendar functions. Different operating schedules can be set for each day of the week and holidays. Specific chilled water setpoints can also be established (ice storage systems). The panel contains a back-up battery to keep time during power failures.

5. Cooldown

"Cooldown" describes a slow-load strategy that limits the amount of system load the chillers will accept. This amount is gradually increased over time. This time period can be adjusted from 0 through 2-hours, in 15-minute increments.

For the specified period, chiller capacity is limited by SCP699. At the start of the period, the difference between the actual temperature and the setpoint is noted. Compressor currents are allowed to increase until the temperature begins to fall. At intervals, a calculation is made to extrapolate the cooldown time. After each calculation, the setpoint is adjusted to make the extrapolated time equal the cooldown time. At the end of the period, the "cooldown" limits are removed. Chiller control is no longer influenced by a slow-load strategy.

6. Reset

Three reset strategies are available. One resets the system control setpoint whenever the returning chilled water temperature is less than the system design return temperature. If the **SYSTEM group menu** "CHILLED WATER RESET" **group data** entry "SET =" is <25, the new setpoint is determined by an equation that permits a variety of reset rates. The new setpoint is raised as the system load decreases.

The second strategy uses outside air temperature as the reset indicator. If the above **SYSTEM** entry is >25, the new setpoint is proportional to the difference between a base design outdoor air temperature and the actual temperature.

A special DIP switch setting permits "normal" or "reverse" authority for this resetting strategy.

Examples of several ***load-based*** reset strategies are shown in Figures 8 through 11. A definition of abbreviations is needed:

- STMP Actual system leaving chilled water temperature.
- AUXTMP Actual system return chilled water temperature.
- SCWS Scheduled or BAS-generated system chilled water setpoint.
- CWR (RATE) Decimal value of the entered reset rate that determines reset aggressiveness.
- CWR (SET) Entered reset temperature that acts as a base amount of reset.
- RSCWS The newly calculated chilled water reset temperature.

The mathematical expression for the resetting equation is:

RSCWS = SCWS + CWR(RATE) x [CWR(SET) + STMP - AUXTMP]

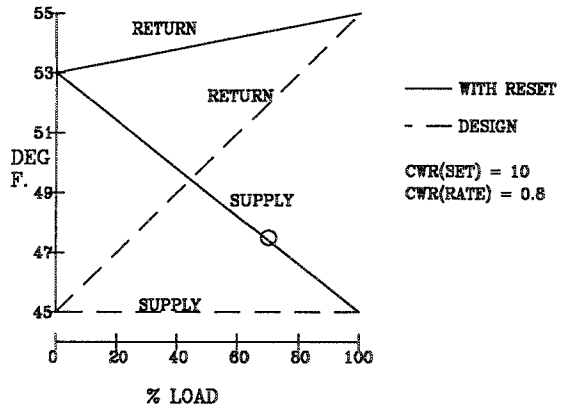

Figure 8

Figure 8 shows what happens if:

The system temperature rise at design is 10 F and, STMP = 45 F, AUXTMP = 52 F, SCWS = 45 F, CWR(RATE) = 0.8 (80%), and CWR(SET) = 10 F.

This particular load condition causes the temperature setpoint to be reset to 47.4 F. The slope of the pictured reset line is expressed mathematically above. Increases in either CWR entries will make resetting more aggresive.

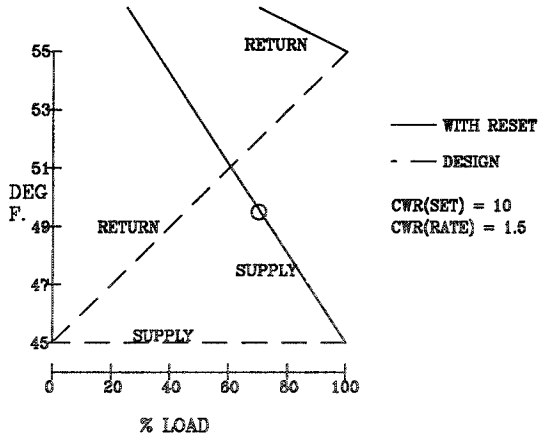

Figure 9

For example, Figure 9 shows the effect of increasing CWR(RATE) to 1.5. RSCWS now is 49.5 F, all other conditions remaining constant. When CWR(RATE) is established at a value higher than 1.0, resetting is so aggressive that the return water temperature rises with decreasing load. If CWR(RATE) is entered at 1.0 (100%), and CWR(SET) is fixed at the system temperature rise at design, the reset schedule will attempt to keep the return water temperature constant. This is shown in Figure 10.

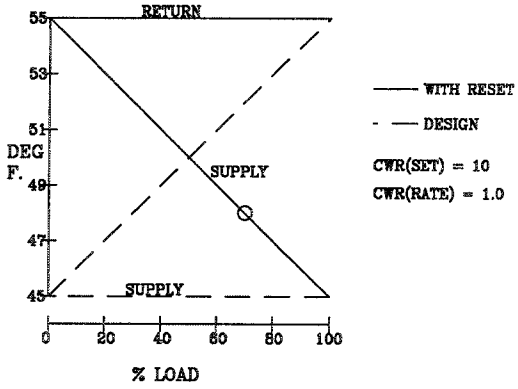

Figure 10

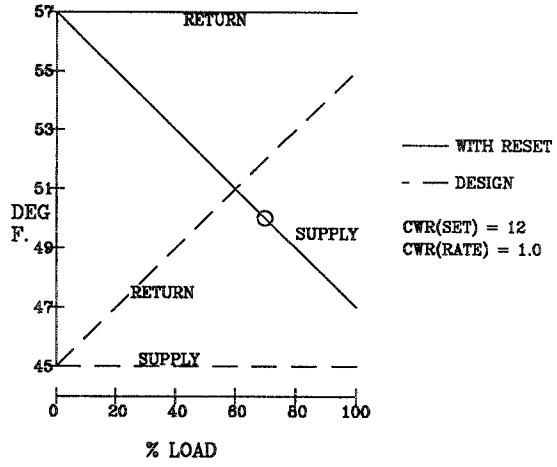

Figure 11

Figure 11 shows what happens when CWR(SET) is established at 12 F. This value, being higher than the system ΔT, causes a 2.0 F "bias" reset at all loads for both supply and return water temperatures. CWR(RATE) of 1.0 establishes a constant return temperature of 57 F.

The second reset strategy is *ambient-based*. The exact meaning of two variables changes:

- AUXTMP The actual ambient temperature.

- CWR(SET) The base reset increment must now be greater than 25 F. This input is usually the design ambient temperature.

Also, the equation is changed to:

RSCWS = SCWS + CWR(RATE) x [CWR(SET)- AUXTMP]

If: SCWS =45 F
CWR (RATE) = 0.3 (30%)
CWR (SET) = 95 F
AUXTMP = 80 F
then,
RSCWS = 49.5 F

The third reset strategy permits an outside analog signal (4 - 20 milliamps, or 0 - 10 volts) to reset system chilled water temperature setpoint directly at the SCP699. This external analog reset can also be used with the "generic BAS" interface, as described on page 10.

7. Demand Limiting

System electrical demand can be limited by sensing the building's (or system's) electrical demand meter pulses. A maximum (percent) of the total building or system demand is input to SCP699. The actual demand is compared to this product. The current draw of all operating chillers is reduced at a minimum rate of 2% per minute whenever the input peak is exceeded.

In order to be most effective, the total chiller electrical power should be a significant portion of the building power, as sensed by the demand meter. Otherwise, the chillers could be unloaded completely without greatly impacting the building electrical demand.

A current limit and temperature control heirarchy protects the chillers. CenTraVac inlet vanes are positioned on the basis of an ordered structure of regulators. Individual chillers are controlled to respond to the minimum capacity determined by these limiters:

- Evaporator refrigerant temperature

- Condenser refrigerant pressure

- Compressor motor load limit current

- CenTraVac electrical demand limit setting

- Chiller system current limits issued by "Cooldown" or Trane BAS interface

- System electrical demand limit

- Leaving chilled water temperature

In other words, control over the leaving chilled water temperature is sacrificed if any of the electrical demand or current limits restrict capacity. And, the supply chilled water temperature will drift upwards if the supplied capacity does not meet the imposed cooling loads.

8. Centralized Manual Control

This capability is simply the coordination of all the preceeding capabilities at one central location....the SCP699 panel. In addition, unit chilled water pump control, condenser water temperature limit control, and free cooling control are also included.

There are significant operating advantages to be gained from this capability. The ability to execute manual control over the operation of a chilled water system from a central location is important to many designers and operators.

The SCP699 panel can be remotely located. The maximum distance for the communications links and sensors (using 14 ga. wire) is 5000 feet. A single twisted pair of wires handles all bi-directional communications between the SCP699 and the chillers, which can be "daisy-chained" (Figure 12). Dedicated wiring for other sensors, inputs, alarms, and system components (pumps) is also required. Specific wiring connections are detailed in the "Installation Manual" CVMA-IN-1A.

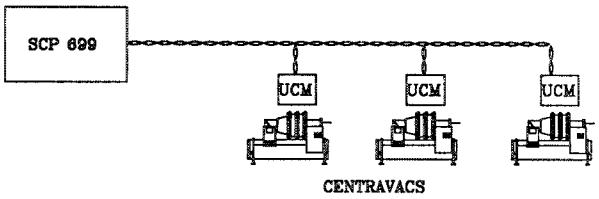

Figure 12

SCP699 is equipped to accept 2 binary pairs of input:

- Scheduled System Enable/Disable. This permits a remote device to enable or disable the entire chiller system. This can be any on/off switch.

- Free Cooling Enable/Disable. This allows a remote on/off device to enable or disable system-wide free cooling.

Either, or both, of these functions can be initiated remotely without effecting other SCP699 capabilities.

9. Auxiliary Components Control

Various water pumps can be controlled by SCP699.

- one (1) system chilled water pump

- three (3) unit chilled water pumps

- no (0) condenser water pumps. No condenser water pumps are controlled by SCP699. Instead, signals to start specific condenser water pumps originate in each CenTraVac UCP695 controller. Interlocking, to verify condenser water flow, also is accomplished at the chiller UCP's.

- no (0) cooling tower fans. No tower fans are controlled by SCP699. The interlocking and temperature control of cooling towers is a separate function and is not integrated with this system. See the next section, "Condenser Water Temperature", for additional information on this subject.

10. Condenser Water Temperature

The condenser limit option is not a condenser water temperature *controller*. Rather, it is an enhancement that permits dual-stage *limitation* of temperature by way of the normal condenser water temperature control system. Its purpose is to maintain a minimum refrigerant pressure differential between each chiller's evaporator and condenser.

An optional "sideboard" is factory-installed inside the SCP699 enclosure. (This sideboard is the same device that serves as a *"generic BAS analog interface"*).

One condenser refrigerant temperature sensor must be installed for each chiller that is to be interfaced with this option. This sensor is connected to terminals in UCP695. The "side board" has one set of terminals dedicated to condenser limiting. These accept a (read only) sensor which can be in water or air. The condenser relays are located on the main board of SCP699.

Evaporator refrigerant temperatures for each chiller are available at SCP699 through the bi-directional communications link (BCL). The difference between the condenser and evaporator refrigerant temperatures is calculated. When this difference increases to a pre-established limit, the output relay is closed, thus enabling the normal tower water control system. Adjustments are in 4 F increments between 36 F and 64 F. Likewise, a drop in this difference opens the output relay, disabling the normal control system. Adjustments to open vary from 24 F to 52 F, and the minimum "open" time is 2 minutes.

SCP699 monitors the refrigerant temperature differential of each operating chiller. It uses the unit with the lowest differential to determine if the cooling tower water temperature control should be disabled.

For example, closure of an output relay at a differential of 50 F (85 - 35) enables the normal tower water control system to function. When the differential temperature falls to 38 F (73 - 35), relay opening can be made to disable the normal control. Or, relay opening could be arranged to open a tower bypass valve. Thus, a minimum limit of 38 F differential temperature is established between the evaporator and condenser refrigerant.

11. Free Cooling Control

The free cooling option on SCP699 permits the system operator to select either manual or automatic switching to (or from) free cooling. Once switched to free cooling, the entire chiller system is in the free cooling mode. It is not possible for individual chiller's free cooling mode to be controlled through SCP699. This can only be accomplished at the chiller UCP.

Manual execution of the system-wide free cooling mode is simply a matter of pressing the

SCP699 front panel push buttons.

A third type of free cooling uses the "free cooling binary input". Closed, free cooling is initiated; open , it is terminated. The open/close decision is external to SCP699.

Automatic, thermostatically-controlled free cooling requires the addition of a sensor in either the common entering condenser water line or outdoor ambient. This sensor is used as a trigger to *start* free cooling, but only if the chillers are not running. The decision to *stop* free cooling is based on the supply chilled water temperature sensor. When a high-limit temperature is reached, free cooling is cancelled and chillers return to the powered cooling mode. To prevent possible cycling, any action to cancel free cooling is suspended during the "cooldown" period.

Chillers not equipped with the free cooling option cannot be operated at the same time with chillers on free cooling without independent condenser water control. Running powered chillers while being supplied with uncontrolled very cold condenser water can cause chiller malfunction or damage. Trane Applications Manual CON-AM-21 provides alternative ways to design and execute condenser water temperature control.

Generic Building Automation System (BAS)

A generic building automation system (BAS) interface to SCP699 is provided at the same "sideboard" terminal strip used for "Condenser Water Temperature Control" (See item 10, page 9). When this connection is made, most SCP699 capabilities are disabled and must be performed separately by the generic BAS. Those SCP699 functions that remain operative are:

- Condenser water temperature limit control
- Remote system enable/disable
- Remote or automatic free cooling enable/disable
- System alarms (system-level only)
- Unit-level chilled water temperature set-points, via 4 - 20 ma., or 0 - 10 vdc. direct resetting inputs.
- Unit-level current limits, via 4 - 20 ma., or 0 - 10 vdc. direct resetting inputs.

All other SCP functions are mute.

Tracer-100 Building Management Controller

(Figure 13) Tracer-100 is a powerful Trane building management controller. The Trane Integrated Comfort System uses the Tracer-100 to orchestrate a system-wide control strategy. It

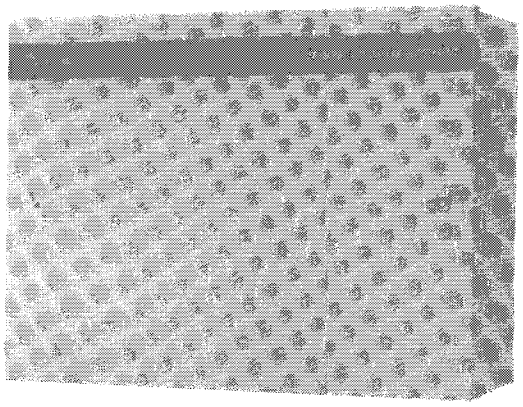

Figure 13

communicates with SCP699 through a twisted pair of wires using a proprietary bi-directional communications link (BCL). All information that is available at the SCP699 user-interface is also available at the Tracer-100. And, the Tracer can be used to communicate all programmable control settings to SCP699.

The bi-directional communications link (BCL) connection is made at terminal board TB2 inside the SCP699 panel. This is a direct serial connection, just as are the SCP699 connections to individual chillers. If more than 15 minutes elapses between Trane BAS communication updates, SCP699 will default to its own internal control values. During a period of "lost Tracer contact", SCP699 sequencing and control logic remain intact.

A Tracer-100 that is connected to SCP699 is probably also being used to perform other system-level chores. A particularly useful application involves the Tracer's ability to monitor data and format reports. The Tracer-100

can interface conventional personal microcomputers via the "Tracer Building Management Network".

This network permits report generation, trend logging, alarm call-out through a telephone modem, and remote data inquiry through the same telephone modem. Service companies find this capability an extremely valuable productivity improvement tool.

Tracer-100 provides other building-level and system-level capabilities. Among these are: control of cooling towers , fans and pumps; extensive building electrical demand limiting; coordinated scheduling; timed override; optimal start/stop; and plant lock-out. All individual chiller monitored points, even those not interfaced by SCP699, are available at the Tracer-100.

Extensive application and user information for Tracer-100 is available in two publications:

- EMTB-OG-1 Tracer-100 Operator's Guide
- EMTN-OG-2 Tracer Building Management Network Operator's Guide

Tracer-1000 Building Management System

The Tracer-1000 system is an extremely powerful building automation and control system, that is part of the Trane Integrated Comfort System architecture. The Tracer 1000 interface to the SCP699 takes full advantage of the bi-directional communications link by way of a Unit Control Interface (UCI) panel. The bi-directional communication link is connected to the UCI which, in turn, is connected via a twisted shielded pair of wires to the Tracer 1000. The UCI serves as a communication translator for the Tracer 1000 system.

When connected to the SCP699, the Tracer 1000 monitoring and control capabilities can be applied to the chilled water mechanical system. Like the Tracer 100, the Tracer 1000 has access to all chiller diagnostic information and can control system chilled water and current limit setpoints.

The Tracer 1000 allows ***all*** SCP699 information points to be assigned as actual Tracer 1000 points. This is unlike the Tracer 100, which allows only a subset of SCP699 information points to be assigned as actual Tracer 100 points. This means that chiller data is available for monitoring via color graphic displays, trend logs, reports, etc., and for control by the Tracer 1000 standard application programs. This adds up to 115 monitoring and control points for each SCP699 panel.

The Tracer 1000 has the added capability to control individual chiller chilled water and current limit setpoints via the SCP699. This permits increased chiller plant control flexibility on an individual chiller basis.

The Tracer 1000 system can interface with multiple SCP699 panels. The maximum configuration will depend upon system hardware and software structure and the applications being performed.

Detailed explanations of Tracer-1000 interfaces to CenTraVacs, programming, and application information are available in the following publications:

- BAS-OG-1
- EMTC-PG-1
- EMTC-AG-1

PART II

This section of the manual is broken into *"How To Design The System"* and *"How To Put The Parts Together"*. They are arranged in "cookbook" fashion in hopes that application to everyday systems will be made more simple.

How To Design The System

1. Qualify the Application

Any CenTraVac installation can be an acceptable "Integrated Comfort System" candidate. In order to qualify, the CenTraVac *must* be equipped with the model UCP695 control panel. Older machines can be retrofitted to have this capability.

Any of the following qualifiers point to a good reason for selecting the ICS option:

- Remote monitoring of chiller(s) or system operating parameters
- Remote adjustment of chiller(s) or system operating parameters
- Coordinated control of multiple chillers
- Automated enable/disable instructions for various chiller(s) or system operating parameters
- Limiting of system-wide electrical demand

2. Establish a clear expression of your goal(s)

In order to translate any concept into reality, a clear expression of the goal is necessary. A fuzzy idea of what you want to accomplish will not do. The clear expression may not be completely doable, but at least it is a starting point. It is best to separate the goals and not combine them into one unmanageable statement. Keep the expressions simple.

Examples of several goal expressions might be:

- Start and stop the chilled water system according to hourly/daily/weekly schedules.
- Remotely reset the system chilled water supply temperature from the building supervisor's office.
- Operate three chillers in a sequence which is changed periodically to equalize chiller operating times.

3. Determine which goals can be accomplished

Part I of this manual describes the various features and functions associated with the four different electronic interface possibilities. If a particular objective is not covered, it may still be possible. Chances are, however, that such objectives, while theoretically possible to achieve, are excessively troublesome to accomplish. Their economic justification should then be researched to avoid the "radar on a canoe" syndrome.

4. Establish the method you will use to accomplish each goal

This step will confirm that the goals are achievable, because a specific method of execution is defined. There may be more than one way to achieve a goal. In that case, the alternative ways must be measured and compared. Not all methods give exactly the same results. And, all do not cost the same.

Further, certain features are grouped. This permits the cost of one option to serve multiple functions. You will want to perform as much grouping as possible, for economical reasons.

How to Put the Parts Together

This section of the manual is a "cookbook".

- Reset chilled water supply temperature
- Remote system start/stop (timeclock)
- Remote alarm(s)
- Reset chiller electrical demand
- Remote monitoring
- Coordinated control of multiple chillers
- Control ice storage system
- Convert existing chiller(s) to permit coordination with new chiller
- Control or monitor Trane chillers from non-Trane BAS

Common objectives are listed. An explanation follows the objective.

Since there are only four pieces of hardware that are used (as indicated on page 3), these are our only "ingredients". The rest is "method".

Reset Chilled Water Supply Temperature

1. Automatic temperature resetting only. This is an optional feature of every CenTraVac equipped with the UCP695 control panel. This feature can be enabled or disabled at the chiller. Logic for resetting can be *load-based* or *ambient temperature-based.* Examples of the results of various reset schedules are shown by Figures 8 through 12.

    a. *To automatically reset the supply chilled water temperature of an individual chiller, use the load or ambient-based optional resetting capability of the CenTraVac control panel.*

2. Remote reset.

    a. *To remotely reset the chilled water temperature setpoint of a* ***single CenTraVac,*** *the Trane Remote Chilled Water Temperature Reset Module, described on page 3, is used.* This is a specific purpose device. It can perform no other function. One module is needed for each chiller, since a pair of communicating wires are tied directly into the 1U4 module in each chiller's control panel. No particular reset strategy is built into this module. Instead, it simply acts as a transducer that interprets an input analog signal and sends out the appropriate reset message directly to a CenTraVac UCP695 panel.

    If this is the only function desired, this is the least expensive way to achieve it. This solution can be applied to any number of multiple chillers. But, one module is needed for each chiller. All modules can be fed from a common analog resetting voltage (0-10 vdc.), or current (4-20 ma). The maximum amount of reset is +20 F.

    b. *Use the capabilities of SCP699 to reset the* ***system*** *chilled water temperature setpoint.* Temperature resetting is but one of the many SCP699 capabilities, as outlined on page 3. A more detailed explanation appears on page 6. Some examples are also shown.

    c. *Use a Tracer 100 or Tracer 1000, through SCP699,to reset the* ***system*** *chilled water temperature setpoint.* Since a Tracer-100 of Tracer 1000 interface through a SCP699 can perform everything that the SCP699 and UCP695 can, remote resetting by way of several strategies is possible. This is done via the bi-directional communications link, and thus does not interfere with other SCP699 functions.

    d. *Use a "generic BAS "through SCP699 to reset the* ***system*** *chilled water temperature setpoint.* Resetting through a "generic BAS" (to SCP699 equipped with the "sideboard" terminal strip) is explained on page 10. When this method is used to reset the chilled water temperature, most other SCP699 capabilities are lost. The maximum amount of reset is +20 F.

Remote System Start/Stop Timeclock

1. Unit-level control. Any CenTraVac requires chilled water flow in order to operate. Consequently, chilled water flow is a required electrical interlock. A CenTraVac will not start, or continue to run, without this interlock being closed.

    a. *An electrical contact in series with the flow interlock can be used to enable/ disable an individual CenTraVac.*

    While this is a simple way to execute remote start/stop commands, it contains an unwelcome flaw: Whenever this contact is opened, the CenTraVac microprocessor interprets the event as a flow stoppage and displays the appropriate diagnostic message. This presents no operational problem other than the misleading message.

2. System-level control. SPC699 embraces a sophisticated scheduling regimen, as explained on page 4.

   a. *Use the 7-day, 24-hour, scheduling capabilities of SCP699 to start and stop the complete chilled water system.*

   b. *Use Tracer 100 or Tracer 1000, through the SCP699 bi-directional communications link, to override established SCP699 schedules.*

   c. *Use binary enable/disable inputs to SCP699 (TB3) to turn the chilled water system on or off.* When this connection is made to SCP699, most other features are retained, as this binary connection does not interfere in the same way as the "generic BAS" interface does.

Alarms

1. Announce chiller diagnostic codes.

   a. *Use the standard CenTraVac control panel to display all chiller diagnostic codes.*

2. Remote annunciation of chiller alarm(s). Remote chiller alarm annunciation schemes cannot reset "latching" diagnostics. Any chiller trip that mandates manual resetting requires that the resetting occur at the effected chiller.

   a. *Use the optional "alarm relay package" on the CenTraVac control panel.* This set of dry contacts can be used to establish continuity in a remote alarm circuit. The signal does not define the nature of the alarm....only that the chiller is inoperative because one or more safety-related devices has tripped.

   b. *Use SCP699 to display all chiller diagnostics.* The full set of standard individual CenTraVac diagnostic codes is automatically displayed at the SCP699 when they occur.

   c. *Use Tracer 100 or Tracer 1000, through SCP699, to display all chiller diagnostics.* This arrangement duplicates the SCP699 monitoring capabilities described in the preceding paragraph.

   d. *Use Tracer Building Management Network, through a Tracer and SCP699, to permit a personal computer (IBM-PC or equivalent) to act as a remote monitor.* Tracers and the Network can be programmed to respond with an audible signal whenever any monitored variable strays outside a permitted range of values.

   e. *Use SCP699 "alarm relay" interface (to generic alarm) to indicate an SCP latching (requiring manual reset) diagnostics.* This connection will not alarm diagnostic conditions that occur at the chiller(s).

Reset Chiller(s) Electrical Demand

1. Individual chiller electrical current demand.

   a. *Reset the maximum current demand of an individual chiller at the **unit control panel.*** This is a manual adjustment made at the CenTraVac control panel.

   b. *Use SCP699 to reset individual chiller current limit values remotely.* This setting will supercede the unit control panel setting.

   c. *Use Tracer 100 or Tracer 1000, through SCP699, to set individual chiller current limit values.*

   d. *Use "generic BAS" interface (to SCP699) to set individual chiller current limit values.* Analog signals (4 - 20 ma. or 0 - 10 vdc.) sent to SCP699 are used to reset the current limits.

2. System-level electrical current demand.

   a. *To establish and maintain chiller(s) ampere demand limit based on the total full load currents of all chillers in the systems, use SCP699.* Whenever the established limit is met, SCP699 controls chiller inlet vane positions on all operating chillers so the limit is not exceeded.

b. *Use SCP699 to establish and maintain a* ***system power (kw) demand limit*** *based on the total power absorbed by the system.*

This method uses a system watt-hour/ pulse initiator to measure the system's instantaneous power level.

Whenever the established limit is met, SCP699 controls chiller inlet vane position on all operating chillers so the limit is not exceeded. Since chillers do not account for all power absorbed, their control over total power is not absolute. To make this strategy more responsive, the chillers must represent a majority of system power requirements.

c. *Use Tracer 100 or Tracer 1000 to perform system-level demand limiting via a connection to the system's power meter.* This concept is similar to the SCP699 method described above. In this case, however, Tracer performs electrical demand limiting on components both within and outside the chilled water system; eg. lights, heaters, etc.

Remote Monitoring

Several strategies of remote monitoring are possible. Major determinants are 1) the number of "points" to be monitored, 2) the nature of monitored items, and 3) the distance between the monitored item and the display. Any remote monitoring, using existing sensors, requires a system control panel SCP699 for communications.

1. <u>All monitored items are accessed by the CenTraVac or SCP699 panels.</u>

   a. *Use SCP699 to display all chiller and/ or system dignostics.* The full set of standard individual chiller diagnostic codes is automatically displayed at the SCP699 when they occur. In addition, the full set of system reports is accessible anytime at the SCP. Four system and as many as 3 chiller "status reports" are available at the SCP699.

   b. *Use Tracer 100 or Tracer 1000 to communicate SCP699 data to a separate telephone modem.* When the full sets of data referenced above need to be transmitted great distances (more than 5000 feet), or need to be sent to a location other than that of the SCP699, a telephone modem and phone line are required. A Tracer Building Management Network, using PC's as monitors, can also be connected to the modem.

2. <u>Monitored points are not restricted to the chiller(s) or the chilled water system.</u>

   a. *Use SCP699 and Tracer 100 or Tracer 1000 to gather data and display it or develop reports at the Tracer.*

   b. *Add Tracer Building Management Network, using PC's as monitiors, to the above equipment if monitoring location is remote from Tracer, or this location is one of several to be monitored.*

   c. *Add modem and telephone line to the above equipment if distances are great, or this location is one of several to be monitored.*

Coordinated Control Of Multiple Chillers

A wide variety of strategies can be used to fit a specific multiple chiller control concept. It is

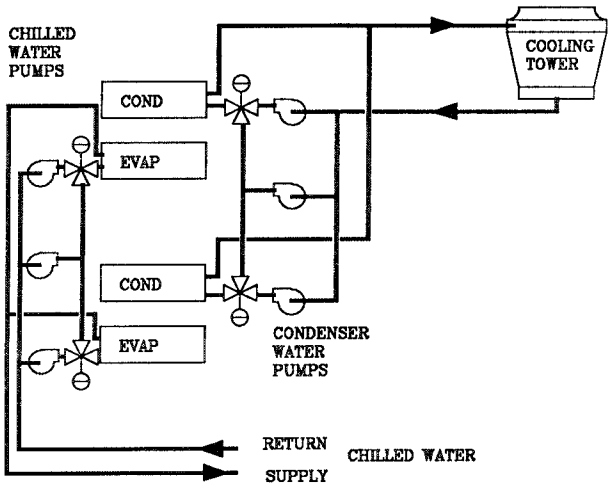

Figure 14

fundamentally crucial to have clear understanding of the physical system....the piping scheme, pumps, sequences of operation, etc. The first step is to make a schematic drawing of the piping and pumping sytem, including the loads and their control elements. This drawing should reduce the system to its most simple elements. A "ladder" diagram is often useful for this purpose. Figure 14 shows an example of a useful schematic drawing.

Next, a brief description of how the system operates should be written. It is often helpful to have someone other than the designer read this description for logic and clarity. Table 2 contains a brief description (not a specification) of the system shown in Figure 14.

Table 2

Two equally sized chillers are piped with evaporators in parallel. Each chiller is served by a dedicated chilled water pump. A third standby chilled water pump is piped and valved so that it can be used in place of either of the two dedicated pumps.
Condenser water pumps are likewise dedicated to a specific chiller and piped in parallel, with a third standby pump availble. Condenser water pumps take tower sump water, push it through its condenser, and send it to the top of the cooling tower, where it is cooled via evaporation and falls back into the sump. Control of condenser water supply temperature is accomplished by fan control separately.
The system is to be controlled by a system panel that sequences pumps and chillers on and off on the basis of load. This panel also changes chiller sequence automatically to equalize running time. The panel will maintain a common chilled water supply temperature.
The system is enabled and disabled by the system panel through a programmed schedule (timeclock function). Chilled water pumps are energized by the system panel. Condenser water pumps are sequenced by the chiller panel interlocking.

Once these steps are completed, the following list of possible combinations can be reviewed for a "fit". If no fit can be found, the two possibilities are: 1) the proposed system may not work, or 2) the proposed system may work but it will require custom engineering and design. And, it may require control devices that are not commonly available, or are improperly applied.

- 2 or 3 chillers, common parallel pumps (Fig. 15).
- 2 chillers, common series flow (Fig. 16).
- 2 or 3 chillers, dedicated parallel pumps (Fig. 14).
- 2 or 3 chillers, decoupled chiller and distribution pumps (Fig. 17).
- 4 or more chillers, decoupled chiller and distribution pumps (Fig. 18).
- any of the above applied to ***constant*** or ***variable*** system chilled water flow.
- any of the above applied to ***common*** or ***dedicated*** condenser water supplies.

Coordinated control of a multiple chiller system requires some kind of system controller. Individual chiller temperature controls are not capable of communicating directly with other chiller controls to establish a system control strategy.

SCP699 is specifically designed to function as a

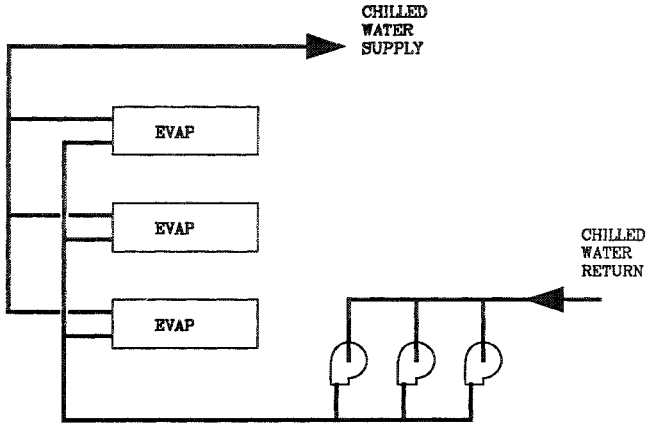

Figure15

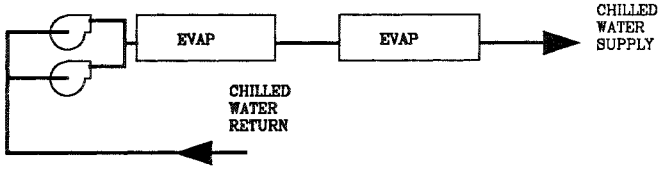

Figure 16

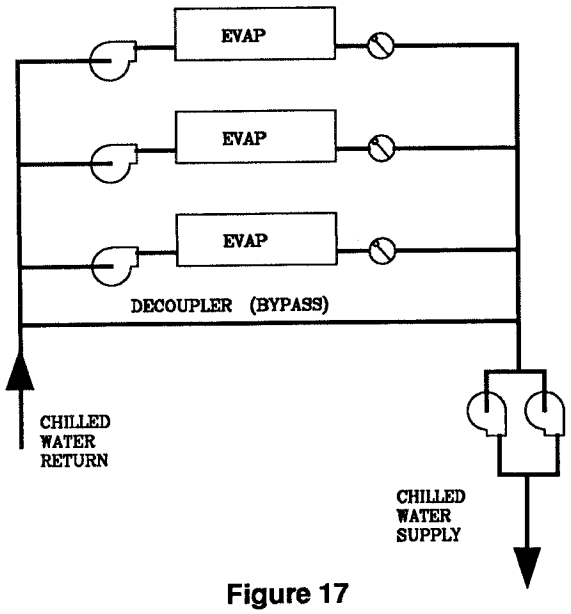

Figure 17

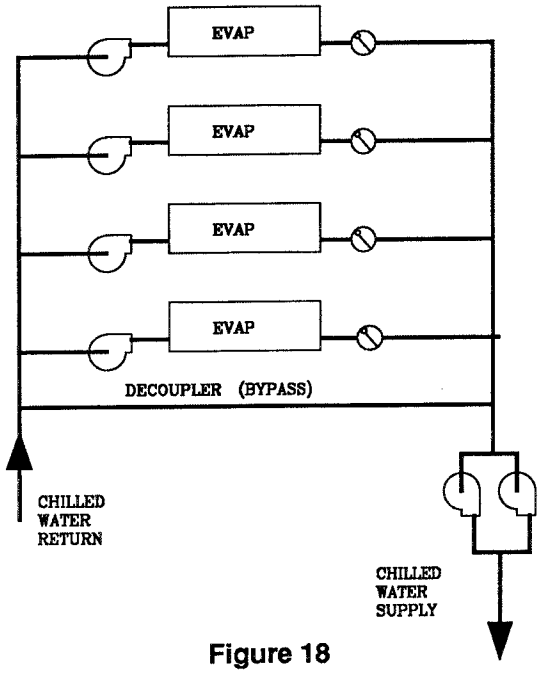

Figure 18

system controller. As is indicated in Table 1 on page 4, this is one of the 11 primary functions of SCP699. In order to set up SCP699 for any of the above named systems, follow the instructions included in the SCP699 Operator's Guide, CVMA-OG-1.

A single SCP699 can control up to 3 chillers. For coordinated control of 4 or more chillers, additional SCP699 panels are needed, a maximum of 3 chillers per panel.

Figure 15. 2 or 3 chillers, common parallel pumps. This arrangement is commonplace. Often, it is seen as using a single pump instead of multiple pumps. Chilled water pump(s) provide circulation in the chillers and the loads. Water flows through the evaporators of all chillers constantly. Loads are either "wild" coils or coils controlled by 3-way valves. This provides a constant flow of water throughout the system.

Since the common supply temperature is a mixture of water from each chiller, it is an average of all chillers, whether they are operating or not. This executes supply water temperature control if each chiller is controlled at a constant temperature. As system load decreases, individual chillers are unequally unloaded or turned off. Some designers feel that this provides "automatic reset" of the common supply temperature.

a. Using this philosophy, system control can be as simple as *using a return chilled water controller (actually, a thermostat) to establish the number of operating chillers.* Once established, the sequence of chiller operation can only be changed electrically with the equivalent of a dpdt switch (2 dpdt switches for 3 chillers) on the output of the controller.

b. *If more sophisticated control coordination or response is required, use SCP699 as a system controller.* See SCP699 Operator's Guide CVMA-OG-1 for details.

Figure 16. 2 chillers, common series flow. A single pump circulates water throughout the system. Flow is constant. Each operating chiller produces chilled water at a different temperature. The inoperative chiller simply allows water to pass through without a temperature change. A pressure loss is sustained in this process.

In its simplest form, coordinated control means setting each chiller for its design temperature. When the load raises the returning chilled water to a temperature high enough to start the downstream chiller, it starts and carries all the load it can. When the return temperature rises so far that the downstream chiller cannot carry the load, the upstream chiller will start. The re-

verse process occurs when the cooling loads decrease.

a. Alternate chiller sequencing may or may not be possible, depending on the specific selection of chillers. If all chillers are designed for the system common supply temperature, *sequencing (first chiller to start) can be changed by setting the temperature controllers for the upstream chiller lower than the downstream chiller.* While this is inelegant and cumbersome, it will work.

b. As in the case of parallel chillers, *a SCP699 panel will coordinate sequencing and alternating of series connected chillers.* This panel sequences chillers by a combination of resetting supply water temperature setpoints and chiller motor loading. Basically, the panel will lower individual chiller setpoints in an effort to maintain the common system supply temperature. A signal to start an additional chiller is given when exiting chillers indicate loading via their motor current consumption.

Figure 14, 2 or 3 chillers, dedicated parallel pumps. Pumps and chillers operate in dedicated pairs. Any given chiller will not operate without its pump, and vice-versa. As in the case of common chilled water pumps, system loads (coils) are either "wild" or controlled by 3-way valves. With this arrangement, system flow varies depending on the number of pumps and chillers running.

Simplistic coordinated multiple chiller control is difficult to achieve, because system loads (demand) are not easily found.

a. *Use SCP699 System Control Panel to coordinate the control of this system.* This controller uses chiller motor current to determine individual chiller loading, and the need for additional chiller capacity. It also sequences pumps appropriately with the chillers.

Figure 17, 2 or 3 chillers, decoupled chiller and distribution pumps. This arrangement dedicates chiller pumps to individual chillers. In addition, it dedicates a system distribution pump to the task of circulating all the water the system loads need. Usually, this flow varies with load changes. Individual chiller flows, however, are constant....either on or off.

a. Two fundamentally different control methods exist. The first scheme *uses a SCP699 to coordinate control of the chillers and all pumps.* As before, chiller sequencing signals are a consequence of motor loading. Since chiller/pump sequencing can dramatically change the perceived return water temperature at each operating chiller, load shifts occur relatively quickly. Thus, the chiller water temperature controller should be set for a faster than normal response time.

b. The second scheme uses the direction and amount of flow in the decoupling bypass water line to determine chiller/pump sequencing activity. A full explanation of the dynamics of this concept appears in Trane Application Manual CON-AM-21 (587). See Figure 14. A single "Annubar" flow measuring probe is used to detect both overflow and reverse flow in the bypass decoupler line. A "zero flow" signal is interpretted as reverse flow and causes the "Eagle-Eye" pressure switch to close and operate the cam switch motor in the direction of "more pumps". The "Eagle Eye" switch is set to close in the "overflow" mode when it detects flow of approximately 115% of the rating of the next pump to stop. *More elegant system control strategies are possible by using a Tracer 100 through SCP699.* When bypass flow is used as the sequencing determinant, the electric outputs of the flow meter (either binary or analog) are fed into the Tracer for processing. SCP699 can still be used for system duties other than coordinated control, which is assumed by the Tracer 100 with this scheme.

c. An alternate approach is to use *Tracer 100 analog temperature inputs*, per Figure 19. These values are then

processed by the Tracer to calculate flows without ever actually measuring them. Classic temperature and flow mixing equations are used. Appropriate timing functions are also included in the Tracer programming.

Figure 18. 4 or more chillers, decoupled chiller and distribution pumps. Once a system reaches this size, it is usually large and complex enough for the power of a Tracer 1000. SCP699 capbilities are limited to monitoring functions only. A

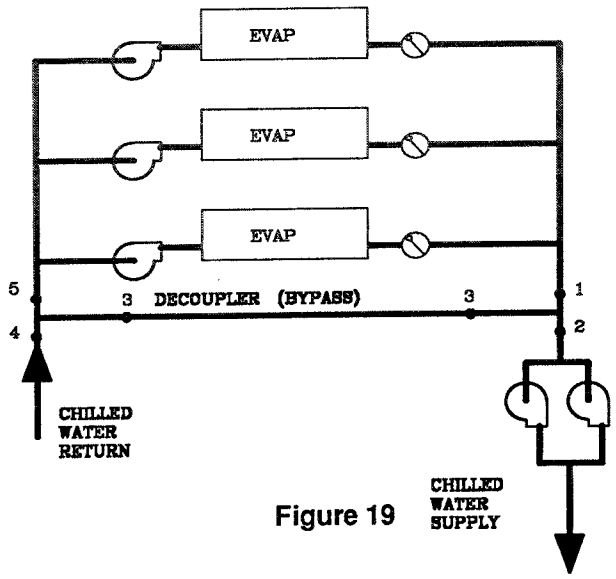

Figure 19

Tracer 100 can accept a "twisted pair" connection to only one SCP699. Therefore, a system of 4 or more chillers would require multiple Tracer 100/SCP699 pairs to accomplish all 11 functions listed in Table 1,page 4, plus remote monitoring.

a. *Use Tracer 1000 to connect multiple SCP699 panels via the "twisted pair".* This scheme permits the Tracer 1000 to function as a single point BAS for all chiller system functions.

b. *Use the mechanical system described on page 18 to sequence multiple chillers and chilled water pumps.* This concept is more thoroughly explained on pages 7 and 8, CON-AM-21 (587). Temperature control remains confined to the individual chillers. System scheduling can be accomplished by a simple "time-clock" to enable the step controller shown in Figure 16, page 8, CON-AM-21 (587).

Ice Storage System Control

The control of only one of several possible ice storage systems is explained here. Figure 20 shows a CenTraVac applied to Calmac® tanks. This system is described more fully in Application Manual SYS-AM-10.

Control strategy focuses on several characteristics of this system:

1. It is not possible for a CenTraVac to "overcool" the chilled anti-freeze solution so

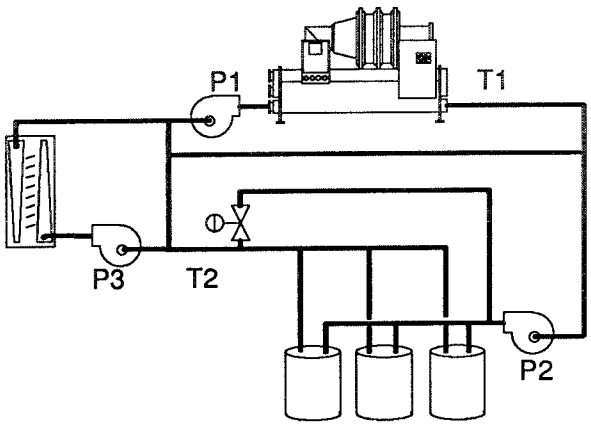

Figure 20

long as the water in the tanks is a liquid.

2. Completion of the tank "freeze cycle" is accompanied by a dramatic and sudden reduction in return chilled solution temperature.

3. The system can have 5 modes of operation:

a. **Build ice.** In this mode the chiller has this one objective. Since this mode occurs when electric energy and demand are at minimum cost, the chiller is allowed to operate without power or temperature restrictions. The chiller temperature controller is reset to a value which it may not be able to reach. In this way, the chiller will run at its maximum capacity for these conditions.

b. **Burn ice.** In this mode, ice is melted by the system chilled water load. The chiller is not operating because this mode of operation occurs at a time when the energy cost of chiller

operation is being avoided.

c. **Build and cool.** Some systems require cooling while the ice is being stored. In this case, the chiller must be capable of accepting the added system load and reaching the output temperature required for ice production, **simultaneously**. This requires the added chiller capacity and the ability to modulate capacity as the cooling load changes.

d. **Burn and chill.** Many ice storage systems employ "partial storage" or "load leveling" as a way to lower energy costs. This scheme involves loading the chiller 24 hours a day to meet design load conditions. During the day, then, system loads are satisfied by melting ice **and** operating the chiller. Further, this strategy permits anticipation of future loads so as to optimally select the lowest cost way (ice or instantaneous chilling) to produce cooling capacity.

e. **Direct cool; save ice.** "Partial storage" systems require some way to save stored ice for a particular high demand period of the day. For example, the chiller can be piped to provide instantaneous cooling directly to the load during morning hours. In the afternoon, when other electrical loads peak, the chiller is either modulated or turned off to allow stored ice to meet the loads.

Table 3

Mode	P1(gpm)	P2(gpm)	P3(gpm)	T1(F)	T2(F)
1	1000	1000	OFF	24	-
2	OFF	1000	800	OFF	40
3	1000	1000	800	24	-
4	1000	1000	800	40	40
5	1000	OFF	800	40	-

Table 3 shows the various pump, valve and control settings to accomplish each of these modes of operation. (See Figure 20).

To automate system control, use SCP699 and Tracer 100. SCP699 is used, with or without multiple CenTraVacs, to permit full bidirectional communications with the Tracer 100 BAS. Tracer is equipped with custom software to execute the above 5 modes of operation at the appropriate times. Tracer software is available in "pattern" form for individual project customization.

"Fail-Safe" Communications

When SCP699 is used as the system controller, it is serially connected to each CenTraVac control panel. If, for any reason, SCP699 communications are lost or interrupted, all CenTraVac controls revert to their own individual settings. Chillers and pumps that were running continue to operate. Idle pumps, and their interlocked chillers, will not start unless they are manually started.

Convert existing chiller(s) to permit coordination with new chiller.

Increasing numbers of chiller installations are additions to or renovations of existing chilled water systems. Consequently, the retrofit of existing chillers to be compatible with the new technologies is an important capability.

Any electrically driven centrifugal chiller can be converted to "look like" a new CenTraVac to the control system. Usually, this conversion involves replacing or reworking the following subassemblies:

1. The chilled water temperature controller
2. The chiller control panel
3. The compressor inlet vane modulation mechanism
4. The compressor motor starter

It is not a trivial project to make the necessary conversion. But, it is often a very worthwhile goal to integrate the complete chilled water system. Accomplishing any or all of the objec-

tives listed on page 12 is difficult, if not impossible, without this integration.

Control,Or Monitor,Trane Chillers From Non-Trane BAS

The "language and protocol" of both the CenTraVac UCP695 and SCP699 are unique. The reason for this has nothing to do with a desire to hold them "secret". Instead, it is a matter of cost. Communications from one microprocessor to another can be done in a variety of ways. Numerous standards exist. One such generic communication standard, for example, is commonly known as "RS232". Everyone familiar with personal computers has heard of "RS232". It could be used to handle all control communications as well.

However, RS232 requires considerable "translation" at both ends of the communications line. Translators are quite expensive, compared to the rest of the microelectronics apparatus in HVAC controls. Therefore, manufacturers normally do not incorporate them in their products. It represents an unnecessary cost burden, whereas the communications protocol Trane uses does not require a translator between microprocessors. The disadvantage, of course, is that the "conversation" is proprietary.

SCP699 is equipped with limited translator capabilities. It is able to communicate with generic control systems through the "generic interface" described on page 10. As indicated, this interface employs specific binary and analog signals, and does not use any particular microelectronics industry communication standard designation, such as RS232 or RS485. The SCP generic interface is a **control** interface, and is **not** intended as a **monitor** interface.

Control, through a generic interface, can be accomplished by:

a. *Use the SCP699 "generic interface" to permit non-Trane BAS to control*:

   (1) System enable/disable

   (2) Free-cooling enable/disable

   (3) Chilled water temperature (unit-level setpoints)

   (4) Current limit (unit-level setpoints)

Several methods permit "generic" **monitoring** of Trane chillers. To gain access to any of the existing CenTraVac control points (sensors), SCP699 must be used. Other monitoring is separate and does not involve either UCP695 or SCP699.

a. *Use Tracer 100 (or Tracer 1000) through SCP699 to output all monitored CenTraVac points through the Tracer RS232 port.*

b. *Use separate hardwired sensors to monitor parameters that are not monitored CenTraVac points.*

Model Number Description

All standard Trane products are identified by a multiple-character model number that precisely identifies a particular type of unit. An explanation of the alphanumeric identification code used with CenTraVac SCP699 System Control Panels is provided below. Its use will enable the owner/operator to define the components, operation and options for a particular unit.

Be sure to refer to the model number stamped on the unit nameplate (shown below, and mounted on the bottom of the panel) when ordering replacement parts or requesting service.

General Information

Literature Change History

CVMA-OG-1 (October 1986)
Original issue of manual; provides start-up, operation, programming, maintenance and troubleshooting information for "A"-design Model CVMA System Control Panels (i.e., SCP699).

CVMA-OG-1A (January 1987)
Revised original manual to remove unnecessary cautions relating to shorted battery terminals from "Maintenance and Trouble Analysis" section; also corrected several typos.

About this Manual

This booklet describes the proper start-up, operation and programming procedures for Model CVMA CenTraVac System Con trol Panels (i.e., SCP699). By carefully reviewing this information and following the instructions given, the owner/ operator can successfully use the SCP699 panel to govern up to 3 CVHE or CVHB chillers equipped with UCP695 control panels.

A "Maintenance and Trouble Analysis" section at the end of this manual describes the minimal maintenance requirements associated with the SCP, and provides troubleshooting information for system-level diagnostic conditions. (Refer to the chiller operation/ maintenance manual when troubleshooting unit-level diagnostic conditions.)

If equipment problems do occur, however, contact a qualified service organization to ensure proper diagnosis and repair.

Notice that an "SCP Operator Reference Guide"–summarizing SCP report and programming menus–is provided at the back of this booklet, and is designed to aid the experienced SCP operator.

Note: To ensure that this operator's guide remains with the SCP once it is installed, store it behind the panel. Rails are mounted on the back of the panel enclosure (i.e., at the top and bottom) for this purpose.

Commonly Used Acronyms

For convenience, the Model CVMA SCP699 System Control Panel is referred to simply as the "SCP" or "SCP699 panel" throughout the rest of this manual.

Other acronyms that appear in this operator's guide are listed (alphabetically) and defined below.

BAS = Building Automation System
BCL = Bidirectional Communication Link

CLS = Current Limit Setpoint
CWR = Chilled Water Reset
CWS = Chilled Water Setpoint

FC = Free Cooling

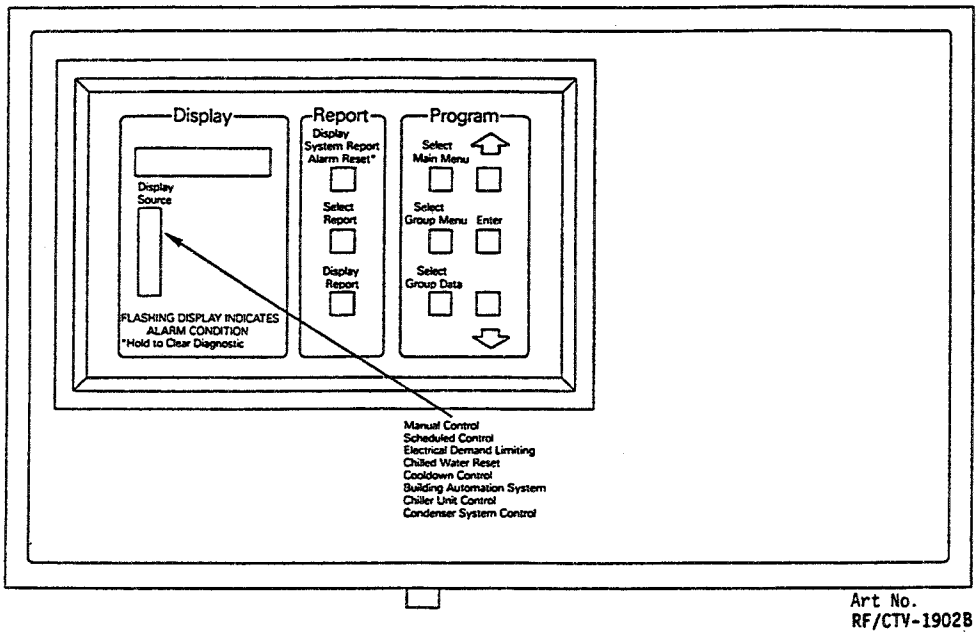
I/O = Input and Output Wiring

NEC = National Electric Code

RLA = Rated Load Amps
RSCWS = Reset System Chilled Water Setpoint

SCLS = System Current Limit Setpoint
SCWS = System Chilled Water Setpoint

Tracer = Type of Trane building automation system (BAS) frequently used to govern chiller system operation via an SCP.



UCLS = Unit Current Limit Setpoint
UCP695 = Microcomputer-based Chiller Control Panel
UCWS = Unit Chilled Water Setpoint

Warnings and Cautions

Notice that **warnings** and **cautions** appear at appropriate intervals throughout this manual. **Warnings** are provided to alert operating and service personnel to potential hazards that could result in personal injury or death, while **cautions** are designed to alert personnel to conditions that could result in equipment damage.

Your personal safety and the proper operation of this system depend upon the strict observance of these precautions.

Figure 1
SCP699 Panel Operator Interface

Art No.
RF/CTV-1902B

SCP699 System Control Panel Overview

The Trane CenTraVac SCP699 System Control Panel (Figure 1) is a computerized, operator-programmable control system intended to operate 1, 2 or 3 centrifugal water chillers as a single system. It is specifically designed for use with Model CVHE or CVHB units equipped with microcomputer-based UCP695 control panels.

Among the standard capabilities of the SCP699 System Control Panel are these:

[ ] a "user interface" that gives the operator access to data available within the chiller system;

[ ] coordinated control--including lead/lag sequencing--of up to 3 CenTraVac chillers with UCP695 control panels (i.e., 3 chillers piped in parallel; 2 chillers piped either in series or parallel);

[ ] maintains system chilled water temperature by regulating chiller loading to meet building cooling requirements;

[ ] scheduled system operation on a 7-day, 24-hour basis, plus holiday scheduling;

[ ] "soft loading"/cooldown control (i.e., to minimize electrical demand peaks);

[ ] system chilled water reset;

[ ] electrical demand limit control;

[ ] a proprietary, bidirectional communications link (i.e., to connect the SCP699 panel with a Tracer® building automation system);

[ ] manual chiller control from a central location; and,

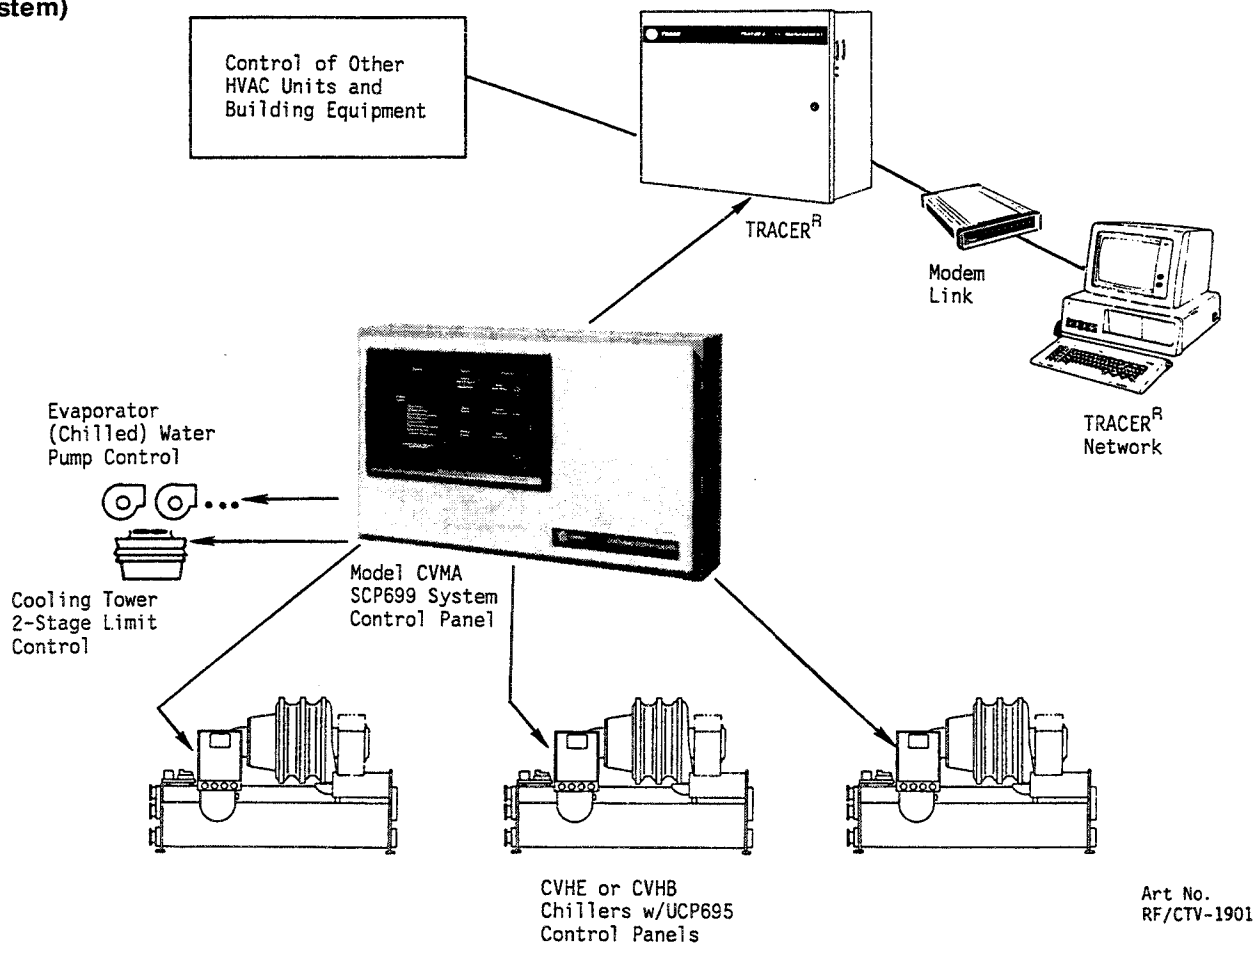
[ ] control of these auxiliary chiller system components:

a. up to 4 chilled water pumps (i.e., 3 for individual chillers plus 1 system pump), and,

b. condenser water pumps (i.e., via the chiller UCP695 control panels).

Several SCP699 control options are also available; these include:

[ ] cooling tower 2-stage limit control;



[ ] thermostatically-controlled, automatic free cooling control; and,

[ ] an analog interface that allows an external analog controller or generic BAS to govern chiller operation.

Refer to the "Operation" section of this manual for explanations of each of the standard and optional SCP699 capabilities outlined above.

For an illustration of a typical SCP699 System Control Panel application, see Figure 2.

Figure 2
Typical SCP699 Application (w/Trane Building Automation System)

After the SCP699 panel is properly installed, several switches–both in the SCP699 and at each of the chiller UCP695 control panels–must be set up before the system is started. Follow the step-by-step instructions provided below.

SCP699 DIP Switch Setup

WARNING: To prevent injury or death due to electrical shock, lock power supply disconnect open before removing SCP panel enclosure. It may be necessary to open several disconnects to remove all connected power from SCP.

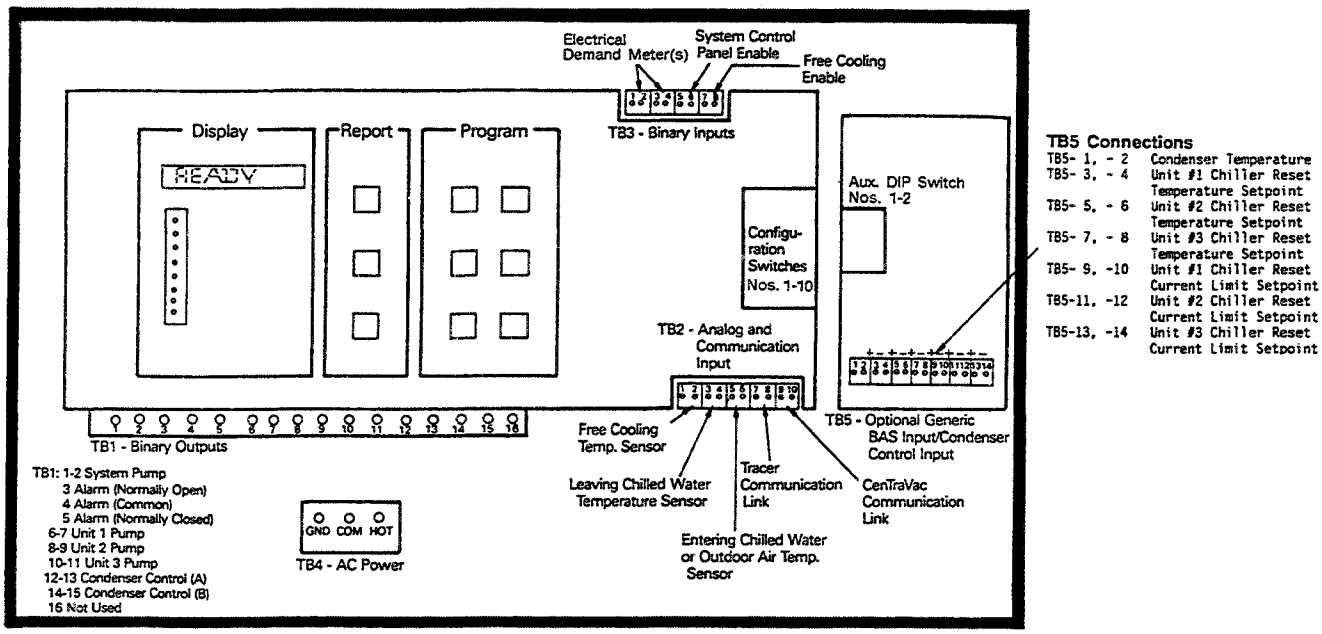
1. Remove the 5 screws that secure the control panel enclosure to the panel back plate; then remove the enclosure from the SCP699.

2. Find the SCP699 configuration switches; see Figure 3. (These switches–numbered 1 through 10–are located to the right of the "Program" block, directly above terminal strip TB2.)

Note: Notice that 2 additional configuration switches are located on the SCP's sideboard. (The optional sideboard is provided whenever the generic BAS or condenser control options are specified.)

3. Refer to Table 1; notice that 11 of the 12 "configuration" DIP switches must be properly set at either ON or OFF. Each of these switch settings is discussed briefly below (i.e., and summarized in Table 1).

a. Pump Relay Command. To ensure proper operation of the system and unit chilled water pumps, DIP Switch No. 1 must be set in the OFF (i.e., "normal") position.



b. Alarm Relay. With DIP Switch No. 2 set at the OFF (i.e., "normal") position, the alarm relay is normally de-energized, and will energize when an alarm condition occurs.

Conversely, the alarm relay is normally energized when DIP Switch No. 2 is in the "reverse" (i.e., ON) position, and will de-energize when an alarm condition is detected.

c. Degrees F/C Display. The position of DIP Switch No. 3 determines what units the SCP will use to display temperatures. Degrees Fahrenheit (F) are displayed when DIP Switch No. 3 is in the OFF position. With this switch set at ON, temperatures are displayed in degrees Centigrade (C).

d. Chilled Water Reset (CWR). DIP Switch No. 4's position determines how the SCP will calculate a new system leaving chilled water temperature using its chilled water reset control function.

Figure 3
SCP699 Terminal Strip Connections

Note: Run the wires for all TB2, TB3 and TB5 connections through the low voltage conduit.

Art No.
RF/CTV-1903

Whenever the CWR setpoint (i.e., "SET = ") is ≤ 25 F, the SCP uses the following load-based equation to determine the reset system chilled water setpoint whether DIP Switch No. 4 is set at OFF or ON.

RSCWS =
SCWS + RATE [CWR SET + STMP - AUXTMP]

where:
RSCWS = Reset System Chilled Water Setpoint
SCWS = Sched./BAS System Chilled Water Setpoint
RATE = Operator-Set CWR Rate
CWR SET = Operator-Set CWR Setpoint Temp.
STMP = Actual Lvg. Chilled Water Temp.
AUXTMP = Actual Ent. Chilled Water Temp.

If the CWR setpoint temperature is > 25 F, then chilled water reset is solely a function of outdoor ambient temperature. When DIP Switch No. 4 is set at OFF (i.e., "normal"), the SCP uses this equation to calculate a new chilled water setpoint:

RSCWS = SCWS + RATE [CWR SET - AUXTMP]

Setting DIP Switch No. 4 at ON (i.e., "reverse") when the CWR setpoint is > 25 F causes the SCP to determine a new chilled water setpoint with this equation:

RSCWS = SCWS + RATE [AUXTMP - CWR SET]

Note: Control logic prevents the SCP from establishing a reset chilled water setpoint that is lower than the original value.

See "Chilled Water Reset" in the SCP699 Operation section of this manual for a further explanation of the CWR control function.

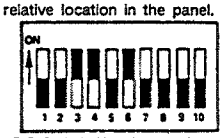
e. BCL Address. DIP Switch Nos. 5, 6, 7, 8 and 9 are used to "tag" the SCP699 panel with an identification number, and are not used unless the SCP is connected to a Trane BAS (i.e., building automation system [Tracer®]).

For your reference, the DIP switch positions corresponding to SCP address numbers of 0 through 31 are provided in Table 2.

Note: "BCL" is used throughout this manual to represent the "bidirectional communication links" that enable the SCP to exchange data with the UCP695 chiller control panels and a Trane BAS.

f. DIP Switch No. 10 is not used, so either switch position (i.e., ON or OFF) is permissible.

g. Condenser Limit Enable. To enable the SCP's optional condenser limit control function, sideboard DIP Switch No. 1 must be positioned at ON. (Field-installation of up to 3 condenser refrigerant temperature sensors is also required; see "Condenser Limit Option" on page 68.)



h. Generic BAS Enable. Positioning sideboard DIP Switch No. 2 at ON allows a generic BAS to interface with the SCP.

Note: Enabling the generic BAS option disables a number of standard SCP control functions; see "Generic BAS Option" on page 63 of this manual.

Table 1
SCP699 "Configuration" Switch Settings (1,4)

DIP Switch No.	DIP Switch Function	Switch Position ON	OFF
1	Pump Relay Command (2)	Service	Normal
2	Alarm Relay	Reverse (NC)	Normal (NO)
3	Degrees F/C Display	Degrees C	Degrees F
4	Chilled Water Reset Mode (3)	Reverse	Normal
5, 6, 7, 8, 9	Address for Bidirectional Communication Link (BCL) with Trane BAS	See Table 2 for DIP switch settings.	
10	Not Used	Either switch position is acceptable.	
1 (Aux.)	Opt. Condenser Limit Control (4)	Enabled	Disabled
2 (Aux.)	Opt. Generic BAS Interface (4)	Enabled	Disabled

Notes:
1. This illustration represents the SCP699 panel's 10 standard "configuration" DIP switches; refer to Figure 3 for their relative location in the panel.

2. Standard "configuration" DIP Switch No. 1 must be positioned at OFF (i.e., normal) to ensure proper chilled water pump operation.
3. The SCP assumes load-based chilled water reset operation when the CWR setpoint is ≤ 25 F, and ambient-based CWR when the CWR setpoint is > 25 F. Control logic for either type of CWR always results in a system chilled water setpoint that is ≥ the scheduled (or Tracer-issued) setpoint.
4. Auxiliary DIP Switch Nos. 1 and 2 are located on the SCP's optional sideboard; Figure 3 indicates their relative location.

Setup for SCP Condenser Relay Rotary Switches (Optional)

When equipped with the condenser option, a "condenser water control/generic BAS analog interface" sideboard is factory-installed inside the SCP's panel enclosure. Four rotary-type switches on this sideboard allow the system operator to set up "open" and "close" values for the contacts of Condenser Relays A (CRA) and B (CRB).

For an explanation of the condenser limit control function--along with an illustration of the sideboard, and available rotary switch settings--see "Condenser Limit Option" (page 68).

UCP695 DIP Switch Setup (Unit Address)

WARNING: To prevent injury or death due to electrical shock, always open unit disconnect switch before opening control panel door.

Each UCP695 chiller control panel connected to the SCP699 must be "tagged" with its own unique address (i.e., either "1", "2" or "3"). This address number is assigned by setting DIP Switch Nos. 1 through 5 on switch block S11.

To access DIP switch block S11, open the unit control panel door and remove the access cover strip located at the top of the micro module. See Figure 4. Notice that S11 is located in the upper left-hand corner of micro module 1U3.

Caution: To ensure proper chiller operation, never tamper with any UCP695 controls located behind panel door without first consulting a qualified service technician.

Refer to Table 3 for S11 DIP switch settings. Since no more than 3 chillers can be connected to any one SCP699 panel, only 3 addresses/switch combinations are listed.

Remember that all chillers communicating with an SCP must have separate, unique addresses. If 2 or more units connected to an SCP share the same address--or if a unit is tagged with an address other than "1", "2" or "3"--communications are automatically terminated.

Note: When only 1 chiller is connected to the SCP--and the SCP's system leaving chilled water temperature sensor is not installed, that unit must be given a chiller address of "1". The SCP will not govern system operation if the S11 DIP switches are "configured" to any other address number!

Table 2
BCL Address/DIP Switch Settings for SCP699 Panel (See Note 1)

SCP699 "Configuration" DIP Switch Nos.					Corresponding SCP Address
No. 5	No. 6	No. 7	No. 8	No. 9	
ON	ON	ON	ON	ON	0
ON	ON	ON	ON	OFF	1

OFF	OFF	OFF	ON	ON	28
OFF	OFF	OFF	ON	OFF	29
OFF	OFF	OFF	OFF	ON	30
OFF	OFF	OFF	OFF	OFF	31 (2)

Notes:
1. "Configuration" DIP switch nos. 5 thru 9 are only used to establish a bidirectional-communication-link (BCL) address when the SCP699 panel is connected to a Trane building automation system.
2. When connected to a Tracer 100 system, the SCP's address must be "31".

SCP/UCP Communication Check

Once DIP switch setup at the SCP and chillers is complete, verify that the SCP is communicating with each of the chillers.

1. Adjust the chiller switch on each UCP695 chiller control panel to the "Standby/Reset" position.

2. Apply power to each of the UCP695 panels; then power up the SCP. (It will be necessary to close several disconnect switches.)

Operating codes A 88 and A 0, respectively, should appear on the UCPs, and the "READY" message should be displayed at the SCP.

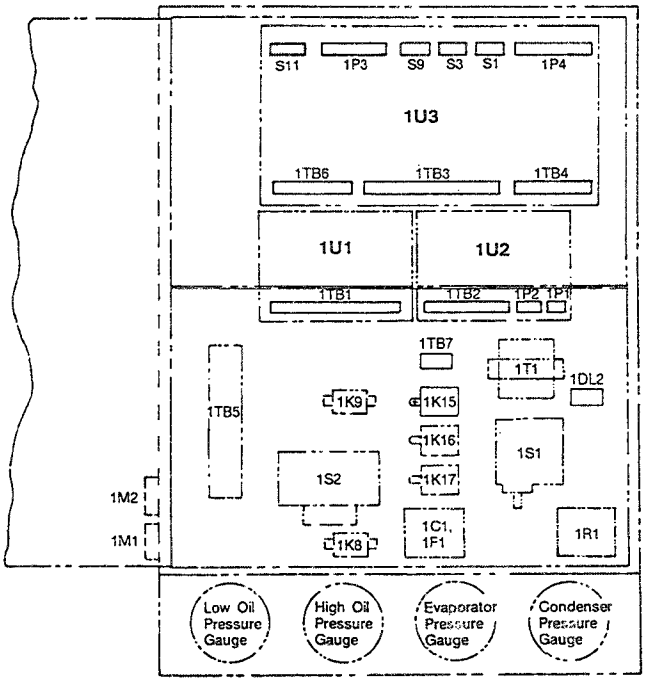
3. Display the SCP's preformatted "Chiller" report.

To do this:

a. press the "Select Report" key (Figure 1) until "CHILLER" appears on the display; then,

b. press the "Display Report" push button. The SCP should now display the operating status of each connected chiller (i.e., UNIT 1, UNIT 2, UNIT 3).

Communication has not been established with a chiller if it is omitted from this report. If this occurs, refer to "Troubleshooting Charts" on pages 71 and 72 of this manual.



* * * * *

Note: Once you have successfully verified communication between the SCP and chillers, adjust the chiller switch on each UCP695 panel to the "Auto/Remote" position before programming the SCP.

ON	ON	ON	ON	OFF	1 (3)
ON	ON	ON	OFF	ON	2
ON	ON	ON	OFF	OFF	3

Notes:
1. No more than 3 chillers can be connected to any one SCP699 panel.
2. All chillers communicating with an SCP must have separate, unique addresses. If 2 or more units connected to an SCP share the same address, communications are automatically terminated.
3. In single-chiller system applications, that unit must be assigned an address of "1" if the SCP's system leaving chilled water temperature sensor is not installed. If any other unit address is assigned, the SCP will not govern system operation.

SCP699 Operator Interface

Overview

The operator interface portion of the SCP699 panel is comprised of an 8-character, alphanumeric display, 8 status indicator lights, and 9 pushbutton switches. All of these devices are accessible without removing the panel front cover. See Figure 1.

Notice that the SCP interface is divided –by function–into 3 groups of related elements:

[ ] the **Display** group, which consists of the 8-character, alphanumeric display and 8 system status indicator lights;

[ ] the **Report** group, which consists of 3 pushbuttons (i.e., "Display System Report/Alarm Reset*", "Select Report" and "Display Report"); and,

[ ] the **Program** group, which consists of these 6 pushbutton switches–"Select Main Menu", "Select Group Menu", "Select Group Data", " ↑ " (increase), "Enter" and " ↓ " (decrease).

Each of these categories is described in detail in the following paragraphs.

"Display" Interface (Figure 5)

Alphanumeric Display

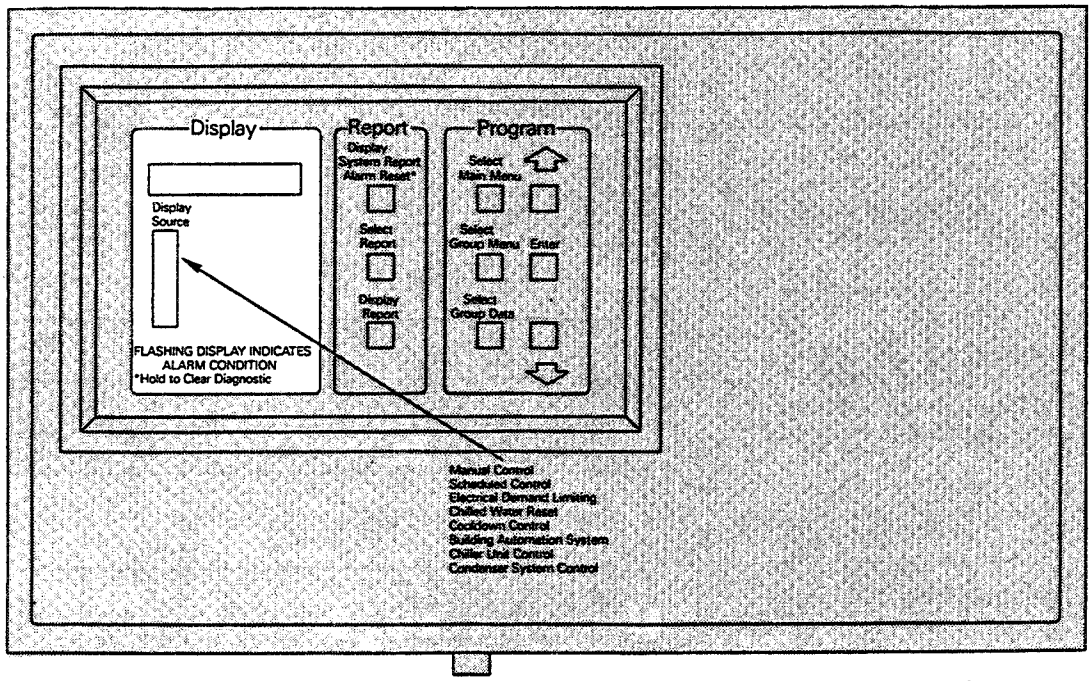
An 8-character, alphanumeric, vacuum-fluorescent display is provided in the horizontal window of the SCP's "Display" block. It allows the operator to:

[ ] check the current system operating status;

[ ] program or display system and individual chiller operating parameters; and,

[ ] view a number of preformatted system and chiller status reports.

Four 1-line messages automatically appear on the display to indentify the present system operating status:



1. **READY** (i.e., no cooling operations are scheduled; or, the SCP is unable to issue chiller control information).

2. **STARTING** (i.e., the SCP is attempting to start a chiller).

3. **INHIBIT** (i.e., the SCP is attempting to bring a chiller on-line, but can't because the unit's restart inhibit period has not yet expired).

4. **COOLING** (i.e., displayed when none of the conditions described in Items 1 through 3 exist).

Figure 5
SCP "Display" Interface

Art No.
RF/CTV-1902B

Note: If the SCP detects an error at the system level, it flashes the system status message appearing on the alphanumeric display and energizes the alarm relay until the "Display System Report/Alarm Reset*" button is pressed. (See Table 4 in "Report Interface" for a list of system-level diagnostic codes and corresponding errors.)

In addition to the 4 system status messages, a number of reports and programming entries can be read in the alphanumeric display window. Since the display is limited to 8 characters, a number of these entries consist of 2 or 3 lines that appear one at a time. For instance, the chilled water reset setpoint is a 2-line display that appears as "RESET", then "TEMP = 48"; the "Chilled Water Reset" status indicator light also illuminates while these entries are displayed.

Note: An "ERROR" message momentarily appears on the alphanumeric display if any of these keys are pressed while the system status message is shown–

[ ] the "Display Report" key;
[ ] the "Select Group Menu" key;
[ ] the " ↑ " (increase) key;
[ ] the "Enter" key; and,
[ ] the " ↓ " (decrease) key.

The present system status message then returns to the display.

If the "Select Group Data" key is pressed while the system status message is displayed, the SCP will test all segments and characters of its alphanumeric display by illuminating "********" for 1 second, followed by "0,0,0,0,0,0,0,0," for 1 second. (Notice that all status indicator lights also illuminate during this 2-second test.) The current system status message returns to the display once the 2-second display check is complete.

For more specific information about the alphanumeric displays used in the SCP's reports, see "Report Interface". The "Program Interface" section of this manual describes the alphanumeric displays that will appear while programming the SCP699 panel.

Status Indicator Lights

A series of 8 status indicator lights are also located in the SCP's "Display" block, directly below the horizontal alphanumeric display window. These blue lights–along with the information presented on the 8-character display–allow the operator to monitor system operation. The purpose of each status indicator light is described below.

Note: No more than 1 status indicator light is ever illuminated at any given time (i.e., unless the SCP malfunctions). If the value of a displayed operating parameter is derived from more than 1 control function, the illuminated status light indicates which control function influenced that value last.

[ ] Manual Control. Illumination of this light indicates that the operating parameter appearing on the alphanumeric display was manually set at the SCP and is not a "scheduled" system setpoint.

[ ] Scheduled Control. This light only illuminates when the operating parameter appearing on the alphanumeric display was established with the SCP's schedule function (i.e., consisting of a 7-day operating list of system chilled water setpoints and "setback" times).

[ ] Electrical Demand Limiting. Illumination of this status light indicates that the displayed operating parameter was established with the SCP's electrical demand limit function.

[ ] Chilled Water Reset. When this light glows, the displayed operating parameter was established with the SCP's chilled water reset function.

[ ] Cooldown Control. The operating parameter that appears on the alphanumeric display while this status light is on was established with the SCP's cooldown control function.

[ ] Building Automation System. Illumination of this light indicates that the displayed operating parameter was set at the building automation system (BAS) level.

[ ] Chiller Unit Control. This status indicator light illuminates whenever the operating parameter shown on the alphanumeric display is governed by the UCP695 control panel of that particular chiller (i.e., Unit 1, Unit 2 or Unit 3).

[ ] Condenser System (Limit) Control. When this status indicator light is on, the displayed operating parameter (i.e., refrigerant temperature differential between the evaporator and condenser [HEAD]; or, the common entering condenser water–or outdoor ambient–temperature [TEMP]) is being monitored by the SCP as a part of the optional condenser limit control function.

"Report" Interface (Figure 6)

Use of the 3 push buttons in the SCP's "Report" block enables the operator to view as many as 7 preformatted status reports (i.e., 4 system reports, and up to 3 chiller reports).

Each of these reports are described briefly in the following paragraphs; for a summary of SCP report access and contents, refer to the flow chart in Figure 7.

System (Status) Report

Pressing the "Display System Report/ Alarm Reset*" push button allows the operator to sequentially view the system operating parameters–itemized below–on the alphanumeric display.

Notice that the SCP automatically advances from one system status report entry to the next; after the last entry appears, the present system status (e.g., READY, COOLING, INHIBIT, etc.) returns to the display.

When applicable, a status indicator light also illuminates, enabling the operator to determine the source of the displayed characteristic.

Note: Each system status report entry below appears as it does on the SCP699 alphanumeric display.

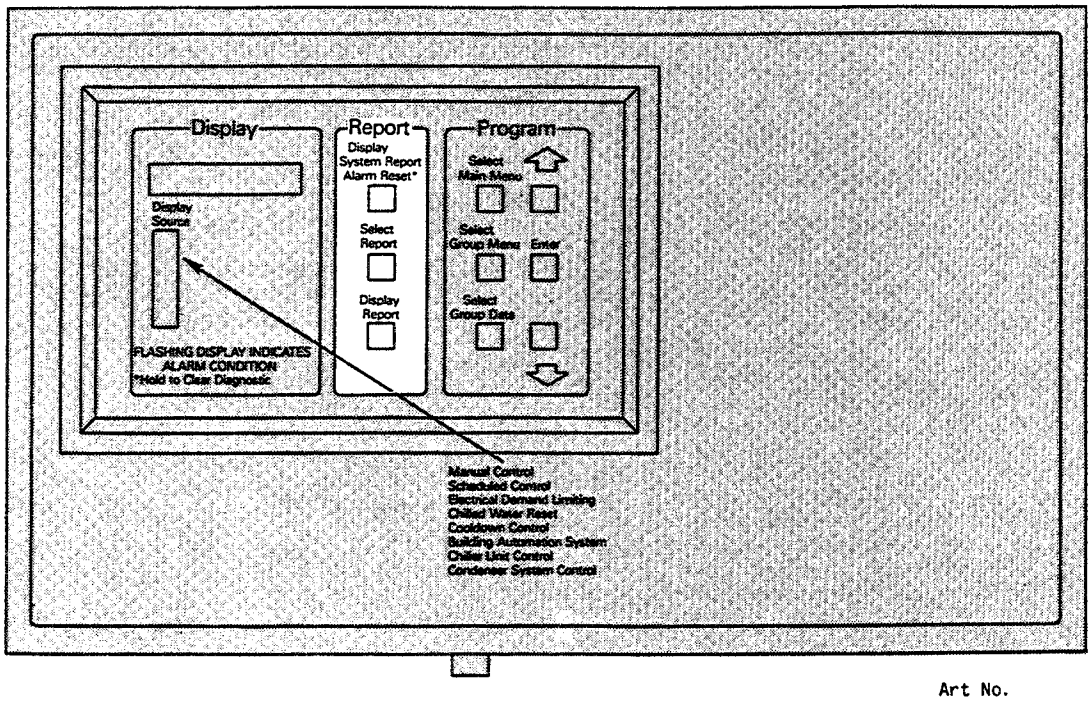
1. System Chilled Water Temperature and Setpoint. This 4-line report entry indicates:

a. the temperature registered by the SCP sensor field-installed in the common system leaving chilled water line; and,

b. the "active" system chilled water temperature setpoint. Illumination of the appropriate status indicator light identifies the source of this setpoint (e.g., manual control, scheduled control, chiller unit control, etc.).

Note: If the SCP controls only a single chiller–and a system temperature sensor is not installed, "UNIT 1" is substituted for "SYSTEM" throughout the report. Also, the "FREECOOL" message appears on the display in lieu of a setpoint value if the system is presently operating in the automatic free cooling mode.

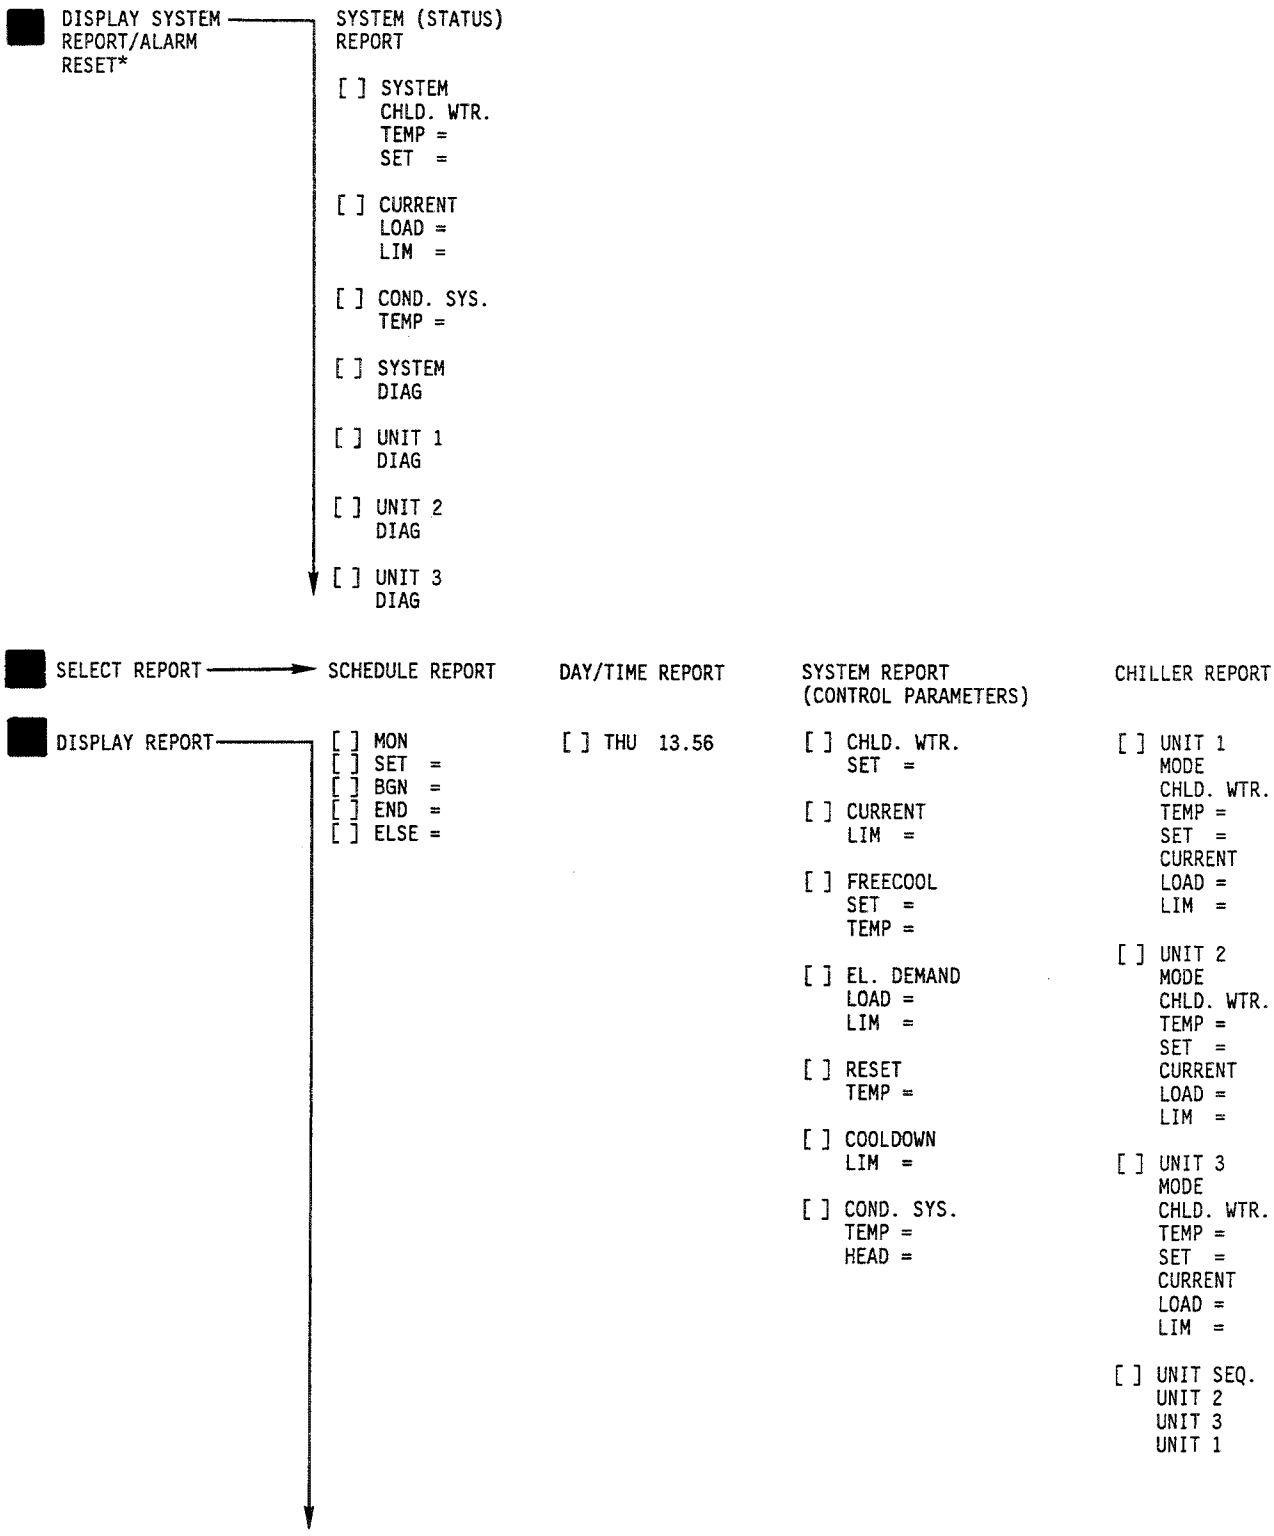
Following is the format used to display this information:



SYSTEM (or UNIT 1)
CHLD. WTR.
TEMP = (0 to 99 F)

SET = (OFF, or 1 to 99 F)

or



FREECOOL

Figure 6
SCP "Report" Interface

Art No.
RF/CTV-1902B

Figure 7
Preformatted SCP Reports

2. System Current Load and Limit. This 3-line report entry displays the following information:

a. the present electrical load (i.e., percent of total chiller rated load amps [RLA]).

b. the "active" system current limit setpoint. Illumination of the appropriate status indicator light indicates the source of this setpoint (e.g., manual control, scheduled control, chiller unit control, etc.).

This data appears in the following format:

CURRENT
LOAD = (0 to 100%)
LIM = (0 to 100% system RLA)

3. Condenser System Temperature. This 2-line report entry indicates the temperature registered by the optional sensor installed in either the common, system entering-condenser water line, or the outdoor ambient. Notice that the "Condenser System Control" status indicator light is illuminated while this report entry is displayed.

This format is used to display the system condenser return water temperature:

COND. SYS.
TEMP = (0 to 140 F; default is 0 F)

"COND. SYS. TEMP = 0" only occurs if the optional condenser water temperature sensor is "open" or not installed.

4. System (or Unit) Diagnostic. This 2-line entry reports the last abnormal condition that was detected at a system or unit level, and was recorded as an error in the SCP's memory.

Following are the formats used to display the last recorded system or unit diagnostic:

SYSTEM
DIAG (see Table 4)
and/or
UNIT 1
DIAG (see Table 5)
and/or
UNIT 2
DIAG (see Table 5)
and/or
UNIT 3
DIAG (see Table 5)

If no diagnostic code was recorded, the system status message returns to the display immediately after the condenser system temperature (see Item 3) is indicated.

Note: To remove the last recorded diagnostic code from the SCP's memory, simply press the "Display System Report/ Alarm Reset*" key and hold it down while the system status report is displayed. After the "SYSTEM (and each UNIT) DIAG " entry appears, the SCP generates a "CLEARED" message. The current system operating status then returns to the display.

Each error condition is represented by a 2-character code. See Table 4 for system-level diagnostic codes; unit-level diagnostic codes are listed in Table 5.

Notice that detection of a system-level diagnostic (other than D9)–or a latching chiller-level diagnostic–causes the SCP to flash the alphanumeric display and energize a customer-supplied and -installed alarm device connected to the SCP's alarm relay. This display will flash (and the alarm relay remain energized) until the "Display System Report/Alarm Reset*" button is pressed.

Table 4
SCP699 System Diagnostic Codes (See Note)

2-Digit Code	Description of Diagnostic Condition
AA	System Leaving Water Temperature Sensor (1,3)
DF	Communications Failure (1,3)
D9	Power Loss (Program Retained) (2,3)
EF	Power Loss (Program Lost) (1,3)
FF	System Control Module (1,3)

Notes:
1. Detection of 1 of these 4 system-level diagnostic conditions causes the alphanumeric display to flash and energizes the alarm relay. To reset the alarm relay–and stop the display from flashing, press the "Display System Report/Alarm Reset*" button.
2. Detection of the "D9" system-level diagnostic causes the SCP to flash its alphanumeric display; however, the alarm relay is not energized.
3. To remove the last recorded diagnostic code from the SCP's memory, press the "Display System Report/Alarm Reset*" button and hold it down while the system status report is displayed. After "SYSTEM DIAG = " appears, the SCP generates a "CLEARED" message.

Table 5
Chiller-Level Diagnostic Codes (See Notes 1, 2)

Diagnostic Codes (3)			
UCP695 Display	SCP Display	Description of Diagnostic Condition	System Reset
b A3	DIAG. A3	Evaporator Refrigerant Temperature Range	Manual

b EE	DIAG. EE	Exceeded Maximum Acceleration Time	Manual
b F0	DIAG. F0	Transition	Manual
b F1	DIAG. F1	Opt. Running External Interlock	Manual
b F2	DIAG. F2	Low Oil Pressure	Manual
b F4	DIAG. F4	High Oil Temperature	Manual
b F5	DIAG. F5	High Condenser Refrigerant Pressure	Manual
*b F7	DIAG. F7	Condenser Water Flow	Automatic
b F8	DIAG. F8	Improper Unit Identification	Manual
b F9	DIAG. F9	Free-Cooling Valves	Manual
b FA	DIAG. FA	Actuator	Manual
b Fb	DIAG. Fb	Low Evaporator Refrigerant Temperature	Manual
b Fd	DIAG. Fd	Opt. External Interlock	Manual
b FF	DIAG. FF	Unit Control Module	Manual

*The SCP does not record and alarm "nonlatching" (i.e., automatic reset) chiller diagnostic conditions.

Notes:

1. It is not possible to clear "latching" diagnostic condition (i.e., one requiring manual reset) from a higher level device such as an SCP699, Tracer or generic BAS. To manually reset the UCP695 panel–after diagnosing and correcting the problem, toggle the 3-position chiller switch to "Standby/Reset", then back to "Auto/Remote" or "Auto/Local".
2. To determine if manual reset is required, check the "Manual Reset Required" status indicator light on the front of the UCP695 control panel.
3. The "b" prefix on the UCP695 diagnostic codes does not appear on the SCP699 display.

Note: When a system diagnostic condition is detected and recorded, the SCP will not:

a. record a subsequent system error until the "Display System Report/Alarm Reset*" button is pressed; nor

b. alarm a diagnostic condition with the same error code previously recorded.

For instance, if the last diagnostic code recorded in the SCP's memory is "DF" [i.e., communications failure]–and the SCP detects another communications failure, it will not flash the display and energize the alarm relay. However, the original "DF" error code will remain in the system status report either until another, different diagnostic [e.g., "AA", system leaving chilled water temperature sensor] is detected and recorded, or until the SCP's diagnostic register is cleared. (See the first note under Item 4 for diagnostic clearance instructions.)

Schedule Report

To view a report of the present day's operating schedule, press the "Select Report" push button until "SCHEDULE" appears on the alphanumeric display. (Notice that the "Scheduled Control" status indicator light comes on and remains lit throughout this report.) Then, press the "Display Report" key.

The SCP automatically displays the current day of the week, the "occupied" system chilled water setpoint, the "on" and "off" times (i.e., based on the 24-hour clock) for this setpoint, and an alternative "unoccupied" chilled water setpoint (i.e., for setback operation).

These report entries are displayed in the following manner:

MON. (TUE. thru SUN.; default is MON.)
SET = (OFF, or 1 to 99 F; default is OFF)
BGN = (00.00 to 23.45; default is 00.00)
END = (00.00 to 23.45; default is 00.00)
ELSE = (OFF, or 1 to 99 F; default is OFF)

After the "ELSE = " entry appears, "SCHEDULE" returns to the display.

Note: If no additional push buttons are pressed within 2 minutes, the present system operating status (e.g., "READY", "COOLING", etc.) reappears on the alphanumeric display.

Day/Time Report

By pressing first the "Select Report" key until "DAY/TIME" appears–then the "Display Report" key–the operator can check the status of the SCP's system clock. The current day of the week, along with the present time of day, appear in a 1-line report entry that follows this format:

THU. 13.56
(MON thru SUN; 00.00 to 23.59; default is MON. 00.00)

The "DAY/TIME" report title then reappears on the display and remains there until either: (a) another SCP key is pressed, or (b) 2 minutes elapses. At the end of the 2-minute interval, the present system operating status recurs on the display.

System Report

Note: This report displays system control parameters, and is not the same as the "System (Status) Report" that is issued when the "Display System Report/ Alarm Reset*" button is pressed.

For a rundown of each of the operating parameters associated with the SCP's various control functions, press the "Select Report" key until "SYSTEM" appears on the alphanumeric display. Next, press the "Display Report" push button.

The SCP automatically advances from one system control parameter to the next; as each report entry is displayed, a status indicator light also illuminates. This allows the operator to determine what control function (or mode) was used to establish that particular operating parameter (e.g., manual control, chilled water reset, building automation system, etc.).

Following is a sequential listing of the standard (5) and optional (2) control function entries included in the system report:

1. System Chilled Water Setpoint. Remember to check the status indicator lights during this 2-line report entry to review where this setpoint was established:

CHLD. WTR.
SET = (OFF, or 1 to 99 F; default is OFF)

2. System Current Limit Setpoint. The value in this 2-line entry is expressed as a percentage of the total chiller RLA; check the status indicator lights to determine where this limit was set:

CURRENT
LIM = (0 to 100%; default is 0%)

3. System Free Cooling Setpoint and Temperature (Optional). If any of the units connected to the SCP is equipped with the free cooling option, the SCP displays a 3-line report entry that indicates:

a. the operator-set, entering-condenser (outdoor) sensor temperature limit for automatic free cooling; and,

b. the temperature registered by the optional SCP sensor field-installed either in the common, system entering-condenser water line, or in the outdoor ambient.

FREECOOL
SET = (OFF, or 1 to 140 F; default is OFF)
TEMP = (0 to 140 F; default is 0 F)

4. Electrical Demand Load and Limit. This 3-line report entry indicates:

a. the actual percentage of metered electrical demand at which the system is currently operating; and,

b. the operator-set electrical demand limit point. (The SCP initiates the electrical demand limit mode if the actual percentage of metered electrical demand exceeds this limit point.)

Notice that the "Electrical Demand Limiting" status indicator light is lit while this report entry is displayed.

Below is a typical electrical demand limit entry for the system report:

EL. DEMAND
LOAD = (0 to 100%; default is 0%)
LIM. = (0 to 100%; default is 0%)

Note: This control function is disabled if the electrical demand limit is set at 0% (zero).

5. Chilled Water Reset Temperature. A 2-line system report entry indicates the actual temperature registered at an SCP sensor field-installed in the common, system entering-evaporator water line (i.e., or in the outdoor ambient).

RESET
TEMP = (0 to 140 F; default is 0 F)

The "Chilled Water Reset" status indicator light also illuminates while this entry is displayed.

6. Cooldown Control Limit. A 2-line entry reports the operator-set current limit point (i.e., as a percentage of total chiller RLA) that is effective while the system is operating in the cooldown mode.

Note: The SCP compares the cooldown limit point with the system current limit point and uses the lowest value.

COOLDOWN
LIM = (0 to 100%; default is 0%)

Notice that the "Cooldown Control" status indicator light is on while this entry is on the display.

Note: If the cooldown limit point is set at 0%, the cooldown control function is disabled.

7. Condenser System Limit Control Temperature and "Head" (Optional). SCPs equipped with this control option generate a 3-line system report entry that illuminates the "Condenser System Control" status indicator light, and yields the following information:

a. the temperature registered by the optional SCP sensor installed in either the common, system entering-condenser water line, or outdoor ambient; and,

b. the difference between the evaporator and condenser refrigerant temperatures for the chiller with the lowest differential. (The SCP looks only at those units that are presently operating, compares their "head" values, and displays the lowest refrigerant temperature differential.)

COND. SYS.
TEMP = (0 to 140 F; default is 0 F)
HEAD = (0 to 140 F; default is 0 F)

Note: This control function is active whenever any chiller in the system is operating; it is not operative when the system is in the automatic free cooling mode.

Once the last system report entry is displayed, the "SYSTEM" report title reappears and remains on the alphanumeric display until either: (a) another SCP key is pressed, or (b) 2 minutes elapses. (The SCP indicates the present system operating status [e.g., "COOLING", "INHIBIT", etc.] at the end of the 2-minute interval.)

Chiller Report(s)

In addition to the preformatted system (operating status), schedule, day/time and system (control parameters) reports already described, the SCP also enables the operator to review chiller operation on a unit-by-unit basis.

Press the "Select Report" key until "CHILLER" appears on the display; then press the "Display Report" push button. The SCP automatically displays each of the chiller report entries--itemized below--in the sequence shown.

When applicable, a status indicator light also illuminates; this allows the operator to determine what control function is presently governing the operation of that unit.

Note: The chiller report begins with a display of the 3 (or 4) operating status report entries associated with "UNIT 1"; corresponding status reports for "UNIT 2" and "UNIT 3" follow, where applicable. (Remember that unit numbers correspond to the addresses set up with DIP switch block S11 in the chiller control panels; so, actual chiller status reports for a particular system may include only "UNIT 2", or "UNIT 1" and "UNIT 3", etc.)

A "unit sequence" entry is included after the last unit status report for systems with multiple chillers.

Refer to the chiller report entry descriptions that follow.

1. Chiller Operating Mode. A 1- or 2-digit code indicates the unit's present mode of operation; notice that this same code (i.e., along with an "A" prefix) is also displayed on the unit's UCP695 control panel. (See Table 6 for a summary of chiller operating codes.)

Below is a typical, 1-line report entry for the chiller's operating mode:

MODE 74 (see Table 6)

2. Unit Chilled Water Temperature and Setpoint. This 3-line chiller report entry provides:

a. the temperature registered by that unit's leaving chilled water temperature sensor (4RT1); and,

b. the "active" unit chilled water temperature setpoint. Check the status indicator lights to determine where this setpoint was established (e.g., SCP manual control, SCP scheduled control, building automation system, etc.).

Note: The "FREECOOL" message is displayed in lieu of a setpoint value if the unit is presently operating in the free cooling mode (i.e., operating code "09").

Following is the format used to display the unit's chilled water temperature and setpoint:

CHLD. WTR.
TEMP = (0 to 99 F; default is 0 F)

SET = (AUTO, OFF, or 1 to 99 F; default is AUTO)

or

FREECOOL

3. Chiller Current Load and Limit. A 3-line report entry displays the following data:

a. chiller load (i.e., represented as a percentage of that unit's compressor RLA); and,

b. the "active" unit current limit setpoint. Again, check the status indicator lights to identify the source of this setpoint (e.g., chiller unit control, SCP scheduled control, etc.).

This data appears in the following report entry format:

CURRENT
LOAD = (0 to 100%; default is 0%)
LIM = (0 to 100%; default is 0%)

The SCP then proceeds to the chiller operating status report for "UNIT 2" (if applicable).

In single-chiller system applications, the "CHILLER" report title reappears on the display, and remains there until either: (a) another SCP key is pressed, or (b) 2 minutes elapses. (A status message–representing the system's present operating status–returns to the display once the 2-minute period expires.)

When the SCP is connected to 2 or 3 chillers, chiller report items 1 through 4 are repeated for "UNIT 2" and–if applicable–"UNIT 3".

Note: Chiller status reports are only displayed for units that have communicated with the SCP during the last 2 minutes.

Table 6
Chiller Operating Codes

Operating Codes (1)		
UCP695 Display	SCP Display	Description of Operating Mode
Blank	Blank	Power Off
A 0	MODE 00	Standby/Reset (or chiller off on diagnostic)
A 1	MODE 01	Auto (Local or Remote)
A 9	MODE 09	Free Cooling
A 70	MODE 70	Restart Inhibit
A 71	MODE 71	Establish Condenser Water Flow
A 72	MODE 72	Start
A 74	MODE 74	Run: Normal
A 75	MODE 75	Run: Current Limit (2)
A 76	MODE 76	Run: Condenser Limit (3)
A 77	MODE 77	Run: Evaporator Limit (4)
A 78	MODE 78	Run: Surge Condition (5)
A 79	MODE 79	Post-Lube
A 88	MODE 88	Reset

Notes:
1. The "A" prefix on the UCP695 chiller operating codes does not appear on the SCP699 display.
2. As the current limit setpoint is approached, the UCP695 restricts further opening of the inlet guide vanes.
3. As the condenser limit setpoint is reached, the UCP695 restricts additional compressor loading to avoid shutdown on high condenser pressure (i.e., diagnostic b F5), and initiates a "head relief request" (i.e., optional UCP695 relay package).
4. The UCP695 restricts further opening of the inlet guide vanes to avoid a shutdown on low evaporator refrigerant temperature (i.e., diagnostic b Fb).
5. The UCP695 limits compressor loading and initiates a "head relief request" (i.e., optional relay) when the unit enters a surge condition. An automatic unit shutdown occurs if the unit remains in surge for 15 minutes (i.e., diagnostic b dA).

4. Unit Sequence. Following the last chiller status report item, the SCP generates a 3- or 4-line report entry that identifies which unit (i.e., "UNIT 1", "UNIT 2" or "UNIT 3") is presently the first chiller in the operating sequence, which is second, and--if applicable--which chiller is third in the operating sequence.

Note: The "UNIT SEQ." report entry is not displayed if the SCP is only connected to--or communicating with--1 chiller.

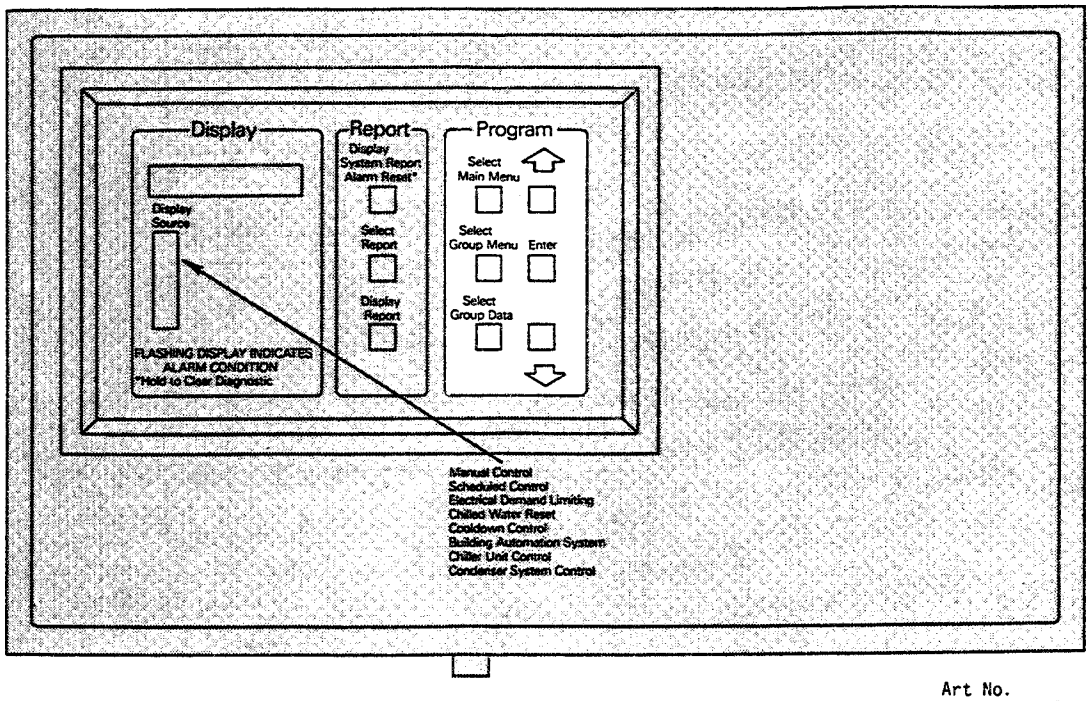
This chiller report entry format indicates the chillers' operating sequence:

UNIT SEQ.
UNIT 2 (1st chiller in operating sequence)
UNIT 3 (2nd chiller in operating sequence)
if applicable,
UNIT 1 (3rd chiller in operating sequence)

After the "UNIT SEQ." report entry is complete (if displayed), the "CHILLER" report title reappears on the display. It remains there either until: (a) another SCP key is pressed, or (b) 2 minutes elapses. (A status message--representing the system's present operating status--returns to the display once the 2-minute period expires.)

"Program" Interface (Figure 8)

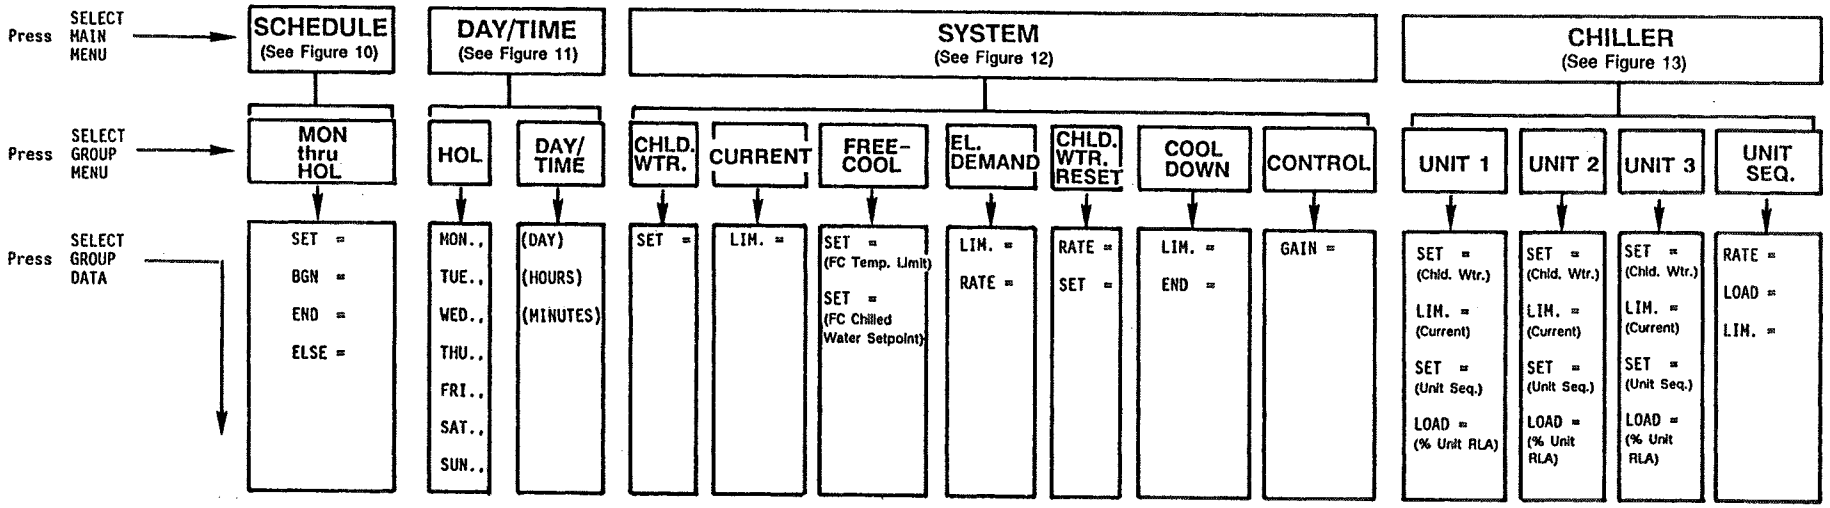
Since the SCP's control strategies are an integral part of the panel's software, very little programming is required. The operator simply inputs scheduled setpoints, and enters values for the control parameters associated with the SCP's standard and optional control functions (e.g., electrical demand limiting, chilled water reset, free cooling, condenser system control, unit sequencing, and cooldown control).



See Figure 8. Notice that the 6 push-button keys--along with the display portion of the panel--allow the operator to set up system operation.

Like the report displays described in the previous section, "programmable" SCP entries are grouped into 4 categories or "main menus": "Schedule", "Day/Time", "System", and "Chiller". The control parameters associated with each of these main menus are described in the following paragraphs, and summarized in Figure 9.

For discussions of how the SCP's major control strategies (i.e., electrical demand limiting, chilled water reset, etc.) work, refer to the SCP699 Operation section of this manual.



Note: An "SCP Programming Aid" worksheet is provided at the back of this manual. It summarizes all operator -programmable control entries, and can be used to record the specific values entered for each.

Figure 8
SCP "Program" Interface

Art No.
RF/CTV-1902B

Figure 9
SCP Program Selection

Note: For a more detailed look at each of the 4 main SCP programming menus (i.e., SCHEDULE, DAY/TIME, SYSTEM and CHILLER), see Figures 10 through 13. The schematics in these illustrations include the range of settings for each programmable SCP control setting.

"Schedule" Program

The SCP's schedule control function is comprised of a 7-day operating list of system chilled water setpoints, daily "begin" and "end" times for these setpoints, and alternative chilled water setpoints for "setback" (i.e., unoccupied or "after-hours") operation.

Notice that 4 distinct types of system schedules are possible; the operator can:

1. schedule the system off all day, with none of the pumps running;

2. schedule the system on all day, with a single system (i.e., common leaving-chiller) chilled water setpoint;

3. schedule the system on for part of the day with one chilled water setpoint, and off for the remainder of the day; and,

4. schedule the system on for part of the day with one chilled water setpoint, and use an alternative setpoint for the remainder of the day.

Once established, the 7-day, Monday-through-Sunday system operating scheme is repeated each week until the schedule is manually changed by the operator, or until the SCP encounters a "holiday" schedule.

Note: In addition to the entries for Monday through Sunday, the "schedule" menu day list includes a "holiday" entry that allows the operator to set up a unique, 24-hour system schedule. When any (or all!) of the weekdays--including Saturday and Sunday--are designated as "holidays" under the Day/Time menu, the temporary, 24-hour holiday schedule is executed. (See "'Day/Time' Program" for a further explanation of holiday programming.)

Schedule Setup

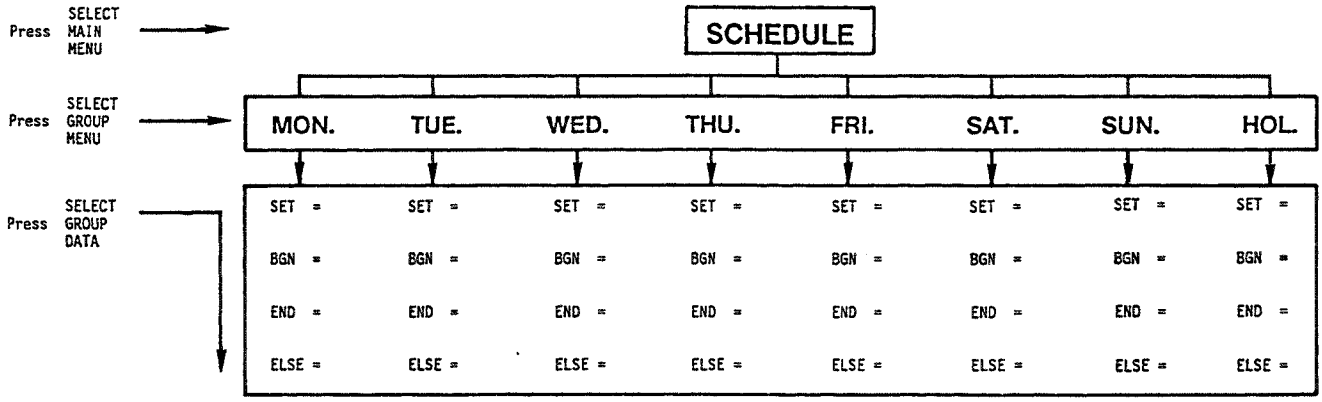
Follow the step-by-step instructions outlined below to set up a system operating plan using the SCP's schedule function. (Refer to Figure 10 for a flow chart that summarizes these steps.)

1. Access the SCP's "Schedule" menu.

Press the "Select Main Menu" key (i.e., located in the SCP's "Program" block; Figure 8) until "SCHEDULE" appears on the alphanumeric display.

Notice that the "Scheduled Control" status indicator light illuminates at this time; it will remain on as long as the operator continues to review entries within the "schedule" menu.

2. Specify the day (i.e., Monday through Sunday, or Hoilday) you wish to schedule.



To establish a day-to-day system operating schedule, press the "Select Group Menu" key; "MON." will appear on the display.

Note: Monday is always the first group heading within the "schedule" menu, followed by Tuesday, Wednesday, and so on. To advance from one day of the week to the next, press the "Select Group Menu" key until the desired day is displayed. (The last "schedule" group heading--following Sunday--is Holiday. If "Select Group Menu" is pressed while "HOL." is displayed, "SCHEDULE" reappears on the display.)

3. Enter the desired system leaving chilled water setpoint for that day's scheduled operation.

With the desired day displayed, press the "Select Group Data" key; "SET = " should now appear on the display. This program entry represents the control setpoint for system leaving chilled water temperature; the SCP regulates system operation as necessary --during scheduled hours--to maintain this setpoint.

Figure 10
"Schedule" Setup

Notes:
1. The "Scheduled Control" status indicator light illuminates when "SCHEDULE" appears on the alphanumeric display, and remains lit while the operator completes the schedule program entries.
2. Possible entries for "SET = " are: OFF (i.e., default setting), MON. thru HOL., and 1 F thru 99 F in increments of 1 F.
3. Possible entries for "BGN = " and "END = " are 00.00 (i.e., default setting) thru 23.45 in 15-minute increments.
4. Possible entries for "ELSE = " are OFF (i.e., default setting), or 1 F thru 99 F in increments of 1 F.

Possible values for this control setting include OFF (i.e., SCP's default value), and 1 F through 99 F, along with MON. through SUN. and HOL. To change the "SET = " value displayed, simply press the " ↑ " (increase) or " ↓ " (decrease) keys until the desired setpoint is obtained; then press "Enter" to store this value in the SCP's memory.

Note: To duplicate the operating schedule of a prior day already programmed, enter the abbreviation of the day to be duplicated for the "SET = " parameter. For instance, if you want Monday's operating schedule (i.e., chilled water setpoint, "begin" and "end" times, and "else" setpoint) to be repeated on Wednesday:

a. Use the "Select Group Menu" key to scroll through the "schedule" menu.

b. When "WED." is displayed, press the "Select Group Data" key; "SET = " should now appear on the display.

c. Press the " ↑ " (increase) and " ↓ " (decrease) keys as needed until "SET = MON." is displayed; then press "Enter". (Notice that the SCP displays the numeric value for Monday's system chilled water setpoint after "Enter" is pressed.)

Important! Although Wednesday's schedule was originally established by entering "SET = MON." (Steps "a" thru "c", above), the SCP will not automatically revise Wednesday's operating schedule if any of Monday's "Schedule" entries are changed!

Note: Entering "SET = HOL." for a given day establishes a permanent holiday! (For example, if "HOL." is entered for Wednesday's "SET = " schedule, the SCP will execute the holiday schedule every Wednesday.) To designate a temporary, one-time-only holiday, be sure to use the "Day/Time" programming menu.

4. Enter the time of day scheduled operation is to begin.

After entering a value for the system leaving chilled water setpoint (Step 3), press the "Select Group Data" key to display "BGN = __.__". This control parameter "tells" the SCP what time of day the scheduled setpoint goes into effect, and is based on the 24-hour clock.

Values ranging from 00.00 (i.e., default setting) to 23.45–in 15-minute increments–are possible. Use the " ↑ " (increase) and " ↓ " (decrease) keys to obtain the desired "begin" time; then press "Enter" to store this value in the SCP's memory.

5. Enter the time of day that scheduled operation should cease.

Once the "begin" time entry is complete (Step 4), press the "Select Group Data" key to display "END = __.__". This parameter "tells" the SCP when to stop maintaining the scheduled system chilled water setpoint established in Step 3.

Again, possible "end" time values are based on the 24-hour clock, and range from 00.00 (i.e., default setting) to 23.45 in increments of 15 minutes. To obtain the desired "end" time, press the " ↑ " and " ↓ " keys until the proper time is displayed; then press "Enter".

Note: If the "begin" and "end" times are identical, the SCP will attempt to maintain the scheduled system leaving chilled water setpoint (i.e., set in Step 3) for 24 continuous hours.

It is possible to enter an "end" time that is earlier than the corresponding "begin" time. For example, if the begin time is 22.15 and the end time is 07.30, the SCP will: begin enforcing the "SET = " value at midnight; stop at 7:30 a.m.; resume enforcement of "SET = " at 10:15 p.m.; and, stop at midnight.

6. Enter the desired alternative ("else") system leaving chilled water setpoint to be used during the remainder of the day (i.e., outside the scheduled "begin" and "end" times).

After completing the "end" time entry (Step 5), press the "Select Group Data" key to display "ELSE = ". This value tells the SCP what system leaving chilled water temperature to maintain during the unscheduled portion of the day (i.e., after the day's scheduled "end" time). Generally, an alternative chilled water setpoint is established for nighttime and weekend (or holiday) operation.

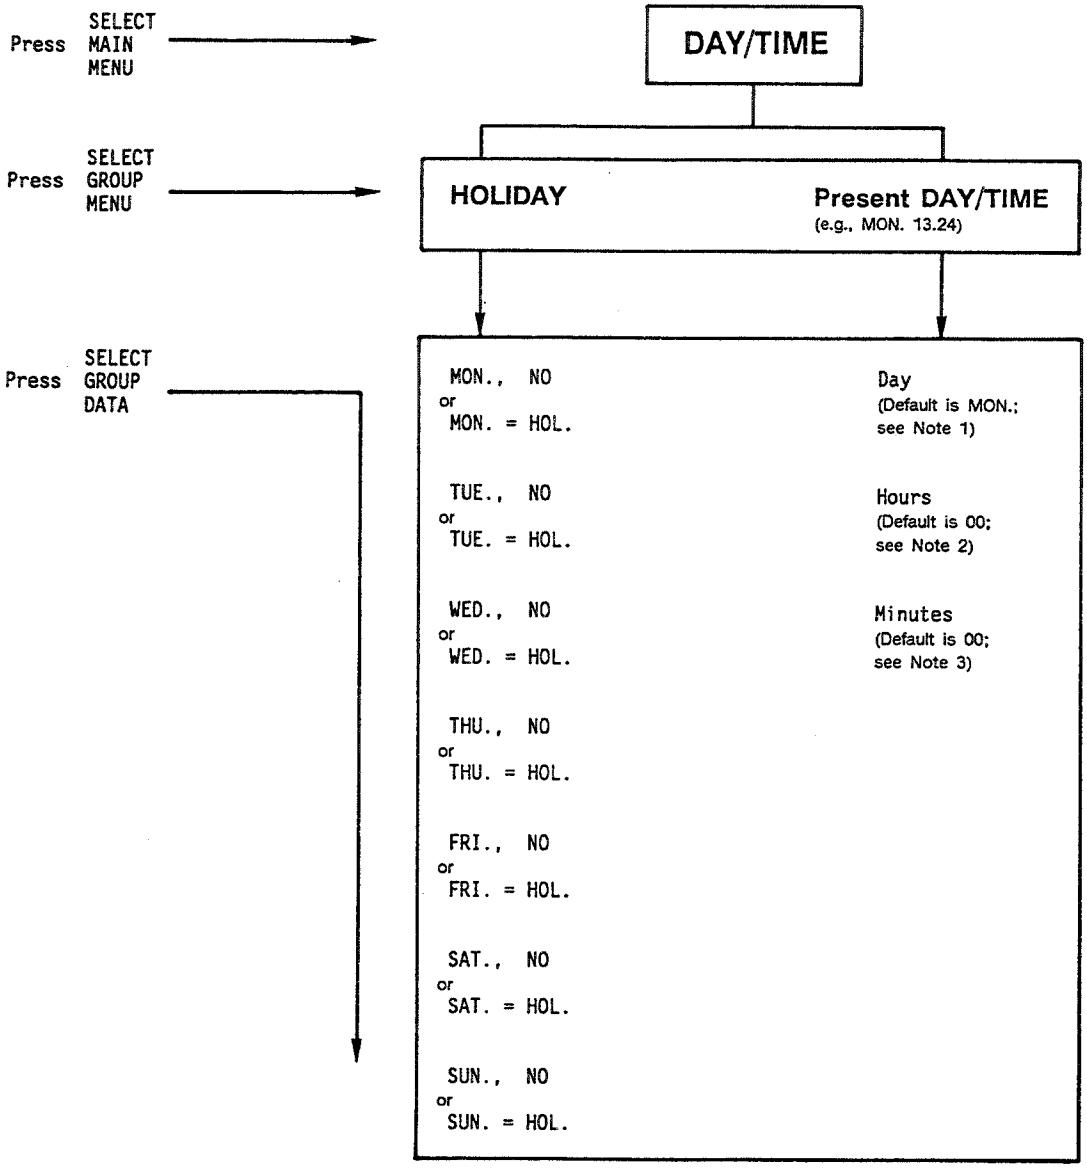
The "ELSE = " control point can be set either at OFF (i.e., default setting), or at any temperature value ranging from 1 F through 99 F in increments of 1 F. Use the " ↑ " and " ↓ " keys to obtain the desired alternative chilled water temperature; then press "Enter" to store this value in the SCP's memory.

Note: If "OFF" is entered for the "ELSE = " chilled water setpoint, the SCP will shut down system operation once the scheduled "end" time is reached.

7. Press the "Select Group Menu" key to advance to the next day to be scheduled.

Note: To schedule a system shutdown through the weekend–or during a holiday–enter "OFF" for Saturday's (or Holiday's) "SET = " program entry. Be sure that the BGN and END times are the same, too. Then enter either "SET = OFF" or "SET = SAT." for Sunday's scheduled system chilled water setpoint.

Repeat the programming procedure described in Steps 3 through 7 until all of the programmable "schedule" menu control settings (i.e., indicated in Figure 10) are complete.



"Day/Time" Program

The SCP's day/time function consists of a 24-hour, 7-day clock/calendar that distinguishes one day of the week from the next (i.e., Monday through Sunday), with each day beginning at 00.00 and ending at 23.59.

See Figure 11. Notice that the "day/time" program menu enables the operator to specify a maximum of 7 days as holidays, and that each holiday can be assigned up to 6 days in advance.

When the operator specifies a particular day of the week as a holiday (e.g., Friday)–and the present day and time match this designated day (e.g., FRI 00.00)–the SCP executes the temporary schedule. At the beginning of the next calendar day (e.g., Saturday), at 00.00, the previous day's holiday "tag" is erased from the SCP's memory. The next time that day occurs (e.g., Friday), its normal operating schedule is used.

Figure 11
"Day/Time" Setup

Notes:

1. Use this entry to establish the present day of the week (i.e., MON., TUE., WED., THU., FRI., SAT. or SUN.).

2. This entry allows the operator to set the SCP's "clock" with the present hour of the day in terms of the 24-hour clock (i.e., 00 thru 23). For example, if it is presently 2:00 p.m., set the "hours" at "14".

3. Use this entry to "tell" the SCP how many minutes past the hour it is (i.e., 00 thru 59).

Day/Time Setup

Follow the instructions outlined below to set up the SCP's clock/calendar.

1. Access the SCP's "Day/Time" menu.

Press the SCP's "Select Main Menu" key until "DAY/TIME" appears on the alphanumeric display.

2. Identify which days of the present 7-day cycle are to be "holidays".

To designate upcoming holidays (i.e., no more than 6 days in advance):

a. Press "Select Group Menu" until "HOLIDAY" appears on the display.

b. Press "Select Group Data"; "MON., NO" (i.e., SCP's default setting) or "MON. = HOL." will appear on the display.

To identify Monday as a holiday, press the " ↑ " or " ↓ " keys until "MON. = HOL." is displayed; then press "Enter".

If Monday is not a holiday, use the " ↑ " and " ↓ " keys to obtain the "MON., NO" display; then press "Enter".

c. Advance to the next day of the week by pressing the "Select Group Data" key. Check the entry displayed to verify that the day is properly tagged as a holiday or non-holiday. Use the " ↑ " and " ↓ " keys as described in Step 2b to change the designation, if necessary.

d. Repeat Steps 2b and 2c for each holiday list entry (i.e., through "SUN"; see Figure 11).

Note: Remember that the holiday designation is temporary; a day tagged as a holiday one week will return to its normal system operating schedule the following week (i.e., unless the SCP is programmed otherwise).

3. Enter the present day and time into the SCP's memory.

a. Press the "Select Group Menu" key until "real time"–according to the SCP's internal clock/calendar–is displayed. (The clock/calendar default setting is "MON. 00.00".)

b. Press "Select Group Data" to display only the day portion of the day/time message. Use the " ↑ " and " ↓ " keys to display the current day of the week; then press "Enter".

c. Once the present day of the week is established, press the "Select Group Data" key again; this time, only the hours portion of the real time entry is displayed. Press the " ↑ " and " ↓ " keys, as appropriate, until the present hour of the day is obtained; then press "Enter".

Note: Remember that the SCP's clock function is based on military time (i.e., 24-hour clock). So, if it is presently 2:00 p.m., change the hours display to read "14".

d. To change the minutes portion of the "real time" display, press "Select Group Data" so that only the minutes portion of the entry is displayed. Then, press the " ↑ " and " ↓ " keys, as required, until the display reflects the actual number of minutes past the hour. Depress "Enter" to store this value in the SCP's memory.

Note: Changing the time of day registered by the SCP's clock/calendar does not reset the SCP's internal seconds counter.

If you wish to doublecheck the status of the SCP's internal clock/calendar, press the "Select Group Menu" key until the present day and time are displayed.

"System" Program

Use of the SCP's system programming menu enables the operator to govern system operation by setting up certain "manual" control setpoints.

Following are the system-level operating parameters that can be regulated by operator-entered "manual" control setpoints:

[ ] leaving chilled water temperature;
[ ] current limit;
[ ] free cooling "enable" and chilled water temperature;
[ ] electrical demand limit and rate settings;
[ ] chilled water reset rate and setpoint; and,
[ ] cooldown limit and duration.

SCP responsiveness to cooling requirement changes can also be regulated via the "system" programming menu.

For an illustration of "system" menu organization, see Figure 12; a summary of control settings for each operating parameter is also included there.

System Setup: Chilled Water

To establish the setpoint for system leaving chilled water temperature:

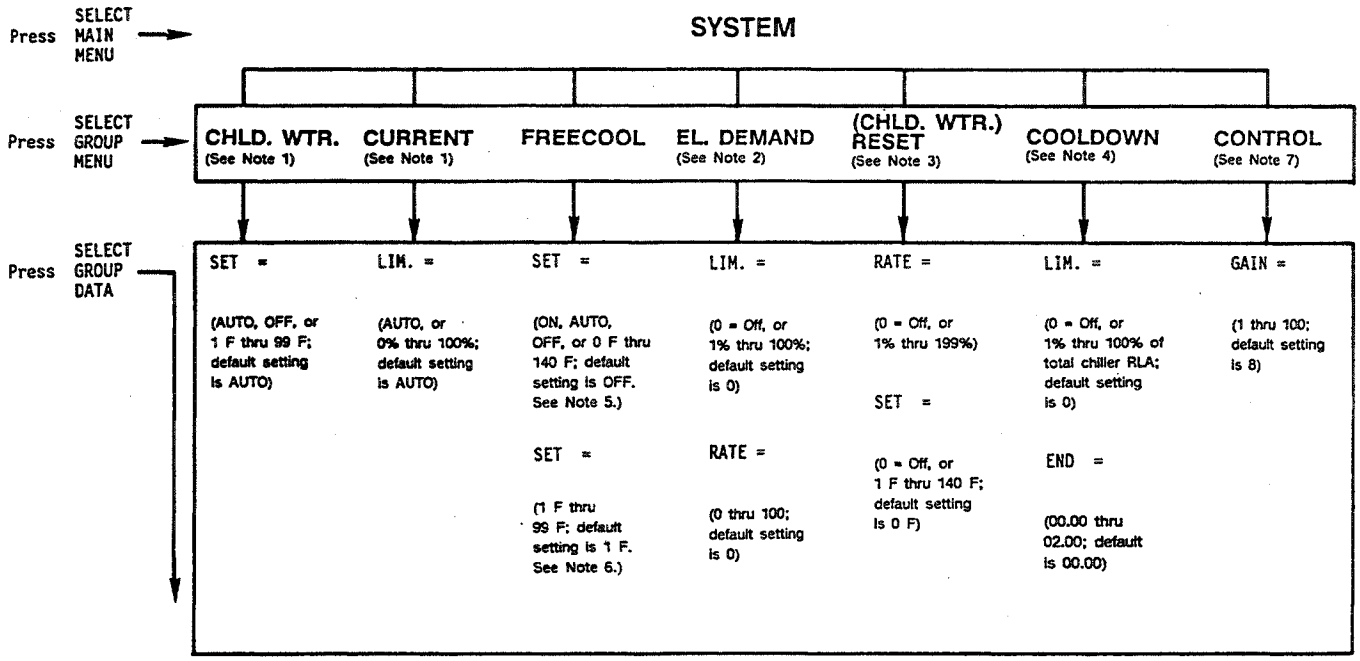
1. Press the "Select Main Menu" push button until "SYSTEM" is displayed.

2. Depress the "Select Group Menu" key once; "CHLD. WTR." should now appear on the alphanumeric display. (Notice that the "Manual Control" status indicator light also illuminates at this time; it will remain on as long as the chilled water setpoint entry is displayed.)

3. With "CHLD. WTR." displayed, push the "Select Group Data" key; "SET = " (or "AUTO") should now appear. This program entry represents the control setpoint for system leaving chilled water temperature; the SCP will regulate system operation as necessary to maintain this setpoint.

Possible values for the system chilled water control setting include AUTO (i.e., default setting), OFF, and 1 F through 99 F in 1-degree increments.

To alter the displayed "SET = " value, press the " ↑ " and " ↓ " keys as necessary until the desired setting appears on the display. Press "Enter" to store this value in the SCP's memory.



Note: When deciding what value to enter for the system chilled water "SET = " control setting, remember that:

a. The SCP will shut down system operation if "SET = OFF" is entered for the system chilled water setpoint.

b. If a numeric value is entered here (e.g., "SET = 40"), the SCP will attempt to maintain that leaving chilled water temperature (e.g., 40 F). Any alternative chilled water setpoint values–determined at the BAS, SCP schedule, or optional chilled water reset control levels–are ignored!

c. Selecting AUTO for the "SET = " value tells the SCP to look elsewhere (e.g., BAS, SCP schedule, optional chilled water reset, etc.) for the effective system leaving chilled water setpoint.

Figure 12
"System" Setup

Notes:

1. Manual system leaving chilled water and current limit setpoints; "Manual Control" status indicator light is illuminated while these program entries are displayed.
2. Electrical demand limit value entered for "LIM. = " is compared with the actual system demand to determine whether chillers should be unloaded; "RATE = " is an SCP program constant used to translate meter pulse input data into a desired peak kw percentage (i.e., computed and entered once). "Electrical Demand Limiting" status indicator light is illuminated while these program entries are displayed.
3. "RATE = " value is multiplied by the CWR temperature differential to calculate the amount of setpoint reset; "SET = " values ≤ 25 indicate load-based CWR, while ambient-based CWR is used for values > 25. "Chilled Water Reset" status indicator light remains lit while the CWR program entries are displayed.
4. Effective current limit setpoint during SCP operation in the cooldown mode; "END = " value determines length of cooldown period (i.e., in increments of 15 minutes), as well as minimum duration for thermostatically-controlled free cooling. "Cooldown Control" status indicator light is on while these entries are displayed.
5. Manual sensor setpoint temperature used to determine system free cooling status.
6. Chilled water setpoint used when the SCP is operating in the thermostatically-controlled free cooling mode. (Also, see Note 4.)
7. "GAIN = " value governs the SCP's responsiveness to changes in cooling requirements; the lower the control gain setting, the slower the response time.

System Setup: Current

Note: If you haven't already accessed the "system" programming menu, press "Select Main Menu" until "SYSTEM" appears on the display. Then follow the instructions outlined below.

To set up a manual system current limit setpoint:

1. Press the "Select Group Menu" key until "CURRENT" appears on the display. (Notice that the "Manual Control" status indicator light illuminates at this time; it will remain on as long as the current limit entry is displayed.)

2. Depress the "Select Group Data" key; "LIM. = " (or "AUTO") is now displayed. This entry allows the operator to enter a current limit setpoint for the system as a percentage of total chiller RLA. (If this value is exceeded, the SCP will begin to unload the chillers until the electrical demand is reduced sufficiently.)

Possible values for the system current limit setpoint are AUTO (i.e., default setting), and 0% through 100% of total chiller RLA in increments of 1%.

3. To alter the displayed "LIM. = " value, press the " ↓ " and " ↑ " keys as necessary until the desired setting appears on the display. Press "Enter" to store this value in the SCP's memory.

Note: When selecting a control setting for the system current limit setpoint, remember that:

a. A numeric value (i.e., from 0 through 100) entered for "LIM. = " becomes the effective system current limit setpoint. Any alternative value–either the SCP's default setting, or a BAS-generated current limit setpoint–is ignored!

b. Entering "AUTO" for the "LIM. = " value tells the SCP to look elsewhere for the effective system current limit setpoint. (Other sources for this setpoint include the BAS, SCP default setting, cooldown control, or electrical demand limit control.)

System Setup: Freecool

Note: If you haven't already accessed the "system" programming menu, press "Select Main Menu" until "SYSTEM" appears on the display. Then follow the instructions outlined below.

To set up the thermostatically-controlled, system automatic free cooling option:

1. Press the "Select Group Menu" key until "FREECOOL" appears on the display.

2. Now, push the "Select Group Data" key to display the free cool system setpoint; "SET = " (or "AUTO") should now appear. The SCP uses this particular program entry to control the operating status of the automatic free cooling option. (For an explanation of the various free cooling control strategies, refer to "Automatic Free Cooling" in the Operation section of this manual.)

3. To alter the displayed "SET = " value, press the " ↓ " and " ↑ " keys as necessary until the desired setting appears on the display.

Possible values for the free cool system setpoint include ON, AUTO, OFF (i.e., default setting), and 0 F through 140 F in 1-degree increments.

Note: When deciding what control setting to enter for the free cooling (FC) system setpoint, remember that:

a. The SCP will disable system-level free cooling operation if "SET = OFF" is entered for the FC system setpoint.

b. Entering "SET = ON" tells the SCP to operate all chillers equipped with the free cooling option in the free cooling mode. Free cooling operation will continue until the FC system setpoint is changed to a numeric value, AUTO or OFF.

c. When the FC system setpoint is AUTO, the SCP looks elsewhere (e.g., BAS) for the effective control setting or "enabling" contact closure(s).

d. Thermostatically-controlled, system -level free cooling is available when a numeric value is entered for the "SET = " FC system setpoint. (See note in Step 6.)

4. Press "Enter" to store the selected free cool system setpoint value in the SCP's memory.

5. Display the system free cool (FC) chilled water setpoint by pressing the "Select Group Data" push button; again, a "SET = " message appears on the display. The value shown there represents the system leaving chilled water setpoint used by the SCP when it is operating in the thermostatically-controlled free cooling mode.

6. Use the " ↓ " and " ↑ " keys to change the displayed FC chilled water setpoint until the desired setting is obtained; then press "Enter". Setpoint values range from 1 F through 99 F (i.e., in 1-degree increments); the SCP default value for the FC chilled water setpoint is 1.

Note: The SCP allows the system to remain in the free cooling mode as long as the system leaving chilled water temperature is less than or equal to the FC chilled water setpoint. When this value is exceeded, the SCP returns the system to the powered cooling mode. Once the thermostatically-controlled FC mode is initiated, however, the system will operate in that mode–regardless of chilled water temperature–for a minimum of either 15 minutes or the duration of the cooldown period, whichever is greater.

System Setup: Electrical Demand Limit

Note: If you haven't already accessed the "system" programming menu, press "Select Main Menu" until "SYSTEM" appears on the display. Then follow the instructions outlined below.

To set up the SCP's electrical demand limit control function:

1. Press the "Select Group Menu" key until "EL. DEMAND" appears on the display.

Notice that the "Electrical Demand Limiting" status indicator light illuminates; it will remain on as long as electrical demand limit program entries are displayed.

2. Depress the "Select Group Data" push button once to display the electrical demand limit setting (i.e., "LIM. = "). The SCP compares the value shown here against actual system electrical demand to determine whether or not chiller unloading is required.

3. To alter the displayed "LIM. = " setting, use the " ↓ " and " ↑ " keys to obtain the desired limit value; then press "Enter" to store this control setting in the SCP's memory.

Possible electrical demand limit settings range from 1% through 100% (i.e., in 1% increments) of total system demand; a default setting of 0% disables the electrical demand limit option.

4. Press "Select Group Data" to display the control setting for the electrical demand meter rate (i.e., "RATE = "). The value entered here is a program constant used to translate meter pulse input data into a percent of electrical load; it is calculated and programmed into the SCP's memory only once. (See "Electrical Demand Limit Option" in the SCP699 Operation section of this manual.)

5. Use the " ↓ " and " ↓ " keys to obtain the desired meter rate setting; meter rate values range from 0 through 100 (i.e., in increments of 1).

Press the "Enter" key when the designated rate setting is displayed.

Note: Remember that the electrical demand limit function is inoperative unless "AUTO" is entered for the system current limit.

System Setup: Chilled Water Reset

Note: If you haven't already accessed the "system" programming menu, press "Select Main Menu" until "SYSTEM" appears on the display. Then follow the instructions outlined below.

To set up the SCP's chilled water reset (CWR) control function:

1. Press the "Select Group Menu" key until "RESET" appears on the display.

Notice that the "Chilled Water Reset" status indicator light comes on at this time; it will remain lit as long as CWR program entries are displayed.

2. Depress the "Select Group Data" key once; the "RATE = " entry displayed represents the chilled water reset rate. This value is used to calculate the amount of reset (i.e., in degrees F) that will be applied to either a scheduled or BAS-generated system leaving chilled water setpoint. (Refer to "Chilled Water Reset Option" in the SCP699 Operation section of this manual.)

3. Press the " ↓ " and " ↓ " keys, as appropriate, until the desired CWR rate is displayed; control settings range from 1% through 199% in increments of 1%. (The SCP default value for CWR rate is 0, which disables the CWR control function.)

To store this value in the SCP's memory, press "Enter".

4. Display the CWR setpoint temperature (i.e., "SET = ") by pressing the "Select Group Data" key. This program entry tells the SCP when to enable the system CWR control function.

5. To change the "SET = " value from the SCP default setting of 0 (i.e., off), press the " ↓ " and " ↓ " keys, as appropriate, until the desired setpoint is displayed. CWR setpoint values range from 1 F through 140 F in increments of 1 F.

Note: Whenever the CWR setpoint is less than or equal to 25 F, it is defined as the system design delta-T (i.e., differential between system entering and leaving chilled water temperatures). If the "SET = " value is greater than 25 F, the SCP identifies this control setting as an outdoor ambient temperature. Check the position of configuration DIP Switch No. 4 (i.e., see "SCP699 DIP Switch Setup):

a. In the "normal" mode, CWR is enabled whenever the actual outdoor ambient temperature is less than or equal to the CWR "SET = " value.

b. When the outdoor ambient "reverse" mode is selected, CWR is enabled when the outdoor temperature is greater than the CWR "SET = " value.

6. Store the selected CWR setpoint temperature in the SCP's memory by pressing the "Enter" key.

System Setup: Cooldown Control

Note: If you haven't already accessed the "system" programming menu, press the "Select Main Menu" key until "SYSTEM" appears on the display. Then follow the instructions outlined below.

To set up the SCP's cooldown control function:

1. Press the "Select Group Menu" key until "COOLDOWN" appears on the display.

Check the SCP's status indicator lights; notice that the "Cooldown Control" light is on. It will remain lit as long as programming entries associated with the cooldown control function are displayed.

2. Depress the "Select Group Data" key once; "LIM. = " should appear on the display. This program entry gives the SCP the effective system current limit setpoint for cooldown operation.

Note: Remember that the current limit aspect of the cooldown control function is inoperative unless "AUTO" is entered for the system current limit setpoint.

3. Enter the desired cooldown current limit setpoint by pressing the " ↓ " and " ↓ " keys until the proper "LIM. = " value is displayed; then press "Enter".

Values for this setpoint range from 1% through 100% of the total chiller RLA. Entering the SCP default setting--"LIM. = 0"--disables the cooldown control function.

4. Press the "Select Group Data" key to display the cooldown period setting (i.e., "END = "). The value entered here not only determines the length of the cooldown period, but also establishes the minimum "on" time for thermostatically-controlled free cooling.

Control setting values for "END = " range from zero (00.00) through 2 hours (02.00) in 15-minute increments. "END = 00.00" serves as the SCP's default setting. For example, if the "END = " setting is 01.15, the cooldown period will last 75 minutes.

5. Enter the desired value for the cooldown period control setting by pressing the " ↓ " and " ↓ " until the proper "END = " setting is displayed; then press "Enter".

System Setup: Control Gain

Note: If you haven't already accessed the "system" programming menu, press the "Select Main Menu" until "SYSTEM" appears on the display. Then follow the instructions outlined below.

To set up the standard SCP control gain function:

1. Press the "Select Group Menu" key until "CONTROL" appears on the display.

2. Depress the "Select Group Data" key once; "GAIN = " should appear on the display. This program entry directly affects the SCP's responsiveness to changes in cooling requirements; the lower the control gain setting, the longer the SCP's reaction time.

SCP control gain is measured in arbitrary units ranging from 1 through 100, with "GAIN = 8" serving as the default setting.

3. Enter the desired control gain setting. To do this, use the " ↓ " and " ↓ " keys to display the proper "GAIN = " value; then press "Enter".

A control gain setting of "15" is appropriate for most system applications.

Note: Entering an increased gain setting at the SCP will not necessarily yield a faster system response time since the SCP must wait for the units to respond to–and stabilize at–their own individual chilled water setpoints. Instead, the higher "GAIN = " value causes the SCP to more rapidly communicate setpoint changes to the units–but only after:

a. all connected units "tell" the SCP that they are in control (and have been for the last 75 consecutive seconds); and,

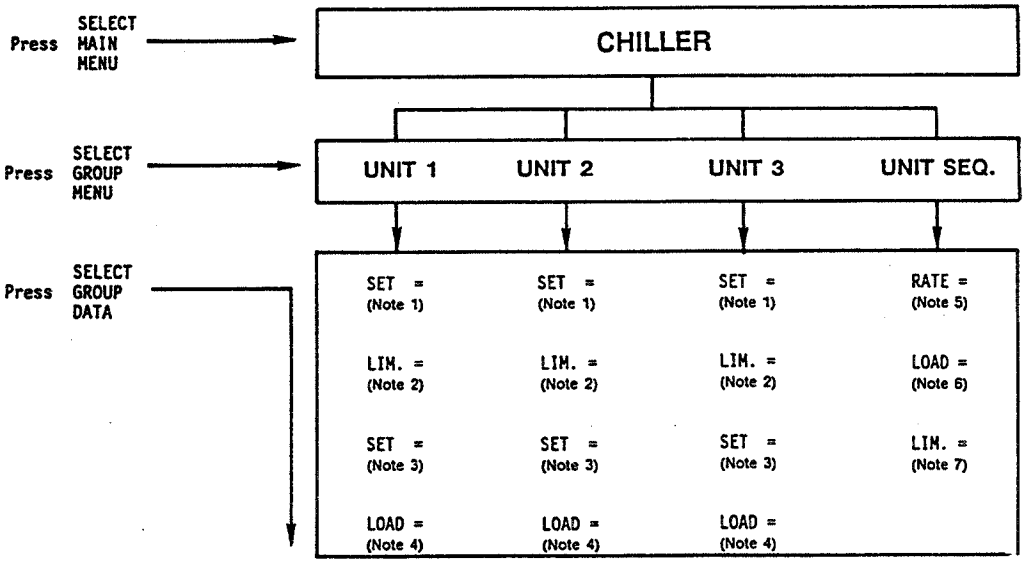
b. a discrepancy exists between the actual chilled water temperature and the system chilled water setpoint.

"Chiller" Program

Use of the SCP's chiller programming menu allows the operator to manually establish the following control settings for each chiller in the system:

1. leaving chilled (evaporator) water temperature setpoint;

2. electrical current limit setpoint;



3. order in the chiller start sequence rotation; and,

4. percentage of total chiller capacity.

Values entered for these chiller settings become the effective operating setpoints for the unit designated, provided that the chiller switch (i.e., located on the UCP695 unit control panel) is set at "Auto/Remote".

For an illustration of "chiller" menu organization, see Figure 13. A summary of available control settings for each operating parameter is also included there.

Figure 13
"Chiller" Setup

Notes:
1. Leaving chilled water setpoint for that particular unit; possible control settings include: AUTO (i.e., default setting), OFF, and 1 F thru 99 F in increments of 1 F. "Manual Control" status indicator light is on.
2. Current limit setpoint–in terms of % compressor RLA–for that particular unit. Values for this control setting are AUTO (i.e., default setting), and 0% thru 100% of the compressor RLA. "Manual Control" status indicator light is on.
3. The "UNIT SEQ. SET = " entry determines whether this particular chiller is to be started first, second or last. Control settings are 1, 2 or 3; the default setting is 1.
4. Use the "LOAD = " entry to indicate the relative current draw of this particular unit when compared to the total chiller RLA. Possible values for this setting range from 1% (i.e., default) thru 100% of the total chiller RLA. The sum of the "LOAD = " entries for Units 1, 2 and 3 should equal 100%.
5. Rotation period–in days–for the chiller start sequence (i.e., see Note 3). Values ranging from 0 thru 99 may be entered; the default setting is 0 (i.e., no rotation).
6. This program entry tells the SCP when to start an additional chiller. Possible values range from 20% (i.e., default) thru 100% of the compressor RLA; however, the load setting entered must exceed the unit sequence "LIM. = " entry (Note 7) by at least 20.
7. Unit sequence limit setpoint; tells the SCP when to shut down an operating chiller running under SCP control. Possible settings range from 0% (i.e., default) through 80% of the compressor RLA.

Remember this equation when entering setpoints for the unit sequence load and limit:

UNIT SEQ. LOAD > UNIT SEQ. LIMIT + 20

Chiller Setup

Follow the instructions outlined below to set up individual chiller operating setpoints from the SCP:

1. Access the SCP's "Chiller" menu. To do this, press the "Select Main Menu" key until "CHILLER" appears on the alphanumeric display.

2. Select the chiller you wish to set up (i.e., "UNIT 1", "UNIT 2" or "UNIT 3") by pressing the "Select Group Menu" key.

Note: Remember that the unit's identity–or "address"–is assigned at switch block S11 in the UCP695 control panel of each chiller. (See "UCP695 DIP Switch Setup" in the Start-Up section of this manual.)

3. Enter the desired leaving chilled water temperature for that unit.

a. Push the "Select Group Data" key once to display the unit's chilled water setpoint. "SET = " (or "AUTO") should appear, and the "Manual Control" status indicator light will illuminate.

b. Press the " ↓ " and " ↑ " keys until the desired "SET = " value is displayed. Possible entries for this control setting are: AUTO (i.e., default setting), OFF, and 1 F through 99 F in increments of 1 F.

Note: The SCP cannot automatically control unit operation unless AUTO is entered for "SET = " .

c. Press "Enter" to store the selected unit chilled water setpoint in the SCP's memory.

4. Enter the desired unit electrical current limit setpoint.

a. After completing the chilled water setpoint entry (Step 3), press "Select Group Data" once. "LIM. = " (or "AUTO") will appear on the display, and the "Manual Control" status indicator light will come on.

b. Use the " ↓ " and " ↑ " keys to obtain the desired "LIM. = " setpoint. Values for the unit current limit setting include AUTO (i.e., default setting), and 0% through 100% of the compressor RLA.

Note: To enable the SCP's electrical demand limit, cooldown, and unloading-before-a-start control functions, enter "LIM. = AUTO".

c. Press "Enter" when the selected "LIM. = " value is displayed.

5. Determine where you wish to place this unit in the chiller start rotation (i.e., first, second or third).

a. After entering a "LIM. = " value (Step 4), press the "Select Group Data" key once to display the chiller start rotation order (i.e., "UNIT SEQ. SET = ") setting for this unit.

b. Use the " ↓ " and " ↑ " keys to obtain the desired sequence order. Control settings of 1, 2 and 3 tell the SCP whether to start this chiller first, second or last, respectively. (The default setting is "UNIT SEQ. SET = 1".)

Note: The SCP changes this value automatically at the end of each rotation period (i.e., "RATE = ").

c. Press "Enter" when the selected order in the start rotation is displayed.

6. Enter the relative current draw of this unit (i.e., percentage of total chiller current draw for the system).

a. Once the unit sequence setting is entered (Step 5), press "Select Group Data" once; "LOAD = " will appear on the display. (The SCP uses this program entry to calculate system current draw.)

b. Determine the relative current draw of this particular unit when compared to the chiller RLA of the system:

$$\text{LOAD \#1} = \frac{\text{UNIT 1 RLA}}{\text{SYSTEM RLA}},$$

where the "LOAD #x" value is rounded to the nearest integer.

For instance, if a system includes 3 chillers of equal size, the "LOAD = " value for each chiller would be 33, 33 and 34.

Note: The sum of the "LOAD = " settings for all chillers connected to the SCP (i.e., Unit 1, Unit 2 and Unit 3, if applicable) must equal 100%.

c. Press the " ↓ " and " ↑ " keys until the correct numeric value for "LOAD = " is displayed; then press "Enter". (Control settings range from 1% through 100% of total chiller current draw.)

7. Repeat Steps 2 through 6 for each remaining chiller in the system.

Note: When fewer than 3 chillers are connected to the SCP, you may wish to change these control settings for the unused chiller designations (i.e., "UNIT 3", or "UNIT 2" and "UNIT 3"):

a. enter "OFF" for the unit "SET = " chilled water temperature setpoint; and,

b. enter "0" for the unit "LIM. = " electrical current limit setpoint.

8. Access the SCP's chiller start sequence function by pressing the "Select Group Menu" key until "UNIT SEQ." is displayed. (See Figure 13.)

9. Set up the frequency of rotations for the chiller start sequence.

a. Press the "Select Group Data" key once to display the unit sequence rate program entry (i.e., "RATE = "). The range of settings extends from 0 days through 99 days; if "RATE = 0" (i.e., default setting), automatic rotation of the chiller start sequence will not occur.

b. Use the " ↓ " and " ↑ " keys as needed to obtain the desired rotation period.

c. Press "Enter" when the selected "RATE = " value is displayed.

10. Enter a value for the unit sequence load setpoint. This numeric value is a percentage of the compressor RLA for each chiller, and is used to tell the SCP when to start another chiller. (The SCP looks at the "UNIT SEQ. SET = " values [entered in Step 5] to determine which chiller to bring "on-line".)

a. Press the "Select Group Data" key once; "LOAD = " will appear on the display.

b. Use " ↓ " and " ↑ " to obtain the desired control setting; values range from 20% (i.e., default setting) through 100% of the compressor RLA for each chiller.

"LOAD = " values of 90% to 95% are recommended for most system applications.

Note: The load setting entered must exceed the unit sequence "LIM. = " entry (Step 11) by at least 20.

c. Press "Enter" when the selected "LOAD = " value is displayed.

11. Enter the desired setting for the unit sequence limit setpoint. The SCP uses this setpoint to decide when to shut down a chiller operating under its control. (The "UNIT SEQ. RATE = " settings entered in Step 5 also determine the order for shutting down the chillers.)

a. Press the "Select Group Data" key once; "LIM. = " will appear on the display.

b. Use the " ↑ " and " ↓ " keys to obtain the desired control setting; values range from 0% (i.e., default setting) through 80% of the compressor RLA for each chiller.

"LIM. = " values of approximately 55% are recommended for most system applications.

c. Press "Enter" when the selected "LIM. = " value is displayed.

Note: When determining the unit sequence limit setpoint, remember this equation:

UNIT SEQ. LOAD > UNIT SEQ. LIM. + 20.

where:

[ ] the unit sequence load setting corresponds to approximately 90% to 95% of a chiller's capacity (i.e., under normal operation, this value must be exceeded by all operating chillers before an additional chiller is started);

[ ] the unit sequence limit setting represents approximately 40% to 45% of a chiller's cooling capacity (i.e., all operating chillers must be operating below this value before a chiller is shut down); and,

[ ] the units affected are only those with chiller switches positioned at AUTO/REMOTE.

Note: Unit sequence load and limit settings are based on chiller RLA. When selecting appropriate values for these setpoints, it is important to remember that there is not a direct relationship between a chiller's RLA and its relative cooling capacity.

* * * * *

For your convenience, an "SCP Operator Reference Guide"--summarizing the SCP's report and programming menus--is provided at the back of this manual.

SCP Setup Recommendations for Typical Systems

Remotely-Controlled SCP

While the SCP controls the operation of connected chiller system equipment, its own operation can–in turn–be governed remotely from a higher-level control device.

There are 3 alternatives for remotely controlling the SCP; the extent or degree of control possible varies with the remote control method selected:

[ ] **Bidirectional Communications Link (BCL).** This method of remote control allows the operator the most flexibility when deciding whether various chiller system control functions are executed by the SCP or a Trane BAS (e.g., Tracer®).

Using the direct serial link established with the BCL, a Tracer can receive all SCP data and control information, as well as communicate all programmable control settings to the SCP.

Notice that chiller and system data can be displayed at either the SCP or the Tracer. Manual overrides for system and individual chiller setpoints are available at the SCP.

[ ] **"Scheduled System Enable/ Disable" Binary Input.** Like a remote "on/off" switch, the SCP's "Scheduled System Enable/Disable" binary input allows a supervisory controller (e.g., time clock or BAS) to turn on the chiller system by closing a set of contacts. Similarly, opening these same contacts will shut down system operation.

To use this method of remote control, the SCP must be: (1) wired to control the chillers and auxiliary equipment; and, (2) programmed to provide either 24-hour, stand-alone operation, 7 days a week, or scheduled system operation.

Again, manual overrides for system and individual chiller setpoints are available at the SCP, but chiller and system data can only be displayed at the SCP.

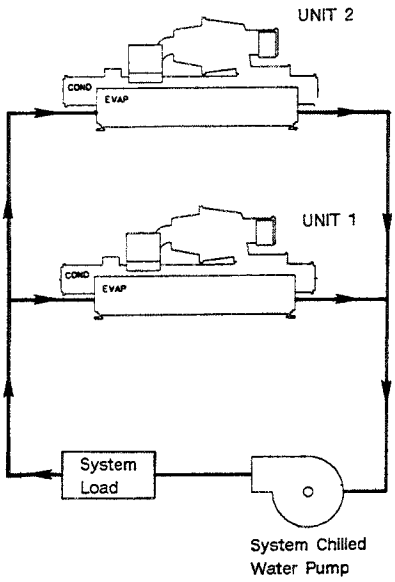
[ ] **Generic BAS Option.** Once the generic BAS option is installed and enabled, the SCP loses all but two of its system control capabilities (i.e., automatic on/off free cooling and condenser limit control functions are retained). Therefore, the generic BAS must be responsible for controlling the chilled water pumps and chillers–as well as issuing any temperature or current setpoint analog inputs.

Notice, too, that manual overrides available at the SCP are restricted to individual unit setpoints.

Note: When programming the SCP to meet the requirements of your chiller system, be sure to account for the impact of any supervisory controller on SCP operation!

Sample SCP Programs

Following are SCP program examples that correspond to 3 typical types of chiller systems:



1. 2 parallel-piped chillers with a common system chilled water pump;

2. 2 series-piped chillers with a common system chilled water pump; and,

3. 3 parallel-piped chillers in a decoupled system with a chilled water pump for each chiller and a common system pump.

These examples–along with the explanations that accompany them–are intended to help you establish an SCP program that meets the requirements and constraints of your chiller system application.

Example 1
2 Parallel-Piped Chillers

System Characteristics

[ ] Common system chilled water pump.
[ ] SCP controls system operating schedule.
[ ] System design delta-T is 10 F.

UCP695 Chiller Control Panel Settings

[ ] chilled water setpoint = 45
[ ] current limit setpoint = 100
[ ] control gain setpoint = 25
[ ] differential-to-start setpoint = 6 (7)
[ ] condenser limit setpoint = 95
[ ] evaporator refrig. trip setpoint = 30

Notes:

1. Notice that Friday has been assigned a holiday operating schedule. In this example, the chiller system will be turned off all day Friday; the normal system operating schedule will be executed the following Friday.

2. The free cooling parameters set up in this sample program allow the SCP to automatically initiate free cooling operation at system start-up if the temperature (i.e., outdoor ambient) registered by the freecool sensor is less than or equal to 50 F.

Notice that the system will remain in the free cooling mode for a minimum of 1 hour (i.e., cooldown period). If there is sufficient free cooling capacity to maintain a system chilled water temperature of 55 F or less, the SCP will remain in this mode.

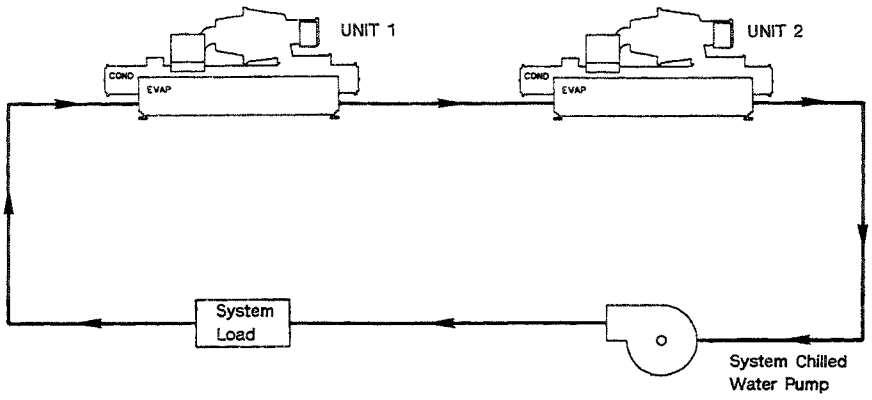
3. Notice that the chilled water reset parameters are programmed to maintain a constant return water temperature (i.e., RATE = 100) that is 10 F (i.e., CWR SET = 10) above the scheduled system chilled water setpoint of 45 F.

Maintenance of a constant return water temperature during chilled water reset can be critical in parallel-piped chiller systems where there may be water flow through a nonoperating chiller(s). In this situation, chilled water from an operating chiller mixes with return water through the nonoperating chiller to supply a warmer "mixed" chilled water temperature to the building.

Because its leaving chilled water temperature sensor is registering this "mixed" temperature, the SCP may step the operating chiller's setpoint significantly below the actual system setpoint in order to satisfy the cooling load. Operating the chiller system at a constant return water temperature will prevent this from occurring.

4. Values entered for the SCP's cooldown control settings in this program will ramp the system chilled water setpoint from the start-up water temperature to 45 F over a 1-hour period. Since the cooldown current limit setting is 100, no current limiting will occur during this time.

System free cooling operation may occur during the cooldown period if the outdoor ambient is low enough (i.e., free cool sensor registers a temperature less than or equal to 50 F).



5. To enable SCP control of the unit chilled water setpoints, each setpoint entry in the SCP's CHILLER menu must be AUTO.

6. AUTO must be entered for each of the unit current limit entries in the CHILLER menu to allow the SCP's electrical demand limit function to operate.

These AUTO current limit entries also cause the SCP to unload the running chiller just before the second chiller is brought on-line; this allows the system to establish a load-balance between the chillers.

7. Notice that the differential-to-start setting at each UCP695 chiller control panel is 6. Setting the unit differential-to-start setpoint at a value slightly higher than 1/2 the unit's design delta-T also helps the SCP achieve a load-balance between the chillers.

Example 2
2 Series-Piped Chillers

System Characteristics

[ ] Common system chilled water pump.
[ ] SCP is enabled remotely from an external control system.
[ ] Chiller design delta-T is 10 F.
[ ] UNIT 1 is the "upstream" chiller.

UCP695 Chiller Control Panel Settings

[ ] chilled water setpoint = 45
[ ] current limit setpoint = 100
[ ] control gain setpoint = 25
[ ] differential-to-start setpoint = 5 (5)
[ ] condenser limit setpoint = 95
[ ] evaporator refrig. trip setpoint = 30

Chilled Water	SET = AUTO (2)	
Current	SET = AUTO	
Freecool	FC SET = OFF	FC SCWS = 1
El. Demand	LIM. = 0	RATE = 0
Reset	RATE = 0	CWR SET = 0
Cooldown	LIM. = 0	END = 0.00
Control	GAIN = 15	

CHILLER Menu

	UNIT 1	UNIT 2	UNIT 3
Chilled Water	SET = AUTO	SET = AUTO	SET = OFF
Current Limit	LIM. = 100	LIM. = 100	LIM. = 0 (3)
Sequence No.	SET = 2	SET = 1	(4)
Load (% Total)	LOAD = 50	LOAD = 50	
Sequence	RATE = 0 (4)	LOAD = 90	LIM. = 55

Notes:

1. Notice that the operator entries in the SCP's SCHEDULE menu set up continuous system operation (i.e., 24 hours each day, 7 days a week). Actual chiller system operation is then enabled and disabled by an external contact closure at the SCP's "Scheduled System Enable/ Disable" binary input (i.e., TB3-5 and -6).

2. To "force" the SCP to obtain its system chilled water setpoint from the SCHEDULE menu, AUTO is entered for the chilled water setpoint entry in the SCP's SYSTEM menu.

3. In this program, a value of 100 was entered for the current limit settings in the SCP's CHILLER menu. While this restrains the SCP from unloading the operating chiller when the second unit is started (i.e., as it would if "LIM. = AUTO"), it may also hinder the SCP's ability to load-balance the 2 chillers.

See Note 6 in Example 1.

4. The sequence number assignments in the SCP's CHILLER menu ensure that the downstream chiller–UNIT 2–is always the first chiller to start (i.e., CHILLER Sequence "RATE = 0"). This arrangement minimizes any disturbance of the system leaving chilled water temperature caused by start-up of the upstream chiller (UNIT 1).

If the downstream chiller in this system (UNIT 2) was turned off first, UNIT 1's chilled water setpoint would be rapidly adjusted to bring the system leaving chilled water temperature to setpoint.

5. In series-piped chiller systems, the SCP will attempt to load-balance both chillers as soon as the second chiller is started; load-balancing is accomplished by adjusting each unit's chilled water setpoint.

Notice that increasing or decreasing the differential-to-start setting at the second unit's UCP695 chiller control panel (i.e., UNIT 1 in this example) can influence the load-balance attained by the SCP.

Lowering the value of the upstream unit's differential-to-start setpoint can cause the downstream chiller to initially assume most of the cooling load. However, further increases in system delta-T will be absorbed by the upstream chiller until it reaches its maximum capacity; additional loading of the downstream chiller will not occur until this point is reached.

Load (% Total)	LOAD = 20	LOAD = 40	LOAD = 40
Sequence	RATE = 0	LOAD = 90	LIM. = 55

System Characteristics

[ ] Decoupled chiller system.
[ ] Individual chilled water pumps for each chiller, and a common system chilled water pump.

UCP695 Chiller Control Panel Settings

[ ] chilled water setpoint = 45
[ ] current limit setpoint = 100
[ ] control gain setpoint = 10 (2)
[ ] differential-to-start setpoint = 5
[ ] condenser limit setpoint = 95
[ ] evaporator refrig. trip setpoint = 30

Notes:

1. Notice that the chiller sequencing shown in this program example is slightly different than that used in the previous examples.

Since all of the chillers are assigned the same sequence number (i.e., SET = 1), the SCP compares the unit addresses to determine the chiller start order. In this example, UNIT 1 would be started first, followed by UNIT 2 and UNIT 3, respectively.

Notice, too, that when the SCP decides to shut down a chiller, UNIT 1 will be turned off first, followed by UNIT 2 and UNIT 3, respectively. In this example, because the unit sequence numbers are the same–and the smallest unit has the lowest unit address, the smallest chiller is always turned off (and turned on) first. Look at the "Load (% Total)" entries in the SCP's CHILLER menu; the values entered there indicate that UNIT 1 is 1/2 the size of UNIT 2 and UNIT 3.

Since the rotation interval is set at 0 (i.e., "RATE = 0" in the CHILLER menu), the chiller start-up and shutdown orders just described will be maintained permanently.

2. In a decoupled chiller system, leaving (supply) chilled water may flow into the entering (return) water circuit whenever there is an imbalance between the amount of water circulating in the chiller loop and that circulating in the load loop. This can significantly reduce the circulation time of the chiller water loop!

When this type of loop imbalance exists, the unit leaving chilled water temperature sensor (4RT1) of each chiller must respond quickly. To ensure the fastest possible response time:

a. verify that each 4RT1 sensor is inserted properly into its bulbwell, and that enough thermoconductive paste has been used to provide good thermal contact.

b. reduce the control response setting at each UCP695 chiller control panel to approximately 1/2 of the calculated value. (Contact a qualified service technician for assistance.)

The chiller control response setting selected for each unit should be high enough that the unit starts properly and remains on-line when it approaches its setpoint, yet low enough to prevent the system temperature from cycling at low loads.

A unit control response setting of 8 to 12 may be appropriate for a chiller used at the rated water flow, and with a design delta-T of 10 F.

SCP699 Operation

Overview

SCP699 System Control Panels are primarily intended to coordinate operation of connected chiller system equipment (Figure 14) to satisfy and maintain an operator-selected system leaving (supply) chilled water temperature.

To determine–automatically–what system- and chiller-level operating states are needed to meet this cooling requirement, the SCP checks the control settings entered by the system operator, and evaluates:

1. the status of its binary input circuits (i.e., "Scheduled System Enable/Disable" [TB3-5, -6], and "Free Cooling Enable/Disable" [TB3-7, -8]);

2. digital data communicated over its bidirectional communication links (BCLs) with the chillers and Trane BAS, if applicable; and,

3. temperature inputs received from field-installed sensors. The following sensors may be connected to the SCP, depending on system application:

a. system leaving chilled water temperature sensor (i.e., part no. 4533-1710-44B);
b. system entering (return) water temperature sensor (i.e., part no. 4533-1710-44B);
c. free cooling temperature sensor (i.e., part no. 4533-1710-41B);
d. condenser control temperature sensor (i.e., part no. 4533-1710-41C).

Collectively, this information influences the SCP's control status. That is, (1) does a system cooling requirement exist?, and–if so, (2) should free cooling or powered cooling operation be used to satisfy the cooling load?

These major SCP control states (i.e., "off", "cooling" and "free cooling"–along with the system inputs that initiate them–are summarized in Table 7.

Besides providing overall system temperature control, the SCP also includes control functions that enable the operator to dictate the system operating state, limit chiller cooling capacity, and modify the established system chilled water setpoint. These "user-oriented" SCP control functions include scheduling, cooldown, system current and electrical demand limiting, free cooling, and chilled water reset.

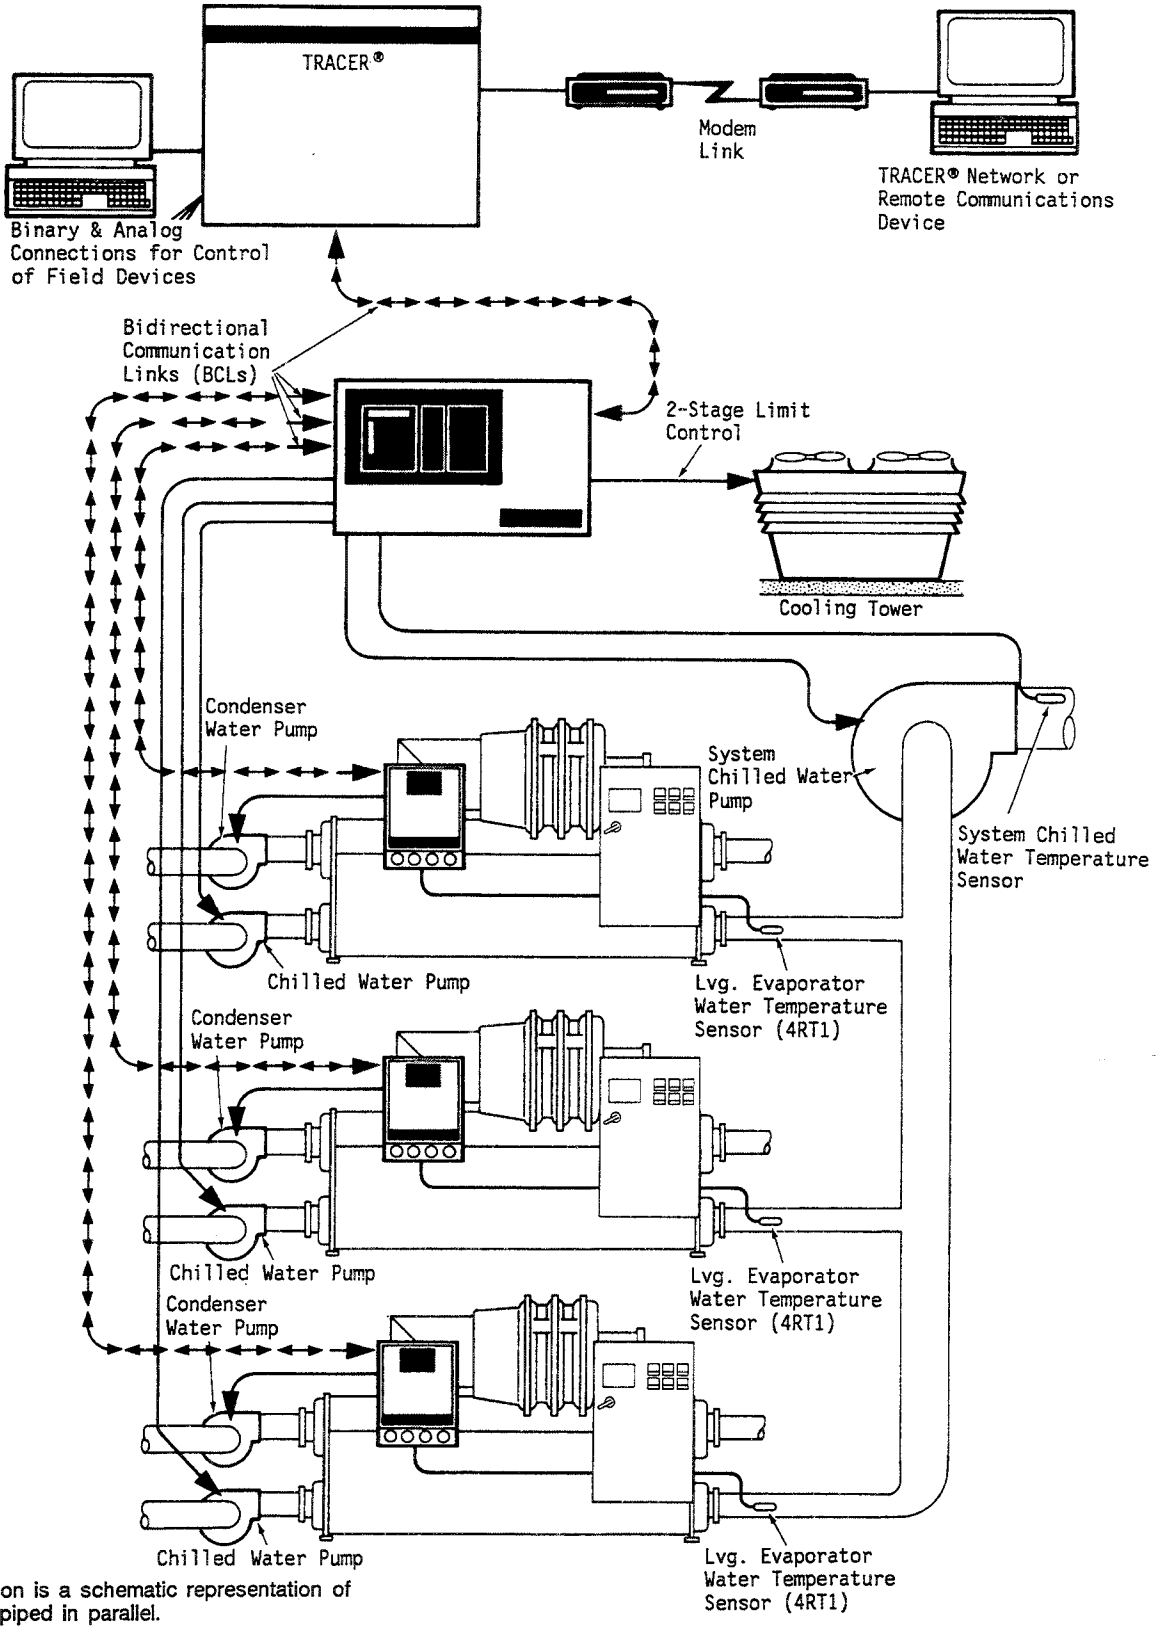

Table 7
Major SCP Control States

Manual System CWS (1)	Trane BAS System CWS (2)	Scheduled System CWS (3)	SCP Enable (Binary Input; See Note 4)	SCP Status (5)
Off On	On or Off " "	On or Off " "	Open or Closed " "	Off Cooling
Auto "	Off On	On or Off " "	Open or Closed " "	Off Cooling
Auto "	Auto "	Off On	Open or Closed Closed	Off Cooling
Auto	Auto	On	Open	Off

Notes:
1. Manual system chilled water setpoint is entered with the SCP's "SYSTEM: CHLD. WTR." programming menu; see Figure 9. It is "on" whenever the manual CWS is a valid setpoint and not OFF.
2. Trane BAS system chilled water setpoint is communicated over the BCL (i.e., SCP Terminals TB2-7, -8). It is "on" whenever the BAS system CWS is a valid setpoint and not OFF.
3. Scheduled system chilled water setpoint is entered using the SCP's "SCHEDULE" programming menu; see Figure 9. It is "on" whenever the scheduled CWS value is a valid setpoint and not OFF.
4. Represents the status of the SCP's "Scheduled System Enable/Disable" binary input circuit at Terminals TB3-5 and -6.
5. Major SCP control states are defined as follows:
   a. "Off" = a "ready" status;
   b. "Cooling" = powered cooling or free cooling operation is enabled.

Table 12 indicates the control hierarchy in effect when the SCP's system-level free cooling function is used.

Figure 14
Typical SCP/Chiller System Application

Note: This illustration is a schematic representation of 3 CenTraVac chillers piped in parallel.

The availability of these (and other) SCP control functions in a particular system application is determined by the field-installed input and output wiring connections. Refer to Figure 15; notice that SCP functions can be categorized into 3 "capability" levels, with each level defined by the types of inputs and outputs (i.e., I/O's) required.

[ ] "Level 1" input/output wiring connections must be field-installed to make the SCP operational. Once these connections (i.e., 120 VAC power supply, system chilled water temperature sensor, and CenTraVac BCL) are complete, the SCP is capable of the following standard control functions:

a. coordinated control of as many as 3 CenTraVac chillers;
b. 7-day, 24-hour scheduling;
c. chiller sequencing and automatic rotation;
d. system chilled water temperature control;
e. system and individual chiller reporting;
f. manual system control override;
g. manual chiller control overrides and,
h. cooldown.

[ ] "Level 2" input/output connections "tailor" SCP control functions to the requirements of a specific chiller system application. All of the control schemes associated with "Level 2" I/O's are standard, and are available in addition to the basic control functions found at "Level 1".

"Level 2" SCP control capabilities include:

a. chilled water reset;
b. remote system enable/disable;
c. remote free cooling enable/disable;
d. electrical demand limit control;
e. bidirectional communication with a Trane BAS or monitoring system;
f. system chilled water pump control;
g. individual chiller evaporator water pump control; and,
h. external alarm function.

Note: Selection of any--or all--"Level 2" control functions will not disable any other SCP function.

[ ] "Level 3" input/output connections are associated with SCP control features that are purchased as options. Two of the 3 functions found at this level will deactivate some of the SCP's standard control functions.

A brief description of all 3 optional control features--including any limitations--is provided below.

a. Thermostatically-Controlled, Automatic Free Cooling. Field installation of the optional free cooling temperature sensor enables the SCP to decide when it is appropriate to initiate system-level free cooling. Use of this optional control function overrides the SCP's remote free cooling binary input.

b. Condenser Limit Control. Use of this option--which consists of an electronic sideboard and 4 temperature sensors--will not disable any other SCP control function. Once installed, the sensors detect unit refrigerant temperature differences between the condensers and evaporators, triggering activation of 2 SCP output relays. Enable/disable setpoint values for these relays are operator-programmable.

c. Generic BAS. Comprised of an electronic sideboard and 6 resistors, this option requires field installation of up to 6 analog input lines (i.e., 2 per chiller) between the generic BAS and the SCP. A DIP switch located on the sideboard serves as an "on/off" switch for the generic BAS/SCP interface.

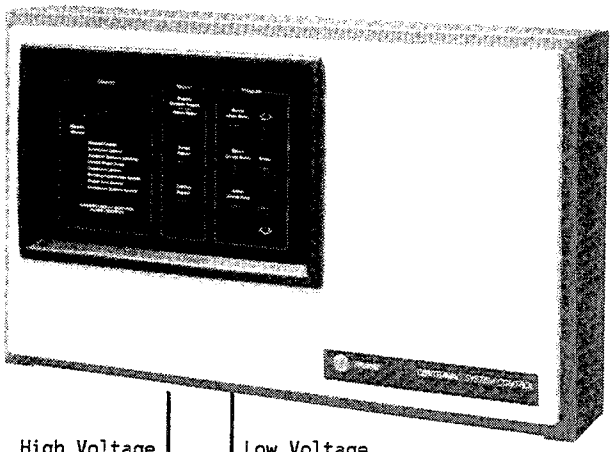
It is important to realize that nearly half of the SCP's inputs, outputs and associated control functions become inoperative when the generic BAS option is installed and enabled. Refer to the asterisked items in Figure 15.

* * * * *

The remainder of this section discusses the basic operation of a number of major SCP control functions; these include:

[ ] system chilled water temperature and current limit control;
[ ] chiller sequencing and automatic rotation;
[ ] cooldown;
[ ] chilled water reset;
[ ] manual and automatic free cooling;
[ ] bidirectional communication with a Trane BAS;
[ ] electrical demand limiting;
[ ] system chilled water and unit evaporator pump control;
[ ] optional generic BAS interface; and,
[ ] optional condenser limit control.

Note: When reviewing the operation of these control functions, remember that the SCP can--in turn--be controlled by a higher-level device. Three "avenues" for SCP interaction with a supervisory controller are available:



1. a bidirectional communication link (i.e., Trane BAS only);

2. an optional analog interface (i.e., generic BAS); and,

3. a "scheduled system enable/disable" binary input.

For explanations of the SCP's scheduling and reporting functions, refer to SCP699 Operator Interface. Manual system- and chiller-level overrides are described where appropriate throughout this manual.

Figure 15
SCP Control Functions and Input/Output Requirements

Art No. RF/CTV-190C

High Voltage (115 VAC)

"Level 1" Inputs/Outputs (Note 1)
[ ] 115 VAC Power Supply

"Level 2" Inputs/Outputs (Note 2)
[*] System Chilled Water Pump Relay, energized when system requires cooling
[ ] System "External" Alarm Relay (NO/NC)
[*] Chiller Evaporator Pump Relays, 1 relay per chiller; energized before corresponding chiller is started

"Level 3" Inputs/Outputs (Note 3)
[ ] Condenser Water Control Relays (2)

Low Voltage (< 30 Volts)

"Level 1" Inputs/Outputs (Note 1)
[*] System Leaving Chilled Water Temperature Sensor (i.e., optional for single-chiller systems, but req'd. for system-level CWR)
[ ] BCL to Chiller Control Panel(s)

"Level 2" Inputs/Outputs (Note 2)
[*] System Entering Chilled Water Temperature Sensor (Req'd. for Chilled Water Reset)
[ ] Scheduled System Enable/Disable (Req'd. for Remote On/Off)
[ ] Free Cooling Enable/Disable (Req'd. for Remote FC On/Off)
[*] Electrical Demand Meter Pulse Input (Req'd. for Elec. Demand Limit)
[ ] BCL to Trane BAS or Monitor (Req'd. for Trane BAS Control)

"Level 3" Inputs/Outputs (Note 3)
[*] Free Cooling Temperature Sensor (Req'd. for Thermostatically-Controlled FC)
[ ] Condenser Water Temperature Sensor, incl. 3 additional sensors for connection at chiller(s) (Req'd. for Condenser Limit Control)
[ ] Generic BAS, 2 analog inputs per chiller

Notes:

1. "Level 1" I/O field wiring connections are required to enable SCP to function at its minimum capability, which includes these standard control functions:
- – multiple-unit control for up to 3 CenTraVacs
- * – 7-day, 24-hour scheduling
- * – chiller sequencing and automatic rotation
- * – system chilled water temperature control
- – system and individual chiller reporting
- * – manual system override
- – manual chiller override(s)
- * – cooldown ("soft start")

2. "Level 2" I/O field wiring connections can be made selectively if associated function is desired for a particular system application. All "Level 2" functions are standard, and will not disable any "Level 1" functions; they include:
- * – chilled water reset
- – remote system enable/disable
- – remote free cooling enable/disable
- * – electrical demand limit control
- – bidirectional communication with Trane BAS or monitor
- * – system chilled water pump control
- * – individual chiller evaporator pump control
- – field-supplied/-installed alarm device

3. "Level 3" I/O field wiring connections are associated with 3 optionally purchased SCP control functions. These optional functions are listed below; notice that 2 of them deactivate a number of standard SCP control functions.

- – thermostatically-controlled automatic free cooling (i.e., overrides remote free cooling enable/disable binary input)
- – condenser limit control (i.e., does not disable any other SCP function)
- – generic BAS (i.e., disables all asterisked I/O's and functions; see asterisked note at right)

***Generic BAS disables all asterisked I/O's and functions when installed and enabled, though system leaving and entering water temperature sensors may still be installed for readout display if desired.**

System Chilled Water Temperature Control

Note: System-level chilled water temperature control is not available when the SCP is used in a generic BAS application.

Designed to perform overall temperature control for CenTraVac water chiller systems, the SCP699 panel determines what coordinated unit chilled water (and current limit) setpoint(s) are needed to maintain a stable system leaving chilled water temperature. To do this, the SCP compares the effective system chilled water setpoint with the actual system leaving chilled water temperature.

Notice that the operator can enter a system chilled water setpoint (SCWS) in several ways; he can (1) schedule a setpoint using the SCP's "SCHEDULE" program, (2) enter a manual setpoint with the SCP's "SYSTEM" program, (3) enable a Trane BAS to communicate a setpoint value to the SCP over the Tracer BCL, or (4) allow a generic BAS to send unit setpoint reset values to the SCP via an optional analog interface.

Since several system chilled water setpoint values may exist at one time, the SCP must decide which value to use (i.e., which takes precedence, or is the effective SCWS). This temperature control decision is based on the setpoint priority shown in Table 8 and described below:

1. Use the **manual SCWS** value (i.e., see "'System' Program" in the section entitled SCP699 Operator Interface).

If this "SET =" entry is "AUTO", then . . .

2. Use the **Trane BAS-issued SCWS** value.

If there have been no BAS communications for the last 15 minutes, or if the BAS setpoint is AUTO, then . . .

3. Check the **status of the "SCP enable" contacts** (i.e., "Scheduled System Enable/Disable" binary input circuit; SCP Terminals TB3-5, -6).

When this circuit is open, shut off the system; if the circuit is closed, then . . .

4. Use the **scheduled SCWS** value.

Note: Keep in mind that an SCWS value issued by a Trane BAS--or scheduled at the SCP--can be modified by the chilled water reset function (if applicable). In turn, the resulting SCWS value can then be altered again by the cooldown control function (if applicable). (Both of these control functions are described later in this section.)

Once the effective SCWS is established, the SCP compares it with the actual system leaving water temperature to determine if a cooling requirement exists.

In multiple-chiller systems, this temperature input is provided by a sensor that ships with the SCP and is field-installed in the common leaving (supply) chilled water line; here, it measures a mixed leaving water temperature.

Where the SCP is connected to a single chiller, a system sensor is not required (i.e., unless chilled water reset is also desired). Instead, the SCP can use the temperature "seen" by the chiller's leaving evaporator water temperature sensor (4RT1).

Note: When only 1 chiller is connected to the SCP--and the SCP's leaving chilled water temperature sensor is not installed, that unit must be assigned a chiller address of "1". (See "UCP695 DIP Switch Setup" on page 8.)

If system cooling is required, the SCP sends appropriate unit chilled water setpoints to each of the communicating chillers (i.e., with chiller switches set at AUTO/REMOTE). When only 1 chiller is controlled by the SCP (and a system chilled water temperature sensor is not installed), it gives that unit a chilled water setpoint equal to the SCWS.

Table 8
System Chilled Water Setpoint Priority (1)

Manual SCP Setpoint	Trane BAS Setpoint	Scheduled SCP Setpoint	SCP Enable/Disable Contact Closure (3)	Effective System Chilled Water Setpoint
1-99 F	------	------	------	1-99 F
Off	------	------	------	Off
Auto	1-99 F (2)	------	------	1-99 F
Auto	Off	------	------	Off
Auto	Auto	------	Open	Off
Auto	Auto	1-99 F (2)	Closed	1-99 F
Auto	Auto	Off	------	Off

"------" = A setpoint value entered at this control level will not determine the actual system chilled water setpoint (SCWS).

Notes:
1. This setpoint hierarchy is only applicable when the generic BAS option is not installed/enabled.
2. Trane BAS and scheduled SCP system chilled water setpoints can be modified by the SCP's chilled water reset and cooldown control functions.
3. This contact closure input is "read" at SCP Terminals TB3-5 and TB3-6; these terminals must be jumpered if not used.

Note: Like the effective SCWS, the actual unit chilled water setpoint value used by the chiller control panel is also subject to a setpoint priority; this hierarchy is summarized in Table 9 and described in Items "a" through "d" below. Notice, too, that although chilled water setpoint values at the SCP range from 1 F to 99 F, the chiller control panel will not accept a setpoint value lower than 37 F (i.e., "standard"-range units).

a. Use the **UCP695 CWS potentiometer setting** if the chiller switch is set at AUTO/LOCAL.

If the chiller switch is set at AUTO/REMOTE, then . . .

b. Use the **manual SCP unit CWS** value entered in the "CHILLER" programming menu.

If this "SET = " entry is "AUTO", then . . .

c. Use the **manual Trane BAS unit CWS** value communicated over the BCL.

If the unit CWS value sent by the Trane BAS is "AUTO", then . . .

d. Use the **calculated unit CWS** that is derived from the SCWS by the SCP's control algorithm.

Two priorities are "built into" the SCP's temperature control logic. As it calculates individual unit chilled water setpoints, it first attempts to equalize chiller loading as much as possible by evaluating each chiller's electrical current load level. Then, it tries to equalize the unit chilled water setpoints as much as possible.

Once a chilled water setpoint is communicated to a particular chiller, it is that unit's responsibility to control its own evaporator leaving water temperature. In other words, the UCP695 chiller control panel is entrusted to modulate its own inlet guide vanes and restrict their movement when limiting is appropriate.

It is important to realize that this "step-and-wait" method of control can result in slow responses to load changes. That is, after sending a new chilled water setpoint to a given unit, the SCP must wait until that unit's leaving chilled water temperature is within 1 F of setpoint for 75 seconds before it can evaluate the effect of the setpoint change.

Table 9
Unit Leaving Chilled Water Setpoint Priority (1)

Chiller Status (2)	UCP695 CWS Pot. Setting (3)	SCP Manual Unit CWS (4)	Trane BAS Unit CWS (5)	SCP Calculated Unit CWS (6)	Effective Unit CWS
Standby	-------	-------	-------	-------	OFF
Alarm (7)	-------	-------	-------	-------	OFF
Auto/Local	37-60 F	-------	-------	-------	37-60 F
Auto/Remote	-------	1-99 F	-------	-------	37-60 F (8)
Auto/Remote	-------	Off	-------	-------	Off
Auto/Remote	-------	Auto	1-99 F	-------	37-60 F (8)
Auto/Remote	-------	Auto	Off	-------	Off
Auto/Remote	-------	Auto	Auto	1-99 F	37-60 F (8)
Auto/Remote	-------	Auto	Auto	Off	Off

"——" = A setpoint value entered at this control level will not determine the actual unit chilled water setpoint (UCWS).

Notes:
1. This setpoint hierarchy is only applicable when the generic BAS option is not installed/enabled.
2. Unit status is determined by the position of the chiller switch on the front of the UCP695 chiller control panel.
3. UCP695 chilled water setpoint adjustments extend from 37 F thru 60 F for standard-range chillers, and 20 F thru 70 F for extended-range chillers.
4. Manual SCP chiller setpoints are entered using the "CHILLER" program menu; see the SCP699 Operator Interface section of this manual.
5. Specific Trane BAS-issued chiller setpoints are communicated to the appropriate chillers via the BCLs that join the BAS, SCP and chillers.
6. "Calculated" unit CWS' are derived from the effective SCWS by the SCP's control algorithm.
7. "Alarm" status indicates the existence of a latching chiller diagnostic condition; manual reset at the UCP695 panel is required to resume chiller operation. Reset the SCP to de-energize the alarm relay.
8. Though Trane BAS-issued unit CWS values–as well as manual or "calculated" SCP CWS values–may be any value between 1 F and 99 F, the UCP695 chiller control panel will only accept what it considers to be a valid entry (i.e., see Note 3). If the Trane BAS- or SCP-issued CWS value is less than 37 F, the effective unit setpoint is 37 F; likewise, if the Trane BAS- or SCP-issued CWS value is greater than 60 F, the effective unit setpoint is 60 F.

Chiller Start-Up and Shutdown

When the system cooling requirement is small enough to be satisfied by only 1 chiller, the SCP allows the first chiller in the start rotation to determine when it will start and stop based on the start differential setpoint selected at the chiller's UCP695 control panel.

Additional chillers are started when the cooling requirement is high enough so that any units presently running are either operating: (1) above the "unit sequence load setpoint", or (2) in a unit limit mode (e.g., evaporator limit). Regardless of how much cooling is required, however, the SCP will limit chiller start-ups to 1 every 6 minutes.

The SCP evaluates unit electrical loads and guide vane positions to decide when to turn off chillers. If the actual current load of each operating chiller is less than the "unit sequence limit setpoint"–or if the chillers' vanes are closed, the SCP will shut down a chiller.

By monitoring the current loads and vane positions of those chillers still running, the SCP uses the same criteria to determine whether another chiller should be turned off.

As long as the SCP is providing normal temperature control, it limits chiller shutdowns to 1 every 6 minutes. However, if the chiller system is scheduled "off", the SCP will shut down any operating units at 1-minute intervals.

Note: Unit sequence load and limit setpoints, as well as the chiller start rotation, are entered with the SCP's "CHILLER" program. Setup instructions for this program are provided in the SCP699 Operator Interface section of this manual.

Temperature Control Near Setpoint

Whenever the actual system leaving chilled water temperature is within 10 F of the system chilled water setpoint, the SCP "fine-tunes" the unit chilled water setpoints until the system chilled water temperature falls within the SCWS deadband range (i.e., ± 1 F).

SCP control logic ensures that unit chilled water setpoint (CWS) changes are limited to 1 F per minute, and that only 1 chiller is given a CWS change per minute.

Further, the SCP will only issue unit CWS changes if all operating chillers have been in control for the last 75 seconds. (If an operating chiller is not in control, the SCP will still issue unit CWS changes if that unit is running in the evaporator- or condenser-limit mode.)

Note: While the SCP will not send a lower CWS to a chiller operating in an evaporator- or condenser-limit mode, that unit will be the first to receive a higher CWS.

Internal (Fast) Cooldown

Designed to bypass the normal "step-and-wait" method of control, internal (or "fast") cooldown allows the SCP to bring the actual system leaving water temperature within proximity of the SCWS in an acceptable period of time.

To do this, the SCP gives the first chiller started a unit chilled water setpoint equal to the system setpoint; it then monitors the system leaving water temperature. If this temperature drops at a sufficient rate, no other chillers will be started. However, if the SCP determines that the temperature is not falling quickly enough, it will bring additional chillers on line (i.e., but no faster than 1 chiller every 5 minutes).

Once the system leaving water temperature is within 5 F of the system chilled water setpoint, the SCP issues new unit chilled water setpoints that are slightly higher than the leaving water temperature. This allows the chillers to unload slowly when the system chilled water temperature is rapidly approaching setpoint.

System Current Limit Control

Besides providing overall temperature control for the chiller system, the SCP also monitors and regulates the current draw of all connected–and controlled–chillers. To do this, the SCP checks the individual chiller current loads reported over the CenTraVac BCL, and compares the sum of these loads to an operator-programmable system current limit setpoint (SCLS).

Note: Setpoint values for the system current limit setting range from 0% through 100% of the total chiller RLA (i.e., in increments of 1%), and AUTO. See "System Setup: Current" in the SCP699 Operator Interface section of this manual.

If the percentage of total chiller RLA "in use" exceeds the system current limit value, the SCP will begin to unload chillers by sending the unit control panels current limit setpoints below their reported electrical load levels. Once the total chiller current load falls below the SCLS, new, increased unit current limit settings will be issued.

Keep in mind that the SCP will current-limit system operation whenever the SCLS is violated regardless of the existing cooling requirement!

Like the system chilled water setpoint, the operator can also enter a system current limit setpoint (SCLS) in 1 of 2 ways. He can either (1) select the desired manual SCLS using the SCP's "SYSTEM" program, or (2) enable a Trane BAS to communicate an SCLS over the Tracer BCL.

If an operator-entered current limit setpoint is not established at either of these levels, the SCP will use a default setting of 100%.

Since as many as 3 system current limit setpoint values may exist at one time, the SCP must decide which value takes precedence–or is the effective SCLS. It selects a controlling SCLS value on the basis of the setpoint priority shown in Table 10 and described below:

1. Use the **manual SCLS** value; but if "LIM. = " is "AUTO", then . . .

2. Use the **Trane BAS-issued SCLS** value.

If there have been no BAS communications for the last 15 minutes, or if the BAS setpoint is AUTO, then . . .

3. Use the **SCP default setting** (i.e., "LIM. = 100%").

Note: Remember that either the Trane BAS-issued SCLS value–or the SCP's default SCLS–can be modified by the cooldown function (if applicable). In turn, the resulting SCLS value can then be altered again by the electrical demand limit function (if applicable). (Both of these control functions are described later in this section.)

Determination of an effective current limit setpoint at the unit level is subject to another control hierarchy (see Table 11) that hinges on:

1. the position of the chiller switch located on each UCP695 chiller control panel; and,

2. what UCP695 chiller panel control logic will accept as a valid unit current limit setpoint.

Table 10
System Current Limit Setpoint Priority (1)

Manual SCP Setpoint	Trane BAS Setpoint	SCP Default Setpoint	Effective System Current Limit Setpoint
0-100% RLA	-------	-------	0-100% RLA
Auto	0-100% RLA (2)	-------	0-100% RLA
Auto	Auto	100% RLA (2)	100% RLA

"——" = A setpoint value entered at this control level will not determine the actual system current limit setpoint (SCLS).

Notes:
1. This setpoint hierarchy is only applicable when the generic BAS option is not installed/enabled.
2. Trane BAS and SCP default system current limit setpoints can be modified by the SCP's cooldown and electrical demand limit control functions.

Table 11
Unit Current Limit Setpoint Priority (1)

Chiller Status (2)	UCP695 CLS Pot. Setting (3)	SCP Manual Unit CLS (4)	Trane BAS Unit CLS (5)	SCP Calculated Unit CLS (6)	Effective Unit CLS
Auto/Local	40-100% RLA	-------	-------	-------	40-100% RLA
Auto/Remote	-------	0-100% RLA	-------	-------	40-100% RLA (7)
Auto/Remote	-------	Auto	0-100% RLA	-------	40-100% RLA (7)
Auto/Remote	-------	Auto	Auto	0-100% RLA	40-100% RLA (7)

"——" = A setpoint value entered at this control level will not determine the actual unit current limit setpoint (UCLS).

Notes:
1. This setpoint hierarchy is only applicable when the generic BAS option is not installed/enabled.
2. Unit status is determined by the position of the chiller switch on the front of the UCP695 chiller control panel.
3. UCP695 current limit setpoint adjustments range from 40% thru 100% of the compressor RLA.
4. Manual SCP chiller current limit setpoints are entered using the "CHILLER" program menu; see the SCP699 Operator Interface section of this manual.
5. Specific Trane BAS-issued chiller setpoints are communicated to the appropriate chillers via the BCLs that join the BAS, SCP and chillers.
6. "Calculated" unit CLS' are derived from the effective SCLS by the SCP's control algorithm.
7. Though Trane BAS-issued unit CLS values–as well as manual or "calculated" SCP CLS values–may be any value between 0% and 100%, the UCP695 chiller control panel will only accept what it considers to be a valid entry (i.e., see Note 3). Therefore, a UCLS value less than 40% issued by the SCP–or a Trane BAS–results in a 40% CLS at the UCP695 control panel.

Chiller Sequencing and Rotation

Several SCP "CHILLER" program entries allow the operator to establish a start-up order for all connected chillers. (See Figure 13 in SCP699 Operator Interface.) That is, the operator can tell the SCP which chiller (i.e., Unit 1, Unit 2 or Unit 3) to start first and which to start next or last.

Note: Remember that each unit's identity or "address" is assigned with DIP switch block S11 in the UCP695 chiller control panel. (See "UCP695 DIP Switch Setup" in the Start-Up section of this manual.) Do not confuse unit address numbers with the unit sequence numbers assigned in the SCP's "CHILLER" program!

When the SCP decides that another chiller must be brought on-line, it checks the unit sequence setpoint and operating status of each chiller. The chiller started is the unit with the lowest sequence number that isn't already running.

If the same sequence number is shared by more than 1 chiller, the SCP will then compare the unit addresses of these chillers and start the unit with the lowest address number. For example, if the unit sequence setpoint value for both Unit 2 and Unit 3 is "SET = 2", then Unit 2 will be the next chiller started when the SCP brings another unit on-line.

Unit sequence numbers also tell the SCP which chiller to stop first when the cooling requirement is low enough to warrant a unit shutdown, or when the system is scheduled off. In either case, the SCP checks the sequence setpoints of the operating chillers and stops the unit with the highest sequence number.

Again, if more than 1 chiller has the same sequence setting, the unit with the lowest address number is stopped first.

Note: For chiller sequencing alternatives, refer to SCP Setup Recommendations for Typical Systems.

The SCP's "CHILLER" program also includes a "unit sequence rate" setting that provides an opportunity for equalizing chiller duty. By entering a whole number between 1 and 99 (days) for the "RATE = " entry, the operator can set up periodic rotations of the chiller start-up order.

Every time this interval elapses, the SCP automatically increases the unit sequence setting of each chiller by one. Notice that the unit sequence number rotation typically occurs at midnight. However, in applications where the chillers operate continuously, the SCP will not shut down units in order to enforce the unit sequence number rotation. Instead, the assigned sequence numbers are changed only when the SCP starts and stops the chillers as a part of its normal control routine.

Once the sequence setting equals "3", the SCP will assign a sequence value of "1" to that unit at the end of the next rotation period. (In systems where "2" is the highest sequence number programmed, the unit sequence setpoint returns to "1" after it reaches "2".)

If "RATE = 0", the default setting, the SCP will not rotate the chiller start-up order.

Note: A power failure will not prevent the SCP from maintaining the established interval between chiller start-up sequence rotations.

Cooldown Control

The SCP's standard cooldown (or "soft loading") control function allows the operator to control the rate of chiller loading when a significant difference exists between the actual leaving chilled water temperature and the system chilled water setpoint.

By "soft loading" the chiller system in situations like this (e.g., system start-up), the operator not only improves temperature control at unstable loads, but also minimizes the associated electrical demands and unit cycling.

Cooldown operation is governed by two operator-entered control settings at the SCP's "SYSTEM" programming level. First, the operator selects a cooldown current limit setpoint that is to be in effect during the cooldown mode. Expressed as a percentage of total chiller RLA, values for the cooldown current limit setpoint entry range from 0% through 100%. If a numeric value of "0" is entered here, the cooldown control function is turned off.

If a BAS-issued system current limit setpoint exists and is lower than the cooldown "LIM. = " setting, then the SCP will use the BAS value as the effective current limit setpoint during the cooldown period.

Note: While the cooldown current limit setpoint may be set as low as 0%, the UCP695 control panels at the chillers will not accept a setpoint lower than 40%.

The operator must also determine the length of the cooldown period, and can tailor its duration to the constraints of that particular chiller system application. Represented by an "END = " program entry, cooldown periods may last up to 2 hours (i.e., "END = 02.00"), and are incremented in 15-minute intervals.

Remember that the SCP will default to "END = 00.00" unless some other value is entered here, and that this program entry also establishes the minimum "on" time for thermostatically-controlled, automatic free cooling.

Several conditions must be met before cooldown can occur:

1. "AUTO" must be entered for the system- and unit-level chilled water temperature setpoint entries in the SCP's "SYSTEM" and "CHILLER" programming menus.

Note: Cooldown can only modify: (a) a BAS-issued, scheduled, or CWR-based system chilled water setpoint; and (b) a BAS-issued or SCP default system current limit setpoint.

2. A value other than zero must be entered for the cooldown current limit setpoint program entry. (The SCP's default setting--"LIM. = 0"--disables the cooldown control function.)

3. The actual system leaving chilled water temperature must be at least 10 F above the present, effective system chilled water setpoint. (This condition usually exists at system start-up.)

Once cooldown is initiated, the SCP creates a "stepped" sequence of decreasing system chilled water setpoints that approach the desired chilled water temperature within the cooldown time period (i.e., "END = "). However, SCP control logic limits cooldown-initiated setpoint changes to a maximum of 1 F per minute unless "END = 00.00".

Note: If cooldown is enabled when "END = 00.00", the SCP will bring the system to its maximum operating capacity at once--within the constraints of the system current limit function--in order to satisfy the cooling requirement.

Recall that one of the operator-entered, cooldown program entries was a system current limit setpoint. If total chiller electrical demand exceeds the effective current limit value during cooldown operation, the SCP will unload the system–regardless of the present chilled water temperature–until electrical demand is sufficiently reduced.

When system electrical demand is again at an acceptable level, "stepped" reduction of the leaving chilled water temperature will continue until: (1) the desired temperature is attained, (2) the next current limit violation occurs, or (3) the cooldown period expires.

Chilled Water Reset (CWR)

Note: The CWR control function can only modify a system chilled water setpoint that is communicated by a Trane BAS or scheduled at the SCP. See Table 8. Chilled water reset will not affect:

a. a manual, system-level setpoint entry;

b. chillers operating under AUTO/LOCAL control; or,

c. chillers given a manual chilled water setpoint–either at the SCP via the "CHILLER" programming menu, or communicated from a Trane BAS over the BCLs between the BAS, SCP and UCP695 chiller control panels.

Chilled water reset is ideal for water-cooled chiller systems that seldom operate at full load, and do not require the design chilled water temperature at part load. In these applications, the system leaving chilled water temperature can be reset upward using the CWR control function.

Two sensor inputs are required for the CWR control function to operate, so a matched pair of thermistor-type sensors (i.e., part no. 4533-1710-44B) is provided with each SCP. Refer to Figure 16. Notice that one sensor must be field-installed in the common system leaving (supply) chilled water line. Never substitute a chiller leaving-evaporator water temperature sensor (4RT1) for this input!

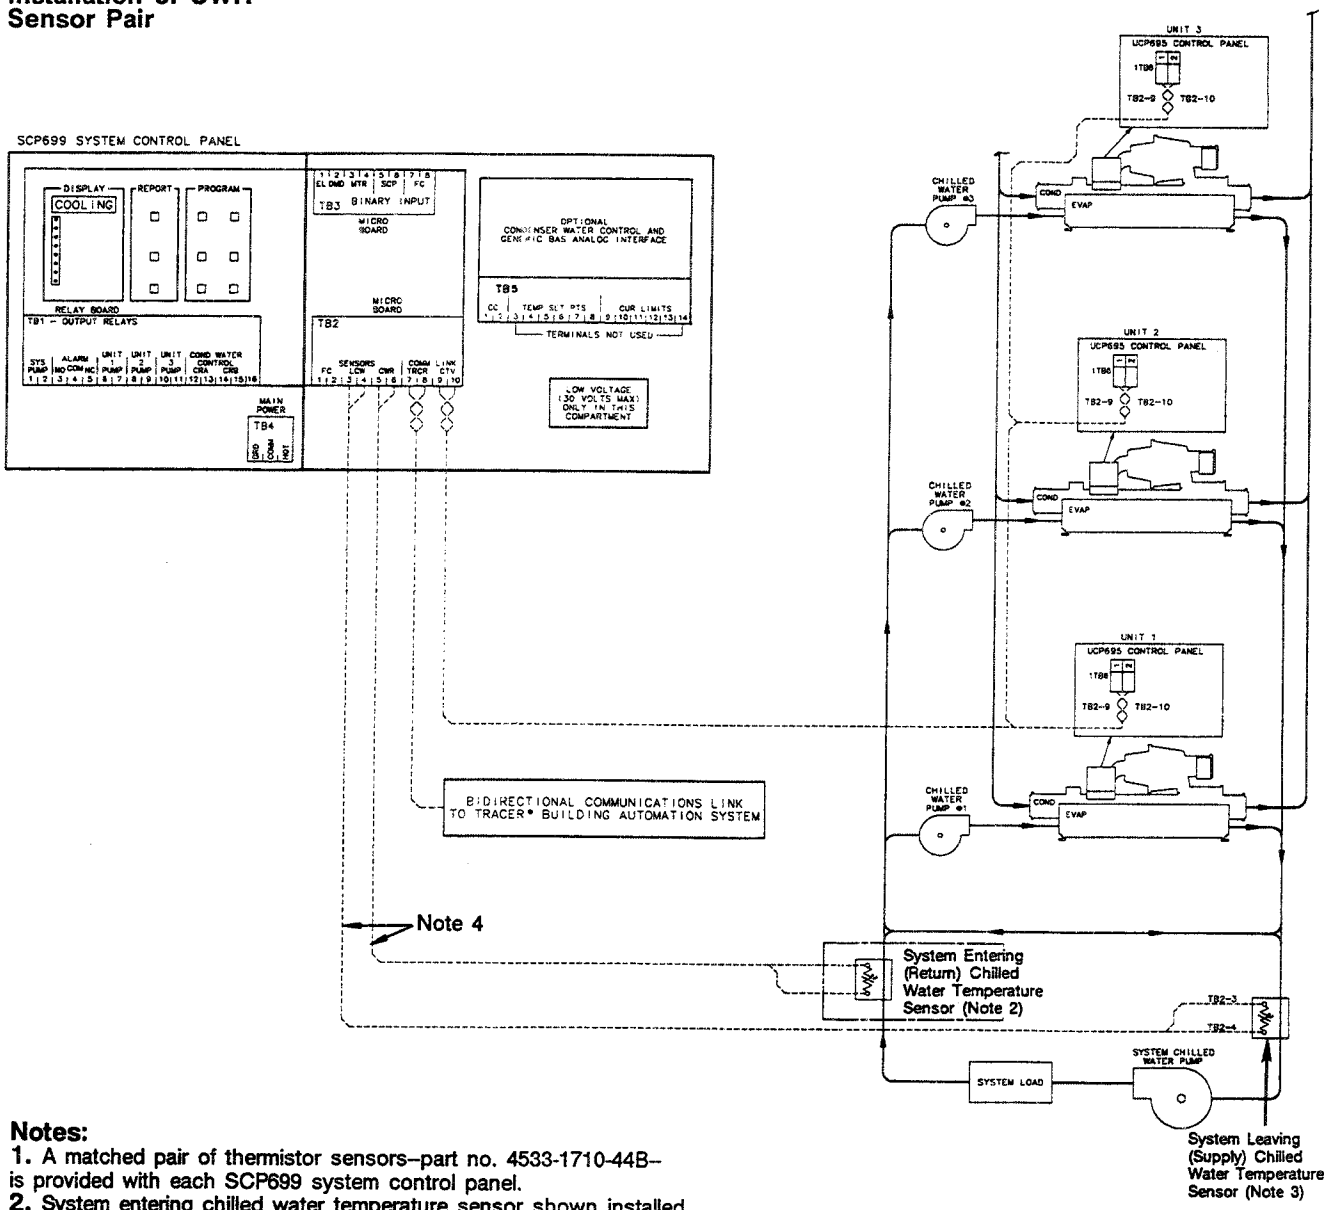
Placement of the remaining sensor depends on whether "load-" or "ambient-based" chilled water setpoint reset is desired:

[ ] When load-based CWR is selected, the remaining sensor is field-installed in the common system entering (return) chilled water line. The difference between the leaving and entering chilled water temperatures–reflecting system cooling requirements–is then used to calculate a new system chilled water setpoint.

[ ] With the selection of ambient-based CWR, the SCP adjusts the system chilled water setpoint in response to a measured temperature, usually the outdoor ambient. In order to monitor this temperature, the remaining sensor is typically field-installed just inside the building's fresh air intake duct, or on the north exterior wall of the building. (In either case, shelter the sensor from direct sunlight and the elements.)

Selection of the type of chilled water reset desired for a given system application is not only determined by the location of the CWR sensors, but is also a function of 2 operator-programmable control settings:

1. Chilled Water Reset Rate (RATE =). The SCP uses this CWR variable to calculate the amount of reset–in degrees F–that will be applied to either a scheduled or Trane BAS-generated system leaving chilled water setpoint. Values for CWR rate extend from 1% through 199%; entering "0" disables the CWR control function.



2. Chilled Water Reset Setpoint Temperature (SET =). This operator-entered temperature tells the SCP when to enable system chilled water reset, and can be set at any integer value from 1 F through 140 F. Again, entering a "0" for the CWR setpoint will turn off this control function.

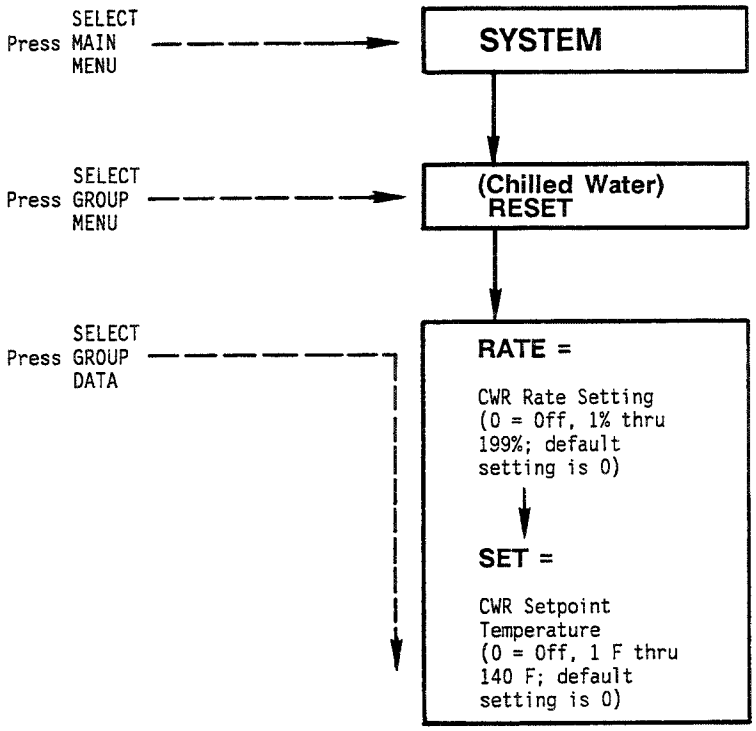
Note: Whenever the CWR setpoint temperature is less than or equal to 25 F, load-based CWR is indicated. If the "SET = " value is greater than 25 F, the SCP identifies this control setting as an outdoor ambient temperature.

"Load-based" system CWR is enabled whenever the actual system delta-T is ≤ the CWR "SET = " value. Enablement of "ambient-based" CWR can occur when the actual outdoor temperature is either ≤ ("normal") or > ("reverse") the CWR "SET = " setting. (See "Ambient-Based CWR".)

Instructions for programming the CWR control function are provided under "System Setup: Chilled Water Reset Option" in the SCP699 Operator Interface section of this manual. For your convenience, the CWR program menu is shown in Figure 17.

Figure 16
Installation of CWR Sensor Pair

Notes:



1. A matched pair of thermistor sensors–part no. 4533-1710-44B– is provided with each SCP699 system control panel.
2. System entering chilled water temperature sensor shown installed in entering (return) water line for load-based CWR. Alternatively, this sensor may be installed in the outdoor air for ambient-based CWR.
3. For single-chiller applications where CWR at the SCP is desired, the SCP's system leaving chilled water temperature sensor must be installed.
4. Sensor wiring is 30V or less, 14-18 AWG 600V wire; it must be shielded or run in conduit w/conductors carrying 30V or less. Following are maximum conductor lengths:
   - 5,000 ft. for 14 AWG
   - 2,000 ft. for 16 AWG
   - 1,000 ft. for 18 AWG
5. Illustrated arrangement of chilled and condenser water piping is not a piping schematic; use it only to identify temperature sensor locations.
6. Dashed lines (—) represent field-installed wiring; phantom lines (— - —) indicate available sales options.
7. All field wiring must be in accordance with the National Electric Code (NEC), and state and local requirements.

WARNING
Disconnect electrical power supply to prevent injury or death due to electrical shock.

Caution
Use copper conductors only to prevent equipment damage.

Drwg. 4532-3789B

Figure 17
Operator-Programmable Entries for System Chilled Water Reset

Note: A CWR "SET = " value ≤ 25 F indicates load-based chilled water reset; ambient-based chilled water reset is indicated by a CWR "SET = " value > 25 F. In order to enable the CWR control function, a setting other than "0" must be entered for both "RATE = " and "SET = ".

Load-Based CWR

The SCP looks at several sensor and operator-entered inputs to arrive at a reset system chilled water setpoint (RSCWS) that reflects the system's reduced cooling requirements. These variables include the:

[ ] actual system leaving (supply) chilled water temperature (STMP);

[ ] actual system entering (return) chilled water temperature (AUXTMP);

[ ] operator-entered CWR rate between 1% and 199% (RATE);

[ ] operator-entered CWR setpoint temperature between 1 F and 25 F (SET); and,

[ ] scheduled or BAS-generated system chilled water setpoint (SCWS).

Based on this information, the SCP then calculates the RSCWS using this equation:

$$RSCWS = SCWS + RATE\ [CWR\ SET + STMP - AUXTMP]$$

To use this equation correctly, remember that:

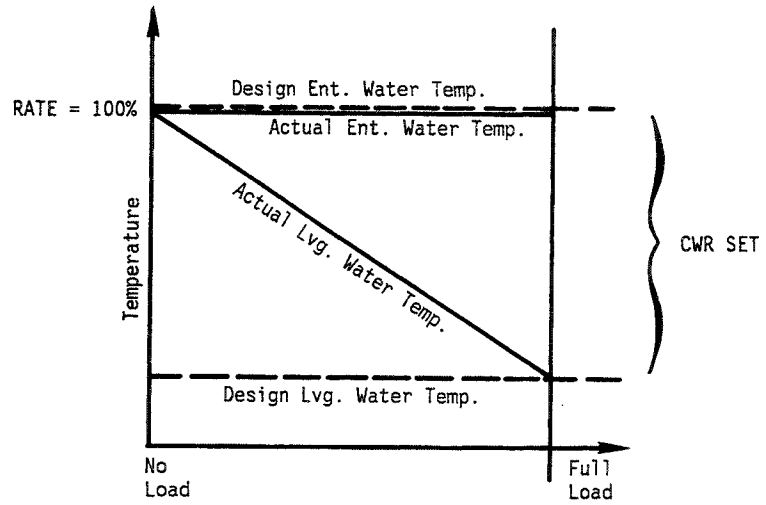
1. Decimal values must be used for the RATE variable in this equation. (Divide the operator-entered "RATE = " value by 100.)

2. The SCP's CWR control function will not use a RSCWS value that is lower than the SCWS, so the effective RSCWS is always ≥ the SCWS.

3. Increasing the CWR "RATE = " and/or "SET = " values results in more reset.

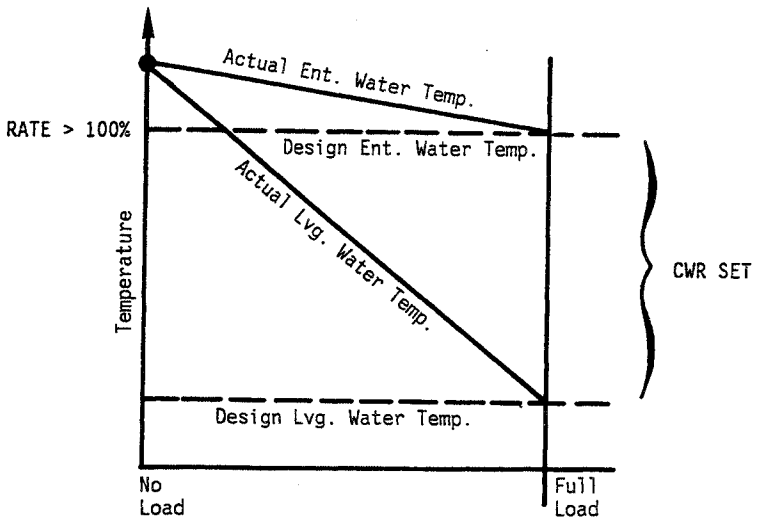
4. If you know (1) when you want to enable the CWR function (CWR SET), and (2) how many degrees of reset are desired (RSCWS), this equation can be rearranged to solve for the appropriate CWR rate setting:

$$RATE = \frac{RSCWS - SCWS}{[CWR\ SET + STMP - AUXTMP]}$$



5. The effective RSCWS value is always ≤ 99 F.

Review the examples that follow to ensure that you understand both how to calculate a load-based reset system chilled water setpoint, and how this reset value changes with the operator-entered CWR rate and setpoint temperature control settings.



* * * * *

First, let's look only at how the value entered for the CWR rate can affect the scheduled (or BAS-generated) system chilled water setpoint. Review Examples 1 through 3 below; Figure 18 provides graphs that illustrate these situations.

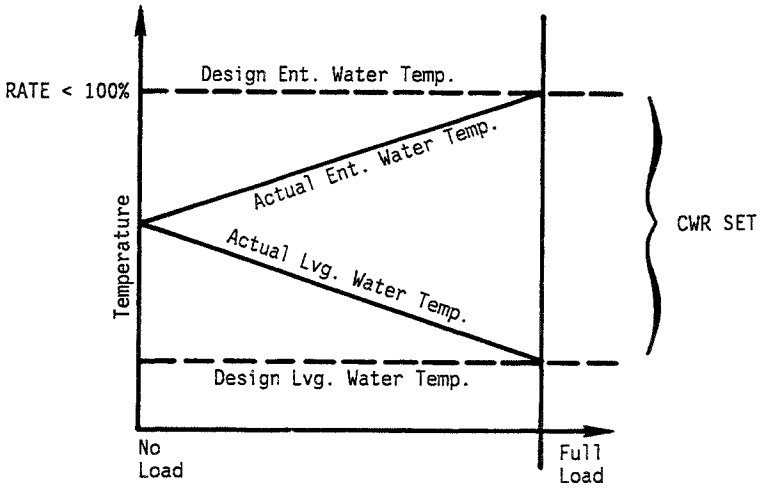


Figure 18
Load-Based CWR—
Variable RATE Settings

Example 1
RATE = 100%
CWR SET = System Design Delta-T

Example 2
RATE > 100%
CWR SET = System Design Delta-T

Example 3
RATE < 100%
CWR SET = System Design Delta-T

Notice that the same value–"SET = 10"–is entered for the CWR setpoint temperature in each of these examples (i.e., although any value ≤ 25 F could be selected).

Example 1. At full load, "System A" is designed to operate with a leaving (supply) chilled water temperature–SCWS–of 45 F, and a common entering-evaporator (return) temperature of 55 F; design delta-T is 10 F.

Presently, System A is only partially loaded, and:
SCWS = 45 F,
STMP = 45 F,
AUXTMP = 50 F,
CWR SET = 10 F, and,
RATE = 100% (i.e., 1.0).

To determine the reset system chilled water setpoint (RSCWS) for this set of operating conditions:

RSCWS = 45 F + 1.0 [10 F + 45 F - 50 F]
RSCWS = 45 F + 5.0 F
RSCWS = 50 F

Refer to the graph labelled "Example 1" in Figure 18. Notice that a constant return water temperature can be attained by selecting a 100% CWR rate when the CWR setpoint is equal to (or greater than) the system design delta-T.

Selection of CWR rate and setpoint temperature values that result in a constant return water temperature may be particularly desirable in parallel-piped systems with 2 chillers and 1 system pump or 2 individual unit pumps. When the system is running at part load (i.e., 1 chiller on and the other off), the operative unit's chilled water setpoint is never stepped below design as long as the system return water temperature remains constant at a level equal to–or greater than the design return water temperature at full load. (See SCP Setup Recommendations for Typical Systems.)

Example 2. Given the same operating conditions listed in Example 1, but with an increased CWR rate–150% or 1.5, notice that the calculated reset chilled water setpoint also increases:

RSCWS = 45 F + 1.5 [10 F + 45 F - 50 F]
RSCWS = 45 F + 7.5 F
RSCWS = 52.5 F or 53 F

(Calculated RSCWS values are always rounded to the nearest integer.)

Example 3. Finally, suppose that a value less than 100% (e.g., 80% or 0.8) is entered for the CWR rate:

RSCWS = 45 F + 0.8 [10 F + 45 F - 50 F]
RSCWS = 45 F + 4 F
RSCWS = 49 F

Compare the RSCWS values obtained in Examples 1, 2 and 3; notice that the degree of reset increases proportionately with the CWR rate setting.

* * * * *

Now let's look at how various CWR setpoint values can affect the degree of reset applied to System A's chilled water setpoint. Review Example 1 again, along with Examples 4 and 5; in each instance, a value of 100% was selected for the CWR "RATE = " program entry. (See Figure 19 for graphs illustrating these examples.)

Example 4. As in Example 1, entering a 100% CWR rate and a CWR setpoint greater than the system design delta-T also yields a constant return temperature. (Compare the corresponding graphs in Figure 19.)

RSCWS = 45 F + 1.0 [12 F + 45 F - 50 F]
RSCWS = 45 F + 7.0 F
RSCWS = 52 F

Example 5. Suppose that the CWR setpoint is changed to a value less than the system design delta-T. Since System A's design delta-T is 10 F, let's use CWR "SET = 8":

RSCWS = 45 F + 1.0 [8 F + 45 F - 50 F]
RSCWS = 45 F + 3.0 F
RSCWS = 48 F

If the CWR setpoint value is low enough, the calculated RSCWS value will be less than the scheduled system chilled water setpoint. However, SCP control logic ensures that the effective RSCWS temperature is always equal to–or greater than–the value of SCWS. This is demonstrated below, and illustrated in the graph labelled "Example 5" in Figure 19.

RSCWS = 45 F + 1.0 [4 F + 45 F - 50 F]
RSCWS = 45 F + -1.0 F
RSCWS = 44 F, but 44 F is not ≥ 45 F,
so
RSCWS = 45 F

Ambient-Based CWR

The SCP relies on essentially the same sensor and operator-entered inputs to perform ambient-based chilled water reset that it uses for load-based CWR:

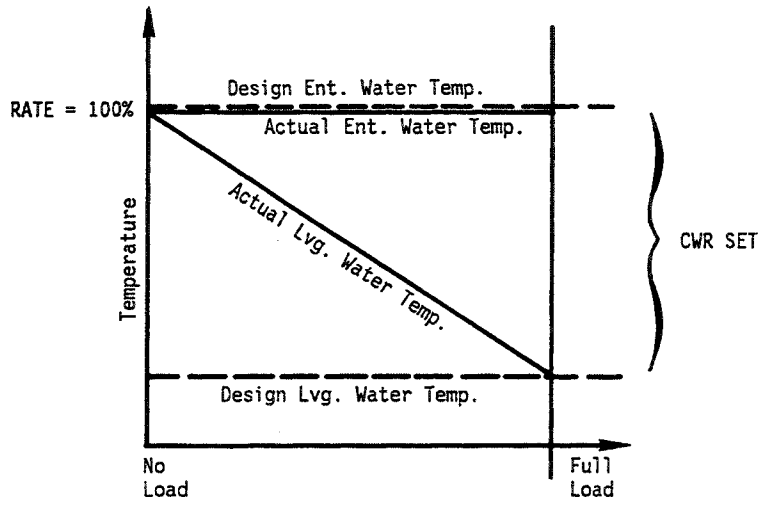
[ ] an operator-entered CWR rate between 1% and 199% (RATE);

[ ] an operator-entered CWR setpoint temperature between 26 F and 140 F (SET);

[ ] a scheduled–or Trane BAS-issued–system chilled water setpoint; and,

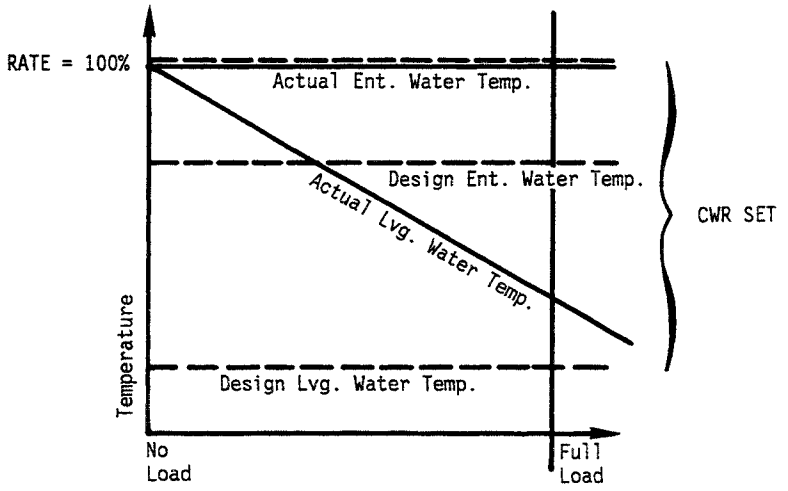
[ ] the actual outdoor ambient temperature (AUXTMP).

But in addition to these variables, the SCP also checks the position of its No. 4 configuration DIP switch to determine whether the operator has selected the "normal" or "reverse" mode of ambient chilled water reset.



Note: DIP Switch No. 4's position only affects the ambient-based chilled water reset control function (i.e., CWR setpoint temperature is > 25 F). Its position has no effect on load-based CWR.

* * * * *



"Normal" CWR. This mode of ambient-based chilled water reset is selected by positioning configuration DIP Switch No. 4 in the OFF position. In effect, this tells the SCP to calculate a reset system chilled water setpoint (RSCWS) using this equation:

RSCWS = SCWS + RATE [CWR SET - AUXTMP]

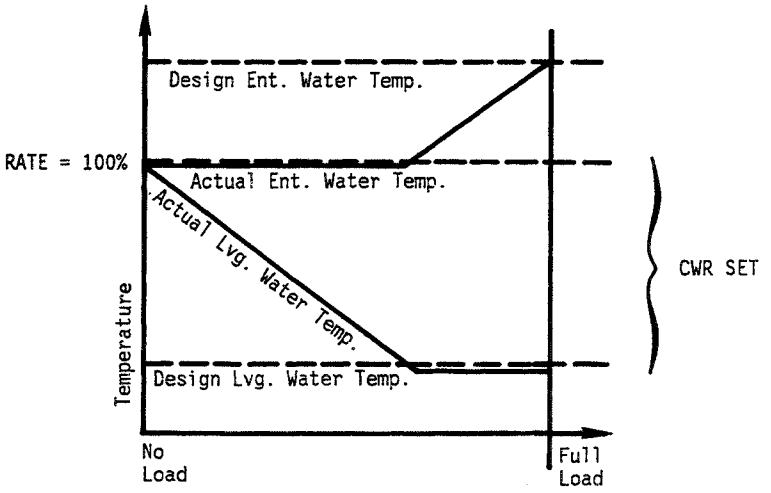


Figure 19
Load-Based CWR—
Variable CWR SET Temperatures

Example 1
RATE = 100%
CWR SET = System Design Delta-T

Example 4
RATE = 100%
CWR SET > System Design Delta-T

Example 5
RATE = 100%
CWR SET < System Design Delta-T

To correctly interpret this equation, remember that:

1. Decimal values must be used for the RATE variable, so divide the operator-entered "RATE = " setting by 100.

2. As the actual outdoor ambient falls, the SCP resets the system chilled water setpoint upward.

3. Increasing the CWR rate setting results in a greater amount of reset.

Figure 20 illustrates the overall relationship between the actual outdoor ambient temperature, CWR setpoint and rate values, and the resulting RSCWS on a graph. In particular, notice that RSCWS is always ≥ SCWS; control logic prevents the SCP from resetting the chilled water setpoint below the originally scheduled (or BAS-issued) value.

Review the examples that follow to ensure that you understand the correlation between CWR rate and reset system chilled water setpoint in "normal" ambient-based chilled water reset. (In each instance, the same value–"SET = 90"–is entered for the CWR setpoint temperature, although any value > 25 F could be selected).

Example 1. "System B" is designed to operate at full load when the outdoor ambient temperature is 90 F, and to produce 45 F chilled water. At the present time, the outdoor air sensor indicates a temperature of 80 F.

Here is a summary of the CWR input values for System B:
SCWS = 45 F,
STMP = 45 F,
AUXTMP = 80 F,
CWR SET = 90 F,
RATE = 100% (i.e., 1.0), and,
DIP Switch No. 4 = OFF/"normal".

To determine how many degrees of reset will be added to the system chilled water setpoint when a CWR rate of 100% is selected:

RSCWS = 45 F + 1.0 [90 F - 80 F]
RSCWS = 45 F + 10.0 F
RSCWS = 55 F

If the outdoor air temperature falls to 70 F–given the same set of operating conditions, then:

RSCWS = 45 F + 1.0 [90 F - 70 F]
RSCWS = 45 F + 20.0 F
RSCWS = 65 F

Notice that 10 F is added to the system chilled water setpoint for every 10 F drop in outdoor air temperature when the CWR rate is 100%.

Example 2. Let's look at the amount of reset produced when 150% (i.e., 1.5) is entered for System B's CWR rate.

RSCWS = 45 F + 1.5 [90 F - 70 F]
RSCWS = 45 F + 30.0 F
RSCWS = 75 F

Example 3. Finally, suppose that a value less than 100% (e.g., 80% or 0.8) is entered for the CWR rate:

RSCWS = 45 F + 0.8 [90 F - 70 F]
RSCWS = 45 F + 16.0 F
RSCWS = 61 F

Compare the RSCWS values obtained in Examples 1, 2 and 3; notice that the degree of reset is directly proportional to the difference between the actual and –in this case–design ambient temperatures.

* * * * *

"Reverse" CWR. When the No. 4 configuration DIP switch is positioned at ON, the SCP uses the following equation to calculate a reset system chilled water setpoint:

RSCWS = SCWS + RATE [AUXTMP - CWR SET]

Notice the difference between this equation and the one used for "normal" ambient CWR. Using this "reverse" equation, the SCP will reset the system chilled water setpoint upward as the outdoor ambient temperature rises (i.e., rather than falls, as in the "normal" mode).

See Examples 3 and 4 below–along with Figure 21–for an interpretation of the SCP's "reverse", ambient-based CWR control function.

Example 3. At full load, "System C" is designed to produce 45 F chilled water when the outdoor ambient temperature is 90 F. The SCP's outdoor air sensor presently indicates an actual ambient temperature of 100 F.

Here is a summary of System C's CWR input values:
SCWS = 45 F,
STMP = 45 F,
AUXTMP = 100 F,
CWR SET = 90 F,
RATE = 100% (i.e., 1.0), and,
DIP Switch No. 4 = ON/"reverse".

To determine how many degrees of reset will be added to the system chilled water setpoint when a CWR rate of 100% is selected:

RSCWS = 45 F - 1.0 [90 F - 100 F]
RSCWS = 45 F - 1.0 [-10 F]
RSCWS = 55 F

If the CWR rate is changed to 150% (i.e., 1.5), given the same operating conditions, then:

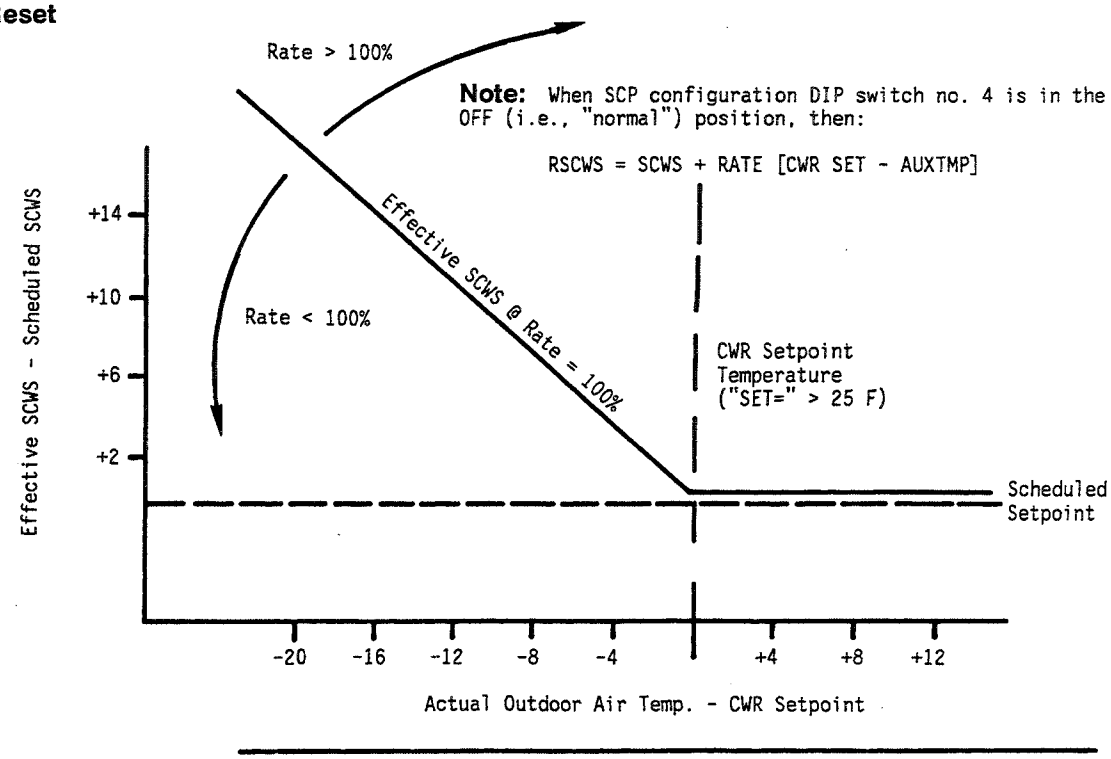
RSCWS = 45 F - 1.5 [90 F - 100 F]
RSCWS = 45 F - 1.5 [-10 F]
RSCWS = 60 F

Or, if a value of 50% is entered for the CWR rate, then:

RSCWS = 45 F - 0.5 [90 F - 100 F]
RSCWS = 45 F - 0.5 [-10 F]
RSCWS = 50 F

A comparison of these RSCWS values and corresponding CWR rate settings reveals that the amount of reset added to the system chilled water setpoint is directly proportional to the difference between the actual ambient temperature and the CWR setpoint.

Figure 20
"Normal" Ambient-Based Chilled Water Reset



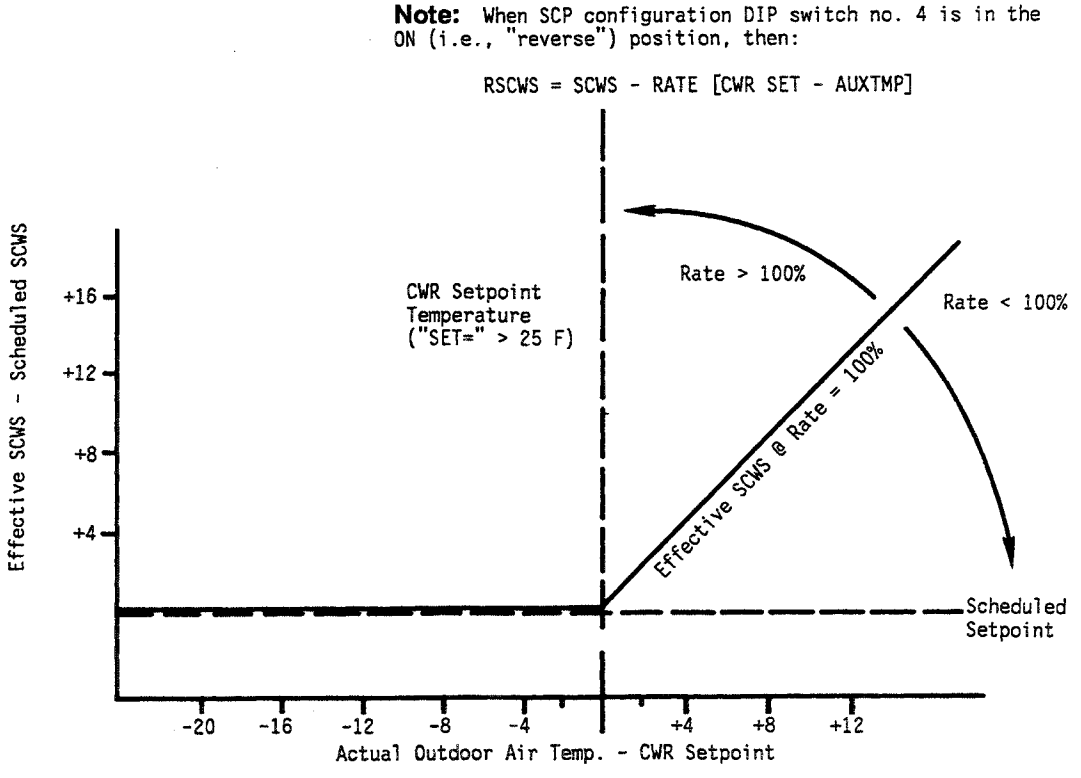


Figure 21
"Reverse" Ambient-Based Chilled Water Reset

Example 4. Let's look at what happens if the actual outdoor ambient temperature falls below the CWR setpoint when "reverse" ambient CWR is in effect.

RSCWS = 45 F - 1.0 [90 F - 80 F]
RSCWS = 45 F - 1.0 [+10 F]
RSCWS = 35 F, but 35 F is not ≥ 45 F,
so,
RSCWS = 45 F

Notice that the calculated reset system chilled water setpoint will be lower than the scheduled system chilled water setpoint whenever the actual outdoor ambient temperature falls below the CWR setpoint. However, SCP control logic prevents it from using any value less than the SCWS as the effective chilled water setpoint.

Free Cooling

Based on the principle that refrigerant migrates to the coldest area(s) in the system, free cooling adapts chillers equipped with that option to function as simple heat exchangers. (An explanation of free cooling at the chiller level is included in the operation/maintenance manual that shipped with the unit.)

The SCP's free cooling (FC) control function enables the operator to select either manual or automatic (i.e., thermostatically-controlled, or on/off input) free cooling on a system-wide basis if at least 1 chiller connected to the SCP is an FC unit. (It is not possible to govern the free cooling operation of individual chillers from the SCP.)

Note: Automatic, thermostatically-controlled free cooling is an SCP control option that requires field installation of a sensor (i.e., part no. 4533-1710-41B) in either the common entering-condenser water line, or the outdoor ambient. See Figure 22.

Bidirectional communications between the SCP and connected chillers enables the SCP to identify which units (i.e., Unit 1, Unit 2 and/or Unit 3) are equipped with the FC option and can be operated in that mode.

Notice that it is possible to govern system free cooling from any of 3 control levels; these levels–in order of priority–are:

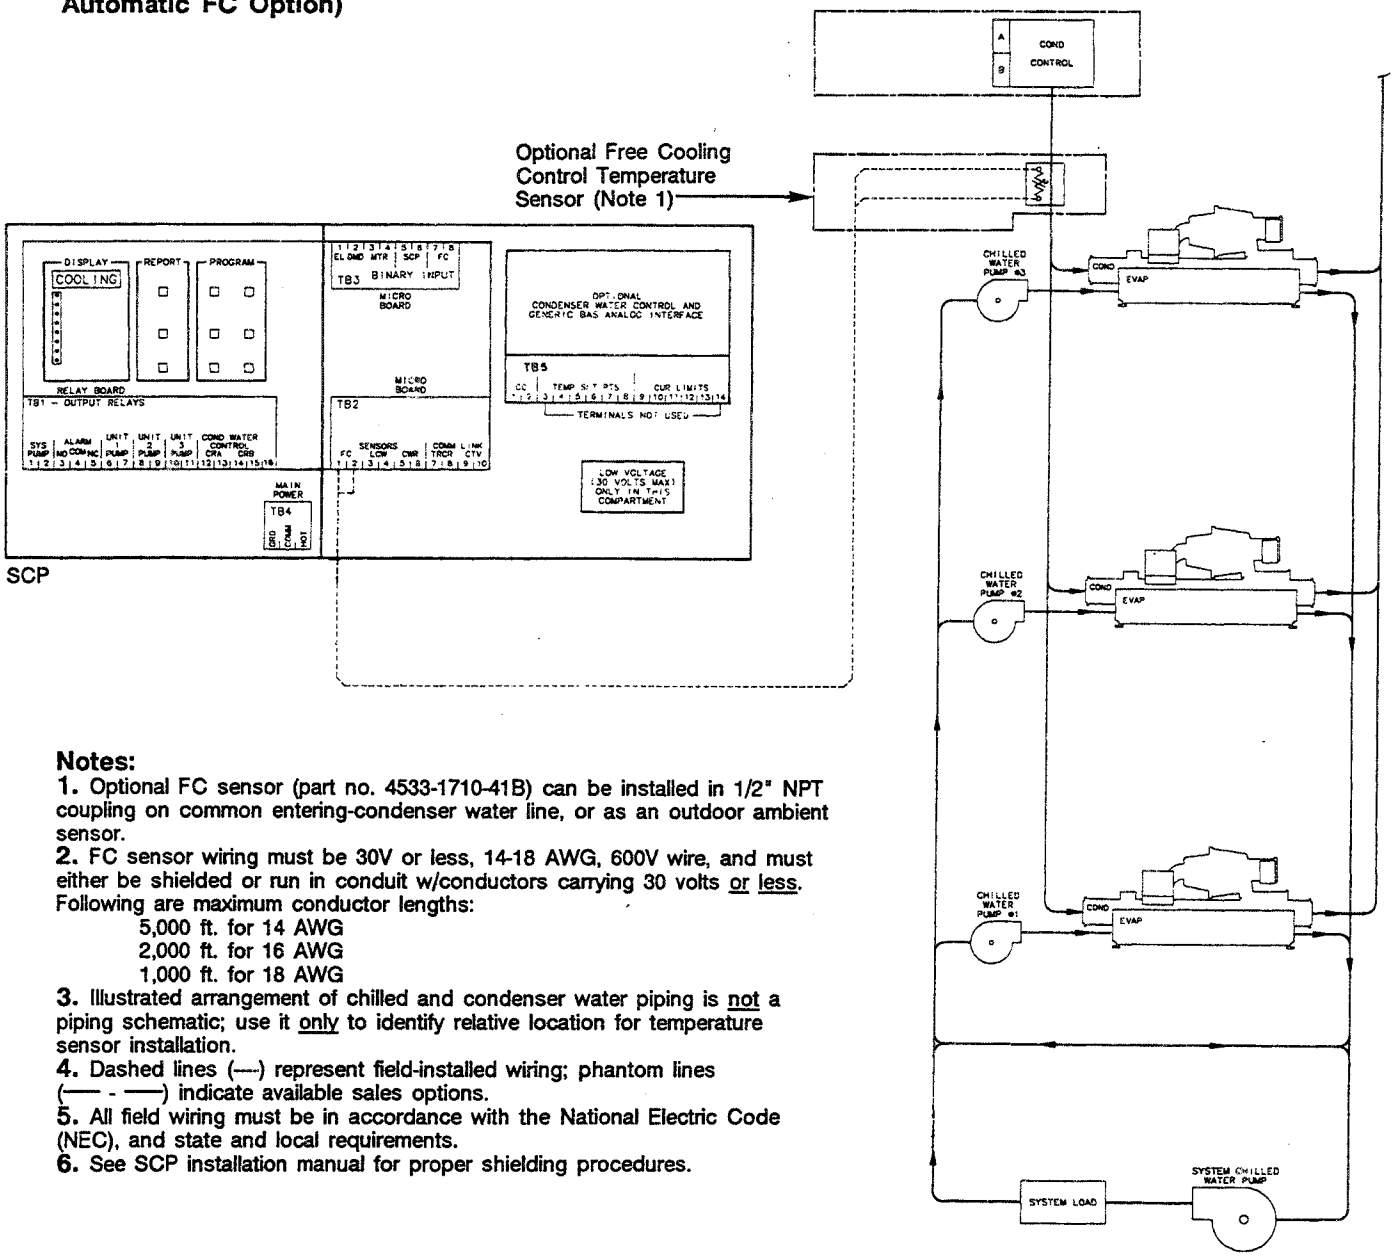
1. the SCP's front panel push buttons;

2. a Trane BAS communicating with the SCP over a bidirectional communication link; and,

3. a contact closure input–in the SCP–produced by a generic BAS or external analog controller.

Note: To automatically initiate free cooling from a generic BAS, an external analog controller, or other similar supervisory control device:

a. "SET = AUTO" must be entered for the FC system setpoint (Figure 24); and,



b. the SCP must "see" closure of both the "Scheduled System Enable/Disable" and "FC Enable/Disable" contacts. See Figure 23.

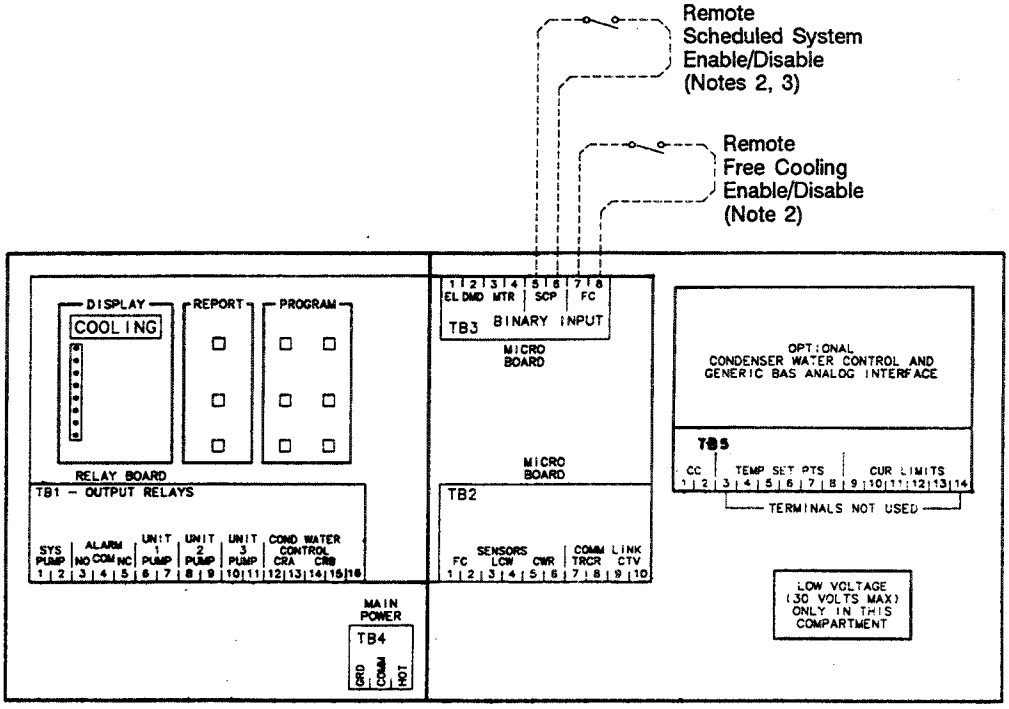
Thermostatically-controlled free cooling is not available via the "FC Enable/Disable" contacts!

Caution: Use generic BAS to turn off all non-FC chillers when system is running in free cooling mode. Running powered cooling units while very low condenser water temperatures exist is detrimental to operating efficiency and equipment life.

To better understand this control hierarchy, refer to Table 12.

Figure 22
Field Installation of Free Cooling Sensor (Thermostatically-Controlled Automatic FC Option)

Notes:



1. Optional FC sensor (part no. 4533-1710-41B) can be installed in 1/2" NPT coupling on common entering-condenser water line, or as an outdoor ambient sensor.
2. FC sensor wiring must be 30V or less, 14-18 AWG, 600V wire, and must either be shielded or run in conduit w/conductors carrying 30 volts or less. Following are maximum conductor lengths:
   - 5,000 ft. for 14 AWG
   - 2,000 ft. for 16 AWG
   - 1,000 ft. for 18 AWG
3. Illustrated arrangement of chilled and condenser water piping is not a piping schematic; use it only to identify relative location for temperature sensor installation.
4. Dashed lines (----) represent field-installed wiring; phantom lines (—— - ——) indicate available sales options.
5. All field wiring must be in accordance with the National Electric Code (NEC), and state and local requirements.
6. See SCP installation manual for proper shielding procedures.

WARNING
Disconnect electrical power supply to prevent injury or death due to electrical shock.

Caution
Use copper conductors only to prevent equipment damage.

Drwg. 4532-3789B

Figure 23
Remote Free Cooling Enable/Disable Contact Closure Inputs (Note 1)

SCP

WARNING
Disconnect electrical power supply to prevent injury or death due to electrical shock.

Caution
Use copper conductors only to prevent equipment damage (unless otherwise specified).

Notes:
1. Use the "Remote Scheduled System Enable/Disable" and "Remote Free Cooling Enable/Disable" contacts if the SCP is connected to a generic BAS, external analog controller, or similar supervisory control device.
2. These control circuits are "enabled" when the contacts are closed, and disabled when the control circuits are open. Wiring is 30 volts or less; use 14-18 AWG, 600V wire. Do not route these wires in conduit with circuits exceeding 30 volts. Silver contacts (or better) are required; do not use series contacts!
3. Jumper Terminals TB3-5 and TB3-6 if the "Scheduled System Enable/Disable" contacts are not used for system control.
4. Dashed lines (—) represent field-installed wiring.

Drwg. 4532-3789B

	Auto	0-140 F	n/a	1-99 F	n/a	(4)	Free Cooling	0-140 F	1-99 F
		0-140 F	1-99 F	Auto	n/a		Free Cooling	0-140 F	1-99 F

n/a = A setpoint entered here will not influence SCP status or system operating mode.

Notes:
1. The freecool system setpoint and freecool system leaving chilled water setpoint (CWS) can be entered using the SCP's "SYSTEM: FREECOOL" program, or communicated by a Trane BAS.
2. Manual ON/OFF free cooling operation.
3. Automatic ON/OFF free cooling operation via the SCP's binary input (i.e., closure of the SCP's "Remote FC Enable" circuit).
4. Thermostatically-controlled, automatic free cooling operation. (This type of free cooling is only possible when the optional free cooling sensor is installed.) When in this mode, the SCP automatically "converts" system operation to the powered cooling mode when the temperature registered by the FC sensor equals or exceeds the operator-entered FC system setpoint.
5. The SCP uses "AUTO" for the Trane BAS-issued FC system setpoint if: (1) the chiller system does not include a Trane BAS; (2) the Trane BAS is not communicating any setpoints to the SCP; or, (3) the Trane BAS is sending a setpoint value of "AUTO".
6. Shaded portions of this table (i.e., excluding the column headings) represent conditions where a Trane BAS is determining SCP status and system operating mode.

Manual Free Cooling

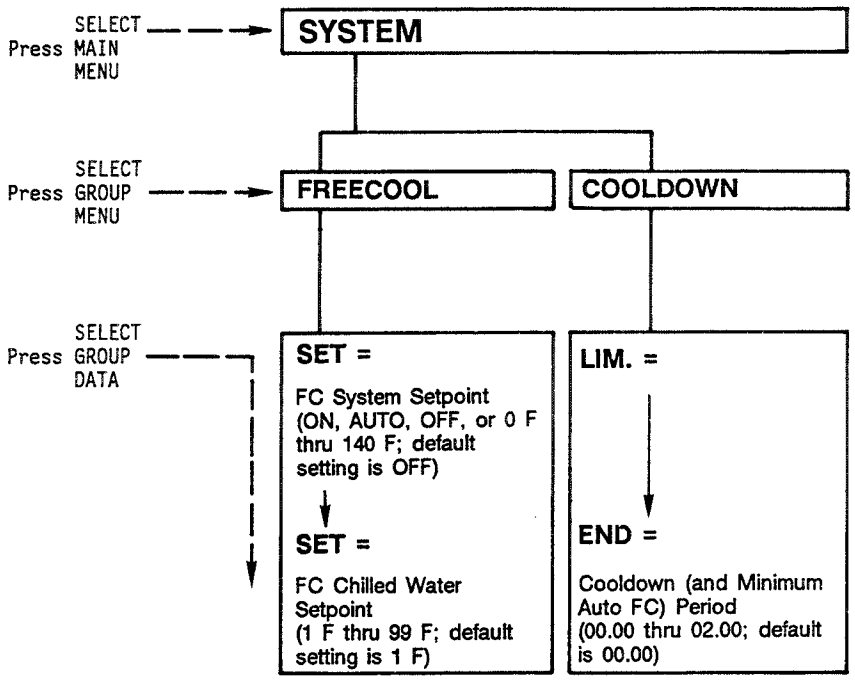
Continuous, system-wide free cooling operation can be initiated manually via the SCP's "SYSTEM" programming menu by entering "ON" for the free cool system setpoint. (See Figure 24, and "System Setup: Freecool" in the SCP699 Operator Interface section of this manual.)

This "SET = ON" entry tells the SCP to shut down all powered CenTraVac cooling –unless a manual chiller operating command exists–and operate all FC-equipped chillers in the free cooling mode.

Free cooling operation will continue–regardless of the system leaving chilled water temperature–until the operator changes the free cool system setpoint to AUTO, OFF, or some numeric value between 0 F and 140 F. Further, as long as the system is running in the free cooling mode, none of the chillers communicating with the SCP (i.e., chiller switch(es) set at AUTO/REMOTE) can resume powered cooling operation unless a manual chiller-level operating command is issued.

Note: Manual, chiller-level operating commands that will override the SCP's freecool "ON" setting include these:

a. UCP695 control panel chiller switch is set at either AUTO/LOCAL or STANDBY/RESET;



b. a manual leaving chilled water setpoint (i.e., OFF, or 1 F through 99 F) was entered for a given unit via the SCP's "CHILLER" programming menu; or,

c. a Trane BAS has communicated a manual chilled water setpoint (i.e., OFF, or 1 F through 99 F) to a specific chiller over the bidirectional communications links between the Trane BAS, SCP and UCP695 chiller control panel.

If continuous free cooling operation is desired on an individual chiller basis, position that unit's chiller switch at AUTO/LOCAL, and set its free cooling switch at ON. Remember that the unit free cooling switch is only operational when the chiller switch is in the AUTO/LOCAL position.

Note: Entering "SET = OFF" for the SCP's free cool system setpoint prevents all system-level free cooling operation –whether manual or automatic.

Figure 24
Operator-Programmable Entries for Automatic Free Cooling Option

Note: "SET = AUTO" must be entered for the FC system setpoint to enable a generic BAS, external analog controller, or similar supervisory control device to provide automatic on/off control of the SCP's system free cooling function.

Automatic Free Cooling

Note: The SCP does not provide control relays to maintain condenser water pump operation during the changeover from powered cooling to free cooling. Use the relays available at the individual chiller control panels for this purpose.

Thermostatically-Controlled FC

Field installation of the optional free cooling sensor enables the SCP to thermostatically initiate system free cooling operation based on either the temperature of the common entering-condenser water or outdoor ambient.

Operating parameters for automatic, thermostatically-controlled free cooling are determined by several operator-set SCP "SYSTEM" program entries (Figure 24). The operator must specify:

[ ] a free cooling (FC) "enable" temperature setpoint; and,

[ ] a system chilled water setpoint to be maintained during the FC mode.

A minimum "on"-time for free cooling operation can also be entered when an interval longer than 15 minutes is desired.

Below is a more detailed explanation of these control settings:

[ ] Freecool System Setpoint (SET =). This control setting determines the status of the SCP's free cooling control mode; several control states are possible:

a. SET = OFF. System-level free cooling operation–whether manual or automatic–is disabled.

b. SET = ON. All units equipped with the FC option are running in the manual free cooling mode, while all other units are turned off unless a manual chiller-level operating command exists. ("Manual" FC override commands are described in a note under "Manual Free Cooling".)

c. SET = 0 thru 140 F. Entering a whole number between 0 and 140 F enables the thermostatically-controlled free cooling control function. The SCP automatically initiates this type of free cooling operation if: (1) the temperature registered by the free cooling sensor is less than the "SET = " value; (2) none of the chillers are running in the powered cooling mode (unless manually controlled); and, (3) the system is scheduled "on", or is given a manual–or BAS–command to operate in the cooling mode.

Note: Since its initiation requires that all powered cooling is "off"–and since the SCP will not automatically interrupt powered cooling operation to attempt free cooling, thermostatically-controlled free cooling typically occurs at daily start-up.

d. SET = AUTO. This prompts the SCP to look to a higher level control device (e.g., BAS) for the effective freecool system setpoint or "enabling" contact closure inputs. (See "Automatic Free Cooling: On/Off FC".)

[ ] Freecool Chilled Water Setpoint (SET =). A value entered here tells the SCP what chilled water temperature to maintain while the system is operating in the automatic, thermostatically-controlled free cooling mode. Setpoint values range from 1 F through 99 F in increments of 1 degree.

The SCP will allow the system to remain in free cooling as long as the system chilled water temperature is less than or equal to this "SET = " value. If the actual chilled water temperature exceeds the freecool chilled water setpoint, the SCP will reinstate powered cooling operation.

Note: Once thermostatically -controlled free cooling is initiated, the system will continue to operate in that mode--regardless of the actual chilled water temperature--for a minimum of either 15 minutes or the time period established for the cooldown mode, whichever is greater. Beyond that, free cooling will remain on until the actual chilled water temperature exceeds the FC chilled water setpoint.

[ ] Cooldown Period (END =). While this operating parameter is an integral part of the SCP's cooldown control function, the value entered there also determines the minimum duration of the thermostatically-controlled free cooling mode. Accessed via the SCP's "SYSTEM" programming menu (Figure 24), "END = " values range from zero (00.00) to 2 hours (02.00) in 15-minute increments.

Note: If "END = 00.00" (i.e., SCP's default setting), the minimum automatic free cooling "on"-time is 15 minutes.

Collectively, these control setting entries tell the SCP when to begin automatic, thermostatically-controlled FC operation, and how much time to allow for the FC chillers to reduce the chilled water temperature to the FC chilled water setpoint. If the system's free cooling capacity is insufficient to reach or maintain this temperature, then the SCP converts system operation to the powered cooling mode.

When system operation is no longer required (i.e., either as a result of the system operating schedule, a BAS command, or a manual setpoint), the SCP shuts down all chillers presently running under its control. (This occurs regardless of whether these units are operating in the free cooling or powered cooling mode.)

On/Off FC

Two contact closure inputs at the SCP allow a generic BAS, external analog controller, or other supervisory control device to "automatically" initiate system-level free cooling. See Figure 23.

Notice that several conditions must be met before free cooling can occur:

1. The SCP's "FC Enable/Disable" control circuit--Terminals TB3-7 and TB3-8--must be closed.

Closure of this circuit could be prompted by a field-supplied and -installed, temperature-sensitive device. Actual "FC Enable/Disable" circuit configuration will vary with system application.

2. The SCP's "Scheduled System Enable/Disable" control circuit--Terminals TB3-5 and TB3-6--must be closed.

Closure of this circuit may be the result of a command from a connected, supervisory control device. A jumper is field-installed across these terminals to close this circuit when the "Scheduled System Enable/Disable" contact closure input is not used.

3. "SET = AUTO" must be entered for the freecool system setpoint in the SCP's "SYSTEM: FREECOOL" programming menu.

When all 3 of these requirements are satisfied, the SCP initiates free cooling operation in those units that are equipped with the FC option--and are presently under its control (i.e., chiller switch set at AUTO/REMOTE). The operating status of non-FC chillers controlled by the SCP (as well as units under manual control) will not change. In other words, simultaneous powered cooling and free cooling operation can occur within the system if both FC and non-FC chillers are present.

Caution: Turn off all non-FC chillers when system is running in free cooling. Operating chillers in powered cooling mode while very low condenser water temperatures exist is detrimental to operating efficiency and equipment life.

Once free cooling has begun, system operation will remain in that mode--regardless of chilled water temperature --until either of the contact closure inputs is open, or the FC system setpoint entry is changed to some value other than AUTO.

Remember that the "FC Enable/Disable" contact closure input only provides on/off control of the system-level free cooling function. Thermostatically-controlled free cooling is not possible without reprogramming the SCP and installing the optional free cooling sensor.

Trane BAS Interface

Field installation of a twisted-pair conductor (BCL) between the SCP (i.e., at Terminals TB2-7 and TB2-8) and a Trane building automation system enables the Trane BAS to send system--or chiller --setpoint and scheduling information to the SCP. In turn, the SCP uses this data to regulate the operation of all connected chiller system equipment (e.g., chillers, pumps, etc.).

Note: SCP control logic is bypassed as long as the Trane BAS is regularly transmitting system and chiller setpoints. However, if more than 15 minutes elapses between Trane BAS communication updates, the SCP will default to its own internal control values.

Notice that the Trane BAS can issue setpoints for all of the SCP's programmable control settings; Figure 9 in SCP699 Operator Interface summarizes these entries. In addition, the BCL allows the Trane BAS to "read" all operating data monitored by the SCP--at both system and chiller levels.

(Remember that the relay settings associated with the optional condenser limit control function must still be adjusted manually on the SCP's sideboard. See "Condenser Limit Option" on page 68 of this manual.)

Electrical Demand Limiting

Note: Remember that the electrical demand limit function is inoperative unless "AUTO" is entered for the system current limit setpoint. See Figure 25 (and Figure 12 in SCP699 Operator Interface).

The SCP's electrical demand limiting function enables it to monitor the building's incoming power level and reduce chiller system current draw accordingly (i.e., at a minimum rate of 2% per minute) when an operator-selected peak demand point is exceeded.

To do this, the SCP compares a sensor input value with an operator-entered, system electrical demand limit setpoint (Figure 25). Whenever the incoming power level registered by the sensor violates the demand limit, the SCP lowers the effective system current limit setpoint (SCLS). Then, using the new SCLS value, it begins to unload chillers by sending the unit control panels current limit setpoints below their individual, reported electrical load levels.

Note: For the SCP's electrical demand limit function to operate properly, the chiller system must constitute a significant percentage of the metered building electrical load. If the chiller system draws a relatively small portion of that load, the SCP may unload all of the chillers in order to reduce electrical demand!

Once system electrical demand falls below the electrical demand limit setpoint, the SCP raises the effective SCLS value and issues new, higher unit current limit settings.

Like the SCP's normal system current limit control function, its electrical demand limit function takes precedence over system temperature control. In other words, the SCP will demand-limit system operation whenever the electrical demand limit setpoint is exceeded–even if the lower unit current limit values force the chillers out of temperature control range!

Note: The SCLS value determined with the SCP's electrical demand limit function is ignored if it is higher than an existing cooldown or Trane BAS-issued SCLS value.

Two programmable entries in the "SYSTEM" menu allow the operator to establish an electrical demand limit setting and an electrical demand meter rate. See Figure 25. The limit setting is compared against the actual system electrical demand to determine whether or not chiller unloading is required. Limit settings range from 1% through 100% of the metered building electrical load (i.e., in increments of 1%); the demand limit function is disabled when "LIM. = 0".

The meter rate entry is a program constant that ranges from 0 through 100 (i.e., in increments of 1), and is used to translate meter pulse input data into a percent of electrical load. It is calculated and entered only once, and numerically converts the frequency of the demand meter contact closure input to a percentage of full-scale output.

See Figure 26. Notice that 4 input connections–SCP Terminals TB3-1 through TB3-4–are associated with the electrical demand limit function. These terminals are field-connected to a 2- or 3-wire contact closure output from some metering device–usually the pulse output of a watt-hour meter.

The SCP is capable of counting pulse rates ranging from 1 pulse/100 seconds to 10 pulses/1 second. However, each contact closure and opening must be maintained for approximately 20 milliseconds for the pulse to be detected.

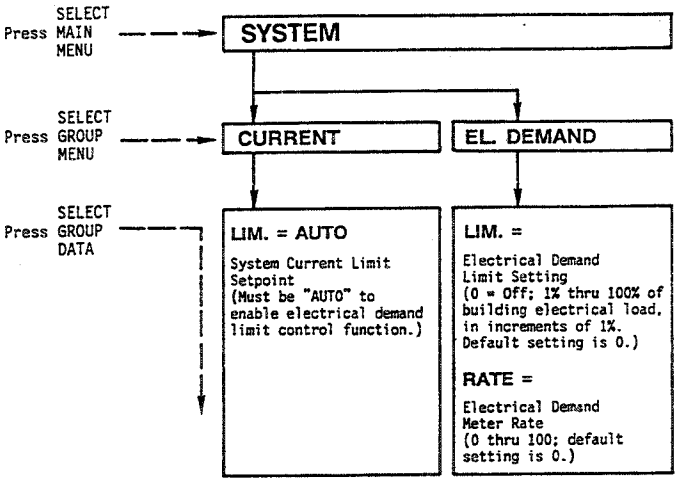
Watt-Hour Meter/ Pulse Initiator Selection

The electrical utility will select and install a suitable watt-hour meter for your chiller system application. If the utility does not "size" the pulse-output device (or "initiator") as well, it will be necessary to calculate a "revolutions -per-pulse" (R/P) value that can then be used to select an appropriate pulse initiator.

A numeric value for the R/P ratio is derived from this equation:

$$\frac{R}{P} = \frac{1000 \times Ke}{PKh},$$

where,
Ke = kilowatt-hours per pulse; and,
PKh = watt-hours per revolution.



In order to solve for "R/P", several preliminary calculations are required:

1. Solve the following equation to arrive at a numeric value for "PKh":

$$PKh = Kh \times CTR \times VTR,$$

where,
Kh = meter constant displayed on the demand meter;
CTR = current transformer ratio; and,
VTR = voltage transformer ratio.

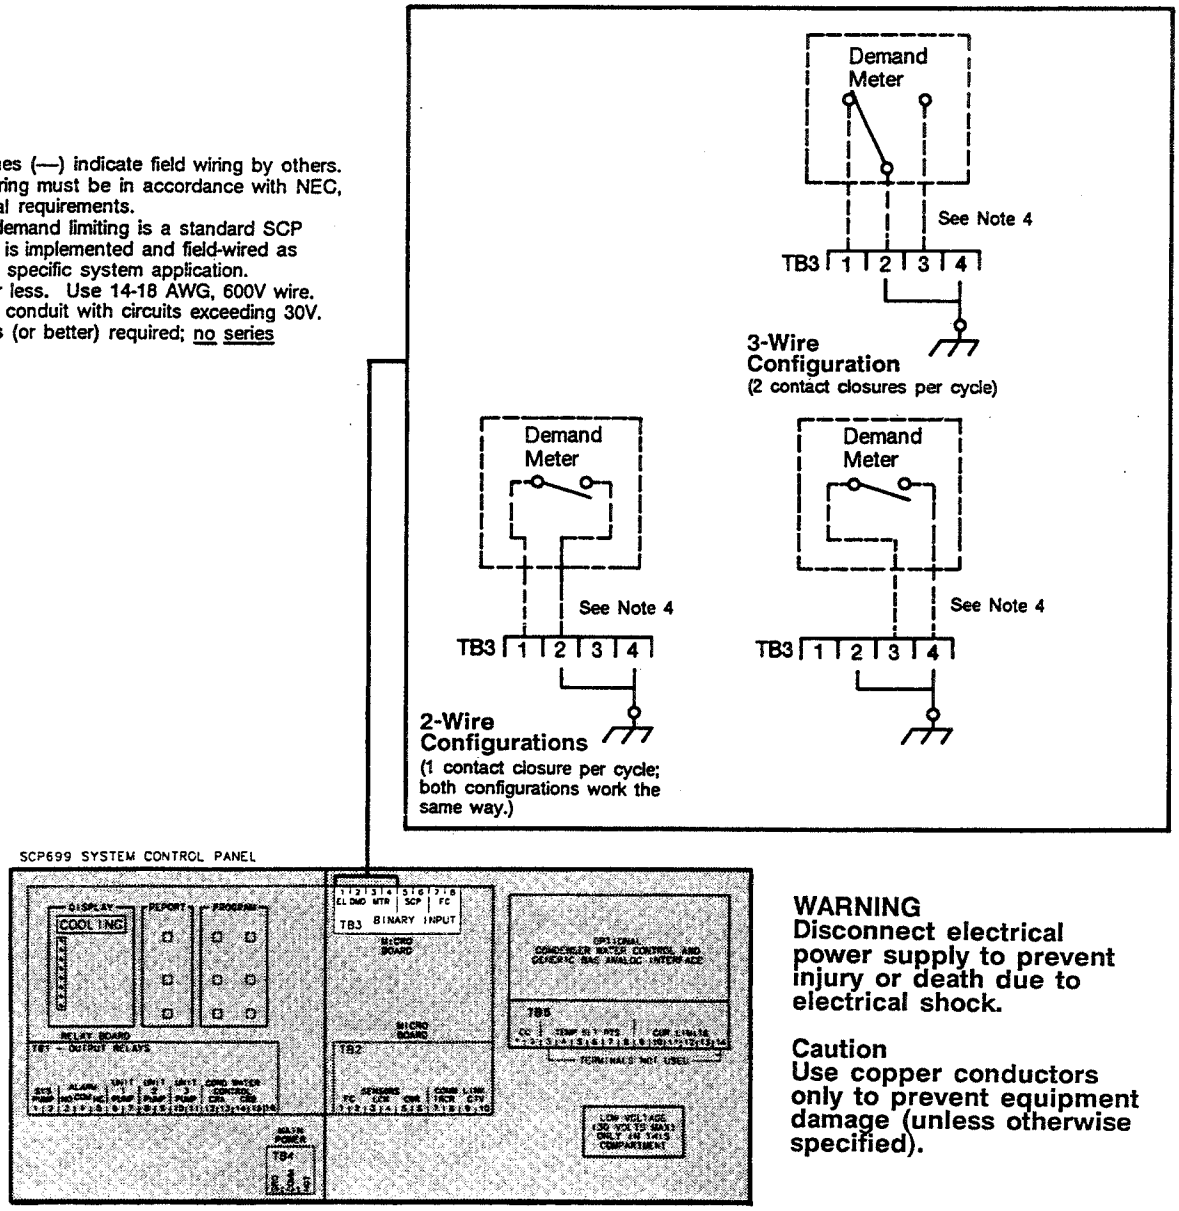
Figure 25
Operator-Programmable Entries for Electrical Demand Limiting

2. Using a pulse rate of 3 pulses per second at maximum power input, calculate a "kilowatt-hours per pulse" (Ke) value with this equation:

$$Ke = \frac{\text{Max. System Kw}}{\text{Pulses per Hour}},$$

where "pulses per hour" is 10,800 (i.e., 3 pulses/sec. x 60 sec./min. x 60 min./hr.).

Note: Using a frequency (or pulse rate) of "3" not only minimizes the effect of rounding off when calculating the SCP's meter rate setting, but also allows more flexibility when selecting meter/pulse gearing. (An "acceptable" frequency input for a 2-wire output at full power draw can be as much as 10 contact closures per second.)



3. Substitute the numeric values calculated for PKh (Step 1) and Ke (Step 2) into the following equation to arrive at an "R/P" ratio for your system.

$$\frac{R}{P} = \frac{1000 \times Ke}{PKh},$$

4. Select a pulse-output device with an "R/P" ratio that most closely matches the R/P ratio calculated in Step 3.

Figure 26
Field Connections for Electrical Demand Meter Wiring

Notes:
1. Dashed lines (—) indicate field wiring by others.
2. All field wiring must be in accordance with NEC, state and local requirements.
3. Electrical demand limiting is a standard SCP feature, but it is implemented and field-wired as required for a specific system application.
4. 30 volts or less. Use 14-18 AWG, 600V wire. Do not run in conduit with circuits exceeding 30V. Silver contacts (or better) required; no series contacts!

WARNING
Disconnect electrical power supply to prevent injury or death due to electrical shock.

Caution
Use copper conductors only to prevent equipment damage (unless otherwise specified).

Drwg. 4532-3789B

Determining Electrical Demand Limit Settings

Once the watt-hour meter and pulse initiator are selected, several additional computations must be made to arrive at appropriate electrical demand limit setpoint and meter rate values for your system application. These calculations are described below.

1. Calculate the kilowatt-hours per pulse (Ke) based on the actual watt-hours/revolution (PKh) and revolutions/pulse (R/P) values of the watt-hour meter installed. Use this equation:

$$Ke = \frac{R}{P} \times \frac{PKh}{1000}$$

(Remember that PKh = Kh x CTR x VTR; see Step 1 of "Watt-Hour Meter/Pulse Initiator Selection".)

2. Determine what kilowatt value will correspond to a 100% electrical demand load.

Note: Select a Kw value that is (1) close to–but greater than–the demand limits that will be set, and (2) a multiple of 10 (e.g., 1000, 5000, etc.) so that any operator-entered demand limit setpoint can be easily converted to a Kw value.

(For example, if a system's electrical demand meter peak is 850 Kw, you may wish to set the 100% load value equal to 1000 Kw. In this instance, the equivalent kilowatt value for a demand limit setpoint of 54% would then be 540 Kw.)

3. Use the following equation to calculate the appropriate value for the SCP's electrical demand limit meter rate setting. Be sure to round off the calculated "RATE = " value to the nearest integer between 0 and 100.

$$RATE = \frac{0.0025 \times Kw(@100\%)}{Ke},$$

where,
Kw (@100%) = kilowatt value equivalent to a 100% electrical demand load (see Step 2); and,
Ke = kilowatt-hours/pulse (see Step 1).

4. Calculate the actual kilowatt value that corresponds to a 100% electrical demand load using the "rounded-off" rate value determined in Step 3. (Because the meter rate was rounded to the nearest integer, the kilowatt value calculated here will not match the value found in Step 2.)

$$Kw(@100\%) = \frac{RATE \times Ke}{0.0025},$$

where,
RATE = integer RATE value calculated in Step 3; and,
Ke = kilowatt-hours/pulse (see Step 1).

5. Using the kilowatt value found in Step 4, determine the peak building load (in kilowatts), and calculate the appropriate electrical demand limit setpoint with this equation:

$$\text{El. Demand Limit} = \frac{\text{Peak Kw} \times 100}{Kw(@100\%)},$$

where,
Peak Kw = desired limit–in kilowatts–for the maximum building load; and,
Kw (@100%) = 100% demand load in kilowatts (see Step 4).

Again, be sure to round off the calculated limit value to the nearest integer.

For example, if the kilowatt value corresponding to a 100% demand load is 1012 kw–and the desired electrical demand limit is 550 kw, then:

$$\text{El. Demand Limit Setpoint} = \frac{550 \text{ Kw} \times 100}{1012 \text{ Kw}}$$

$$\text{El. Demand Limit Setpoint} = 54.35 \text{ or } 54$$

Note: Repeat Step 5 to determine the electrical demand limit setpoint for other peak load conditions, but do not change the value used for RATE.

Once calculated, enter the electrical demand limit setpoint and meter rate values in the SCP's "SYSTEM" program menu. (See "System Setup: Electrical Demand Limit" in the SCP699 Operator Interface section of this manual.)

* * * * *

Review the example below to ensure that you understand the calculations used first to size a pulse initiator, and then to determine appropriate SCP electrical demand limit settings.

"Suppose a building operator installs a 2-wire electrical demand meter on the 480-volt, 3-phase incoming power lines of a building. The metered circuit includes a 1000:5 current transformer, and a voltage (potential) transformer with a ratio equal to 1. The desired peak building load is 750 Kw.

"Both the meter and transformers are designed for a maximum input of 1,000 Kw, and the meter constant is 2.4."

Calculate the values needed to establish appropriate electrical demand limit setpoint and meter rate values.

a. Determine the value of PKh (i.e., watt-hours per revolution).

$$PKh = 2.4 \times \frac{1000}{5} \times 1 = 480$$

b. Calculate a value for Ke (i.e., kilowatt-hours per pulse); remember to base this calculation on a frequency of 3 pulses per second.

$$Ke = \frac{1{,}000}{10{,}800} = 0.093 \text{ or } 0.09$$

c. Determine the proper R/P value for this application.

$$\frac{R}{P} = \frac{1000 \times 0.09}{480} = \frac{90}{480} \text{ or } \frac{1}{5.3}$$

d. Since the "R/P" ratio found in Step c is 1/5.3, select a pulse initiator that will produce 1 revolution per 6 pulses (i.e., R/P = 1/6).

e. Using the PKh and R/P values determined in Steps a and d, compute an "actual" value for Ke.

$$Ke = \frac{1}{6} \times \frac{480}{1000} = 0.08$$

f. Remember that the desired peak building load is 750 Kw; therefore, let's use a value of 1000 Kw as the "100% electrical demand load".

g. Solve for RATE; be sure to round off the calculated RATE value to the nearest integer.

$$RATE = \frac{0.0025 \times 1000}{0.08} = 31.25 \text{ or } 31$$

h. Use the integer value for RATE (calculated in Step g) to determine the actual Kw value that corresponds to a 100% electrical demand load.

$$Kw(@100\%) = \frac{31 \times 0.08}{0.0025} = 992$$

i. Calculate the appropriate electrical demand limit setpoint; in this example, use the desired peak building load of 750 Kw.

$$\text{El. Demand Limit} = \frac{750 \times 100}{992} = 75.6 \text{ or } 76$$

j. Access the SCP's "SYSTEM" programming menu, and enter "LIM. = 76" and "RATE = 31".

Evaporator Water Pump Control

Note: SCP control of evaporator water pump(s) is not possible in generic BAS applications.

Besides operating the connected centrifugal water chillers, the SCP also provides coordinated control of as many as 3 individual chiller evaporator pumps and 1 system pump.

Four normally-open relays on the SCP's output relay board are designated for evaporator pump control, and can be wired into the pump starter interlock control circuits. Specific pump relay terminal connections at the SCP are listed below (and illustrated in Figure 27):

[ ] system pump starter connected to SCP Terminals TB1-1 and -2;

[ ] Unit 1's pump starter connected to SCP Terminals TB1-6 and -7;

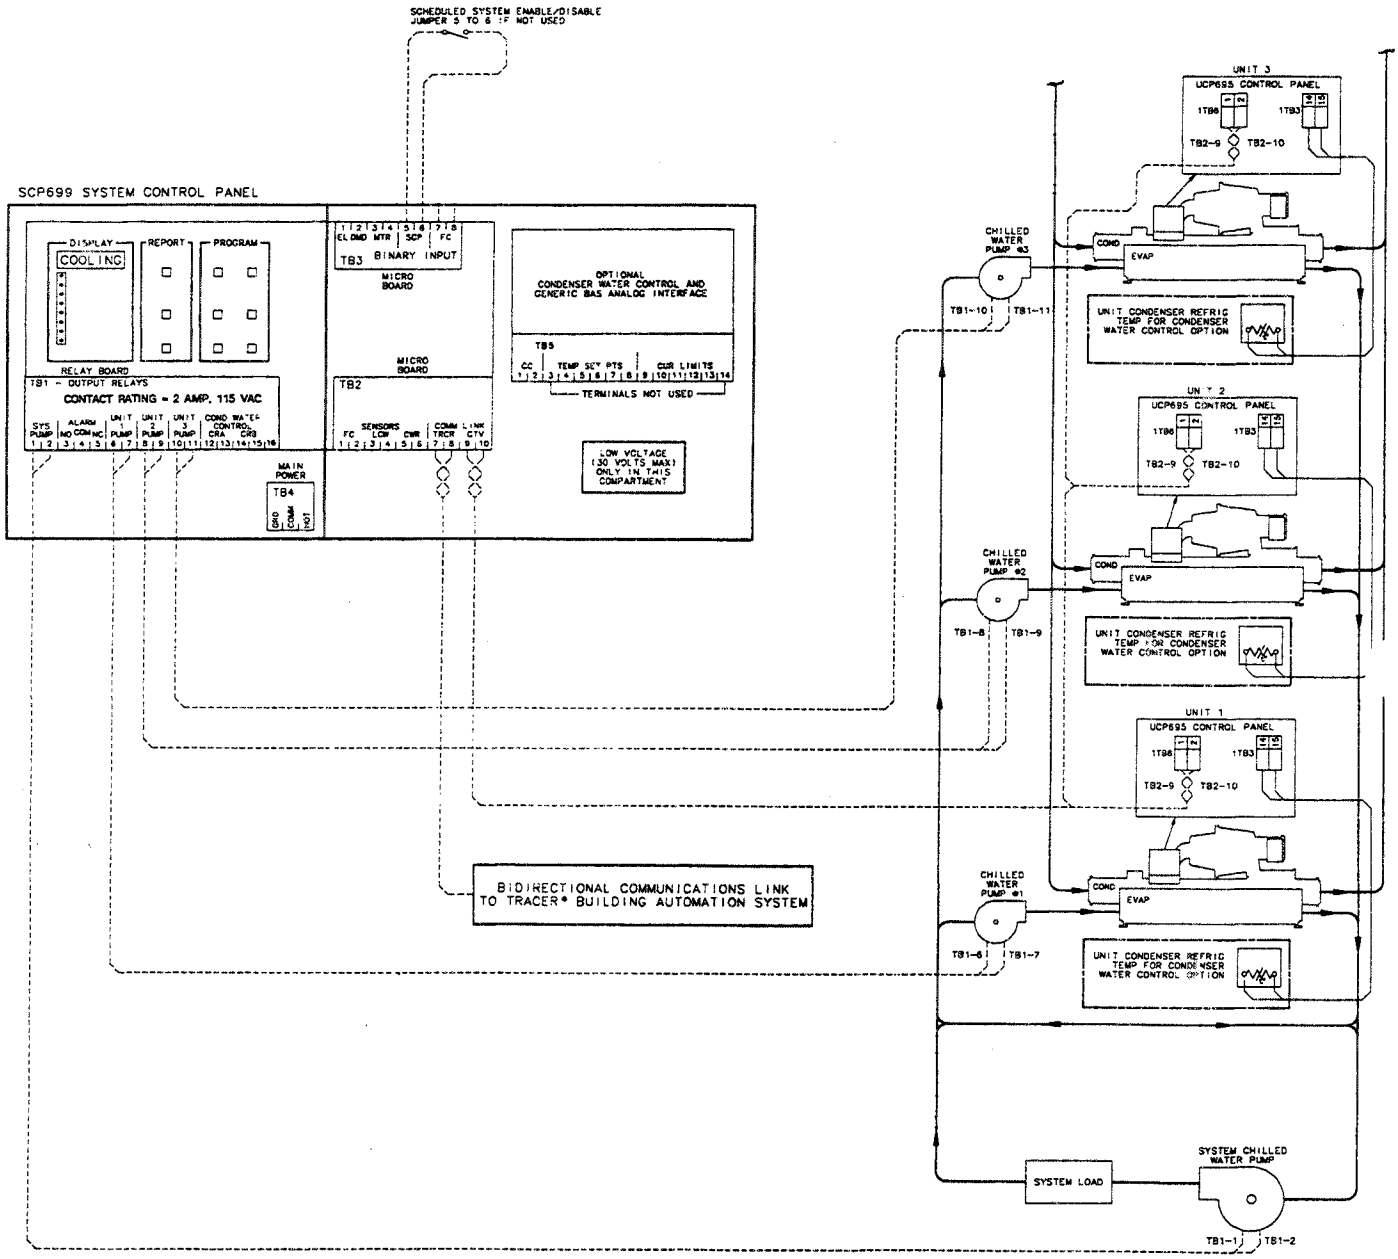
[ ] Unit 2's pump starter connected to SCP Terminals TB1-8 and -9; and,

[ ] Unit 3's pump starter connected to SCP Terminals TB1-10 and -11.

Note: Remember that each of the "Unit 1", "Unit 2" and "Unit 3" designators corresponds to the address set up with DIP Switch Block S11 in each chiller control panel. (See "UCP695 DIP Switch Setup" in the Start-Up section of this manual.)

Together, (1) SCP operating status, (2) unit chilled water setpoint(s), and (3) the position of SCP configuration DIP Switch No. 1 determine whether any--or all--of the chilled water pumps are running at a given time. (Recall that DIP Switch No. 1 must be in the OFF--or "normal"--position to assure proper SCP control of pump operation.)

Table 13 summarizes the relationship between these factors and the status (i.e., open or closed) of the SCP's chilled water pump control relays.



Notice that as long as any unit connected to the SCP is running, the SCP will not de-energize the system or chiller pump until the unit is shut down. This is true regardless of whether the unit is actually "scheduled" off (but running under a manual command), or operating in the "Auto/Local" mode--provided that the BCL between the SCP and chiller remains intact.

Table 13
Operation of SCP Evaporator Control Output Relays (1)

SCP Operating Status	Unit(s) Chilled Water Setpoint Status	Pump Relay Status	
		System Pump	Chiller Pump(s)
Off	Manual On	On	On
Off	Manual Off	Off	Off
Off	Auto	Off	Off
On	Off	On	Off
On	Free Cooling	On	On
On	On	On	On

Notes:
1. All SCP evaporator pump output relays are subject to minimum "on" (i.e., 5 ± 1 minutes) and "off" (i.e., 0 minutes) times unless configuration DIP Switch No. 1 is in the ON--or "service" position.
2. Whether DIP Switch No. 1 is set at OFF or ON, the system pump relay will energize whenever:
   a. a chiller evaporator pump relay energizes; or,
   b. the system is turned ON.
3. Whenever the SCP's operating status is "ON", it starts the chiller evaporator pump associated with the first chiller in rotation.

Figure 27
SCP/Evaporator Water Pump
Field Wiring Connections

Notes:

1. Dashed lines (—) represent field-installed wiring; phantom lines (—— - ——) indicate available sales options.
2. All field wiring must be in accordance with the National Electric Code (NEC), and state and local requirements.
3. Control circuit wiring between the SCP relay board and evaporator pump starters is 14 AWG, 600V wire rated for 105 C. A separate 120 VAC power supply is required.
4. While SCP evaporator pump control is a standard feature, its actual implementation is optional. Field wiring is dictated by the specific system application.
5. Illustrated arrangement of chilled and condenser water piping is not a piping schematic; use it only to identify temperature sensor locations.

WARNING
Disconnect all electrical power supplies to prevent injury or death due to electrical shock.

Caution
Use copper conductors only to prevent equipment damage.

Drwg. 4532-3789B

System Pump

The normally-open contacts of the **system pump** control relay close whenever the SCP is enabled and the system is scheduled--or manually commanded--to maintain a chilled water setpoint. Once closed, an internal timer function ensures that the contacts do not reopen for at least 5 minutes; during this period, the SCP can verify the existence of a cooling requirement.

Note: Remember that the SCP is "enabled" whenever its "Scheduled System Enable/Disable" circuit (i.e., TB3-5 to TB3-6) is closed.

System pump operation will continue until the system is scheduled off, or the SCP is disabled.

In the event of a power loss or an SCP malfunction, the system pump output relay is de-energized, shutting down system pump operation.

Chiller Pumps

Like the system pump, each chiller evaporator pump is governed by its own normally-open set of SCP output relay contacts. Any valid numerical setpoint for a particular unit--whether issued by the SCP, communicated from a Trane BAS, or manually entered at the SCP by the operator--will cause the associated chiller pump (along with the system pump) relay to energize.

Notice that SCP control logic anticipates chiller operation by energizing the chiller pump relay associated with the first unit in the start rotation whenever the system is scheduled "on". (See Table 13.) This assures that the unit pump is running before that chiller is expected to operate in either the powered cooling or free cooling mode. Further, once the pump relay contacts "make", they will remain closed for a minimum of 5 minutes.

When a unit is issued an "off" value for its chilled water setpoint, its evaporator pump control relay is de-energized once post-lube is complete--but only if the SCP does not anticipate restarting that chiller in the immediate future.

All chiller evaporator pump operation is shut down if a power loss or SCP malfunction occurs.

Condenser Water Pump Control

SCP699 system control panels do not include control output relays for each chiller's condenser water pump. Instead, condenser pump control is handled at the chiller level by the UCP695 control panel. Integration of condenser pump control with unit operation is explained in the installation and operation/maintenance manuals that ship with each CenTraVac chiller.

Generic BAS Option

Note: It is important to remember that when the SCP is used in a generic BAS application, its role is reduced to one of relaying setpoint changes from the generic BAS to the chillers. All system control functions--such as scheduling and chilled water pump control--must be performed by the generic BAS.

As a result, operator setup at the SCP is limited to ensuring that DIP Switch No. 2 (i.e., located on the sideboard; see Figures 28 and 29) is set at the ON position to enable SCP interface with the generic BAS.

Required SCP program entries are limited to the following:

[ ] In the "FREECOOL" portion of the "SYSTEM" program, enter "AUTO" for the free cooling system setpoint.

[ ] In the Unit 1, Unit 2 and Unit 3 portions of the SCP's "CHILLER" program, enter:

a. "AUTO" for each unit's leaving chilled water setpoint;

b. "AUTO" for each unit's current limit setpoint; and,

c. the percentage of total chiller current draw--"LOAD = "--of each unit. (This entry is an important part of the SCP's reports.)

In addition to these entries, you may also wish to set up the SCP's clock/calendar. (See "Program Interface" in the SCP699 Operator Interface section of this manual for instructions.)

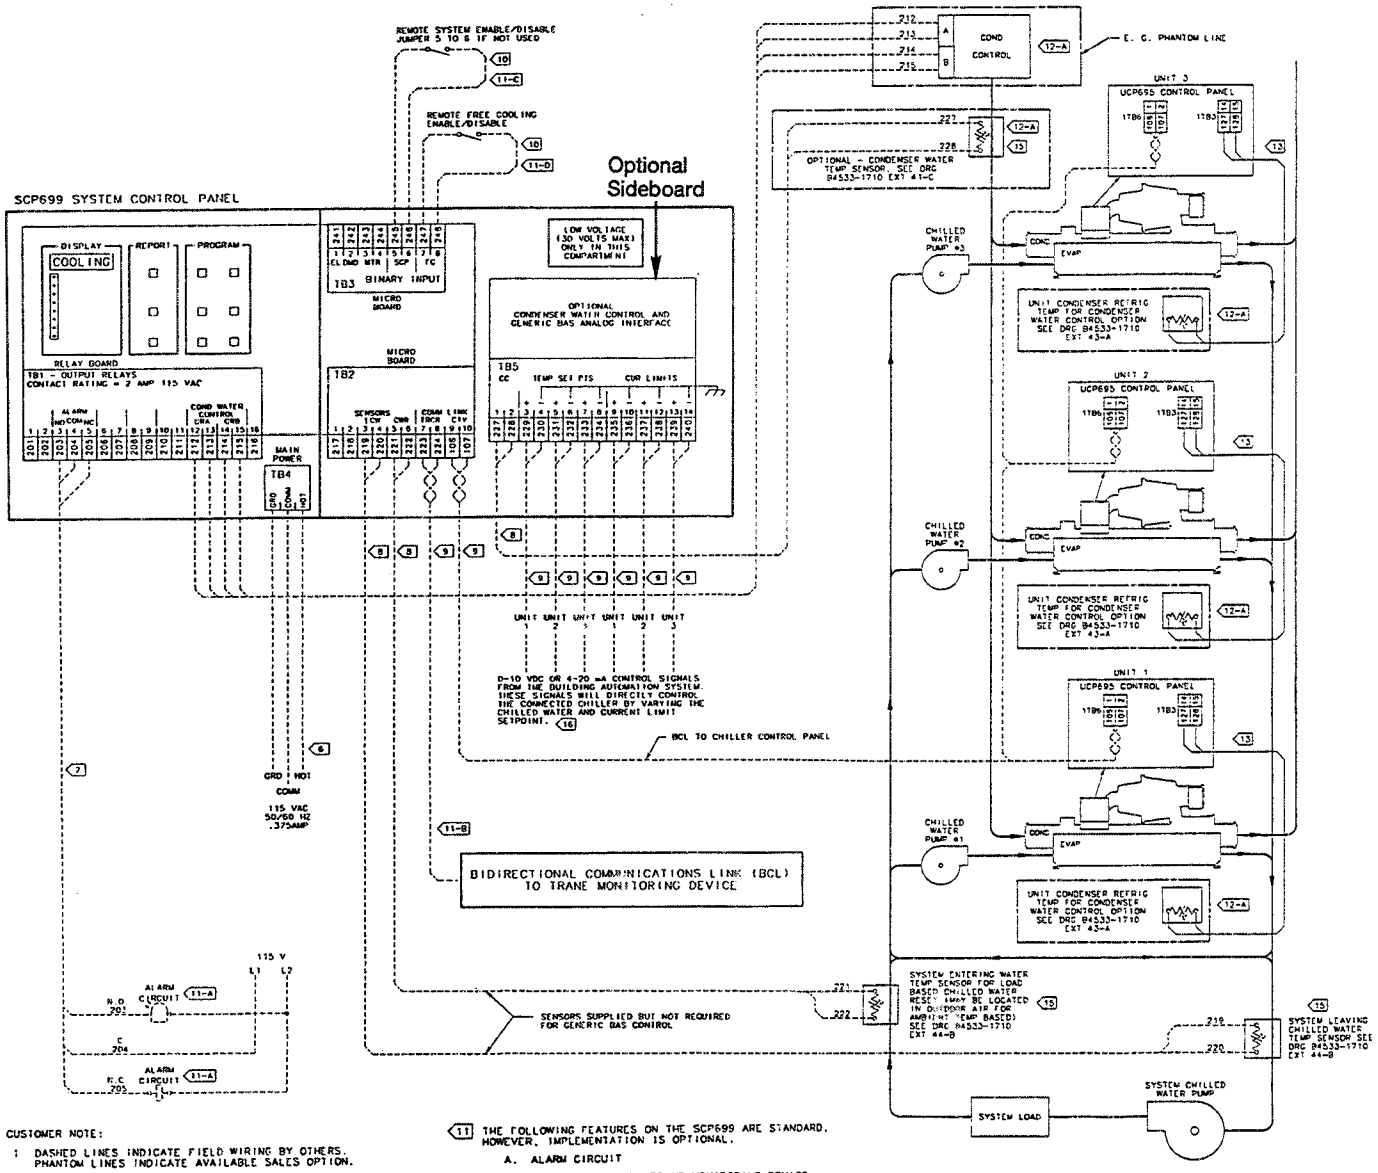
Note: In generic BAS system applications, the SCP will only record and alarm system-level diagnostic conditions; it will not alarm diagnostic conditions that occur at the chillers.

Factory-installation of a sideboard within the SCP panel enclosure provides the means for a non-Trane BAS to directly control chiller operation by varying unit chilled water and current limit setpoints.

Analog control signals issued by the generic BAS for each unit's chilled water setpoint and current limit setting are sent to the SCP over twisted-pair conductors field-connected to Terminals TB5-3 through TB5-14 on the sideboard. Specific terminal connections are listed below and shown in Figure 28:

[ ] Chilled Water Temperature Setpoints:
Unit 1 = Terminals TB5- 3, - 4
Unit 2 = Terminals TB5- 5, - 6
Unit 3 = Terminals TB5- 7, - 8

[ ] Current Limit Settings:
Unit 1 = Terminals TB5- 9, -10
Unit 2 = Terminals TB5-11, -12
Unit 3 = Terminals TB5-13, -14



The SCP's generic BAS input terminals are designed to receive control signals of 0 to +10 VDC; SCP load is 96.4 kilo-ohms. Alternatively, 4 to 20 maDC signals may be substituted if the six 499-ohm resistors (i.e., R23 thru R28; supplied with the SCP) are field-installed on the sideboard for each pair of analog input terminals. In this instance, each 4 to 20 maDC current signal is driven into the appropriate 499-ohm load. See Figure 29.

To automatically control chiller operation, the "System Enable/Disable" circuit between SCP Terminals TB3-5 and TB3-6 must be closed. Closure of this input circuit allows the SCP to enable powered cooling operation of all connected chillers (i.e., with chiller switches set at AUTO/REMOTE).

For system applications that require individual on/off chiller control, field-wire a contact closure into the chilled water flow interlock circuit of each unit. (Typically, this set of contacts would be positioned in series with the starter auxiliary and chilled water flow switch.) If individual pumps are allocated for each chiller, the generic BAS can enable operation of a specific chiller simply by starting the appropriate chilled water pump.

Note: If the chiller switch of a particular unit is moved to AUTO/LOCAL, setpoints established at the UCP695 chiller control panel override any setpoints communicated by the SCP.

Figure 28
SCP Field Wiring Connections for Generic BAS Applications

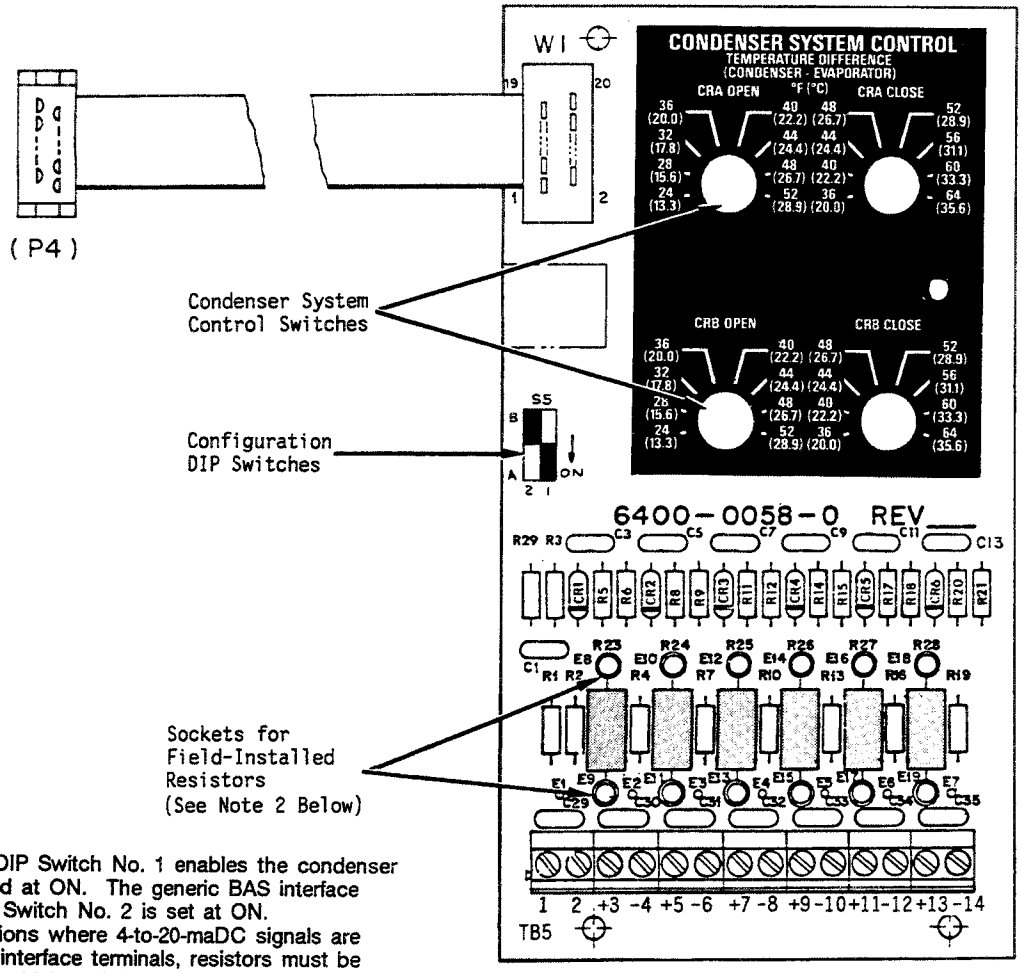
CUSTOMER NOTE:

1. DASHED LINES INDICATE FIELD WIRING BY OTHERS. PHANTOM LINES INDICATE AVAILABLE SALES OPTION.
2. ALL FIELD WIRING MUST BE IN ACCORDANCE WITH THE NATIONAL ELECTRIC CODE (NEC), STATE AND LOCAL REQUIREMENTS. OTHER COUNTRIES APPLICABLE NATIONAL AND OR LOCAL REQUIREMENTS SHALL APPLY.
3. ALL CHILLED WATER PUMPS ARE CONTROLLED BY THE BAS. CONDENSER WATER PUMPS CAN BE ENABLED BY THE CONTROL CONTACT PROVIDED IN THE CENTRAVAC CHILLER UNIT CONTROL PANEL (UCP695).
4. PROVISION SHOULD BE MADE TO TURN THE CONTROLLED CHILLERS ON AND OFF VIA THE CHILLED WATER FLOW INTERLOCK ON THE UCP695.
5. CHILLED WATER AND CONDENSER PIPING ARRANGEMENT IS NOT INTENDED AS A PIPING SCHEMATIC. IT IS USED TO ILLUSTRATE TEMPERATURE SENSOR LOCATIONS.

6. #14-16 AWG, 105°C, 600 VOLT WIRE.
7. #14 AWG, 105°C, 600V WIRE, SEPARATE 120 VAC POWER SUPPLY IS REQUIRED.
8. 30V OR LESS, #14-18 AWG 600V WIRE. MUST BE SHIELDED OR RUN IN CONDUIT. DO NOT RUN IN CONDUIT W/CIRCUITS GREATER THEN 30V. SEE TABLE 1 FOR MAX LENGTH.
9. SHIELDED TWISTED PAIR, #14-18 AWG 600V WIRE. MAX LENGTH 5000 FT. DO NOT RUN IN CONDUIT W/CIRCUITS GREATER THAN 30V.
10. #14-18 AWG 600V WIRE. DO NOT RUN IN CONDUIT W/CIRCUITS GREATER THAN 30V. SILVER CONTACTS OR BETTER REQUIRED (NO SERIES CONTACTS).

11. THE FOLLOWING FEATURES ON THE SCP699 ARE STANDARD, HOWEVER, IMPLEMENTATION IS OPTIONAL.
    - A. ALARM CIRCUIT
    - B. COMMUNICATION TO TRANE MONITORING DEVICE
    - C. REMOTE SYSTEM ENABLE/DISABLE
    - D. REMOTE FREE COOLING ENABLE/DISABLE
12. THE FOLLOWING CAPABILITIES ARE OPTIONAL - THEY ARE IMPLEMENTED AND WIRED AS REQUIRED FOR A SPECIFIC SYSTEM APPLICATION.
    - A. CONDENSER LIMIT CONTROL
13. WIRING INCLUDED WITH SENSOR. FIELD CONNECTION REQUIRED.
14. SEE SCP699 INSTALLATION MANUAL (CVMA-IN-1) FOR PROPER SHIELDING CONNECTIONS.
15. 1/2 NPT COUPLINGS REQUIRED FOR WATER TEMPERATURE SENSOR WELLS.
16. NEGATIVE SIGNAL INPUTS ARE GROUNDED TO SCP ENCLOSURE. FOR CORRECT OPERATION, EXTERNAL EQUIPMENT SIGNALS SHALL BE ISOLATED OR FLOATING WITH RESPECT TO SCP ELECTRICAL SERVICE GROUND AND ISOLATED FROM EACH OTHER. SPECIAL CONSIDERATION MUST BE GIVEN TO 4-20 mA SIGNALS. IF THE CURRENT SOURCE REGULATES CURRENT FLOW ON THE NEGATIVE LEAD, USE A SEPERATE POWER SUPPLY FOR EACH CHANNEL. IN SOME APPLICATIONS, IT MAY BE NECESSARY TO INSTALL A LOOP ISOLATOR IN EACH CHANNEL TO PREVENT LOOP INTERFERENCE.

TABLE 1



WIRE SIZE	MAX LENGTH FOR SENSOR LEADS
14 AWG	5000 FT
16 AWG	2000 FT
18 AWG	1000 FT

WARNING
Disconnect electrical power supply to prevent injury or death due to electrical shock.

Caution
Use copper conductors only to prevent equipment damage (unless otherwise specified).

Drwg. 4533-1707B

Figure 29
Optional SCP Sideboard for Condenser Water Control and Generic BAS Interface

Drwg. 6400-0058C

Notes:

1. Sideboard configuration DIP Switch No. 1 enables the condenser limit function when positioned at ON. The generic BAS interface option is enabled when DIP Switch No. 2 is set at ON.

2. For generic BAS applications where 4-to-20-maDC signals are issued to the SCP's analog interface terminals, resistors must be field-installed on the optional sideboard–just above terminal strip TB5.

Six resistors are factory-included with the optional sideboard–2 resistors for each chiller in the system. To install the resistors, bend the resistor leads at a 90-degree angle; then insert each resistor into the appropriate set of sockets.

Resistor designations are stamped on the sideboard, and are as follows:

R23 = Unit 1 chilled water setpoint
R24 = Unit 2 chilled water setpoint
R25 = Unit 3 chilled water setpoint

R26 = Unit 1 current limit setpoint
R27 = Unit 2 current limit setpoint
R28 = Unit 3 current limit septoint

Remember that chiller designations (i.e., Unit 1, Unit 2 and Unit 3) are determined by DIP switch settings (S11) in each UCP695 chiller control panel.

3. SCP input impedance values for generic BAS applications are as follows:

a. 96.4 kilo-ohms for 0 to +10 VDC control signals (optional sideboard without field-installed resistors); and,

b. 499 ohms for 4 to 20 maDC control signals (optional sideboard with field-installed resistors).

Analog input signals sent to the SCP from the generic BAS are "converted" into unit chilled water and current limit setpoints that are then communicated to the appropriate chiller over the SCP/CenTraVac BCL (i.e., bidirectional communications link).

Note: Remember that each UCP695 chiller control panel connected to the SCP is "tagged" with its own, unique address ("Unit 1", "Unit 2" or "Unit 3") by the setup of DIP Switch Block S11. See "UCP695 DIP Switch Setup" in the Start-Up section of this manual.

When the generic BAS schedules the SCP "off" by opening the "System Enable/ Disable" circuit, the SCP shuts down all chiller operation (i.e., except for those units running under AUTO/LOCAL control).

Unit Chilled Water Setpoints. The value of the analog signal is used to determine how many degrees (F)--if any--are added to the temperature setpoint established at the designated chiller's UCP695 control panel. See Figure 30. If the change upward in the analog signal value is great enough, the chiller may be shut down (i.e., the SCP does not "slew-rate limit" unit setpoint changes issued by a generic BAS).

The SCP uses the following criteria to arrive at a chilled water setpoint that corresponds to the analog control signal issued by the generic BAS:

[ ] When the analog input voltage for a given unit is greater than 0 VDC but less than 1.5 VDC, the SCP will not transmit a chilled water setpoint (CWS) to that unit. (Therefore, the "Remote Chilled Water Setpoint" status indicator light on the chiller panel will not be lit.)

[ ] If the analog input for a given unit is greater than 1.5 VDC but less than 2.0 VDC, the SCP will send a CWS that is equal to that chiller's front panel setpoint (and the "Remote Chilled Water Setpoint" status indicator light on the chiller panel will illuminate).

[ ] The SCP uses this equation to calculate a new CWS for a particular unit when the analog input signal is greater than 2.0 VDC but less than 10.0 VDC:

$$\text{"New" CWS} = \text{Front Panel CWS} + 15\ \text{F}\ \frac{(\text{Analog input} - 2)}{8}$$

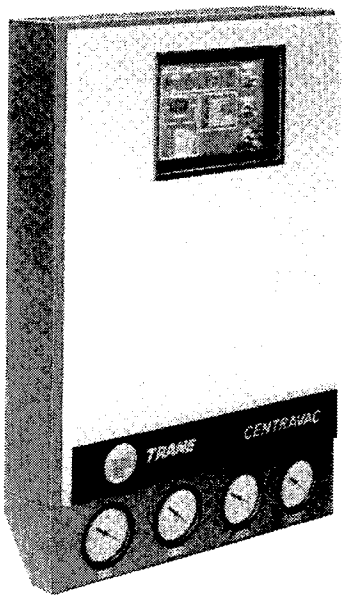


Table 14 indicates the amount of chilled water setpoint reset associated with various analog input voltage values ranging from 2.1 VDC to 9.9 VDC.

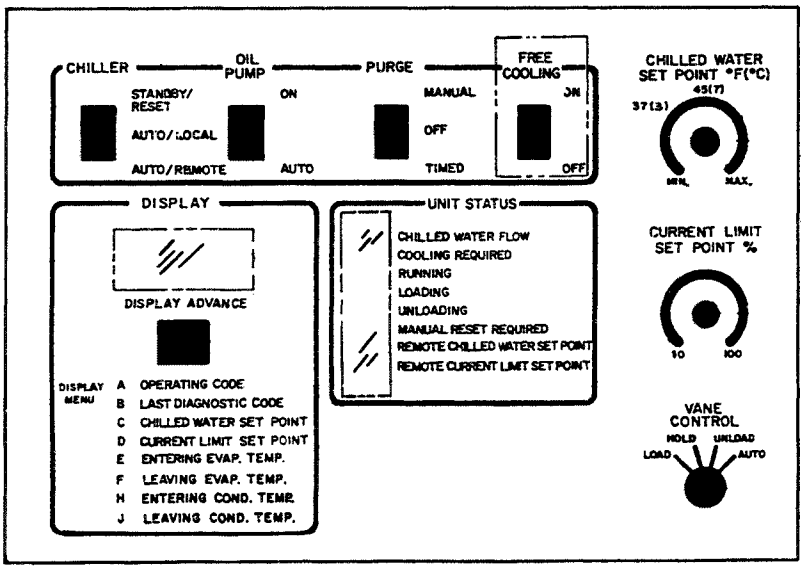


[ ] Whenever the analog input voltage is greater than 10.0 VDC but less than 12.0 VDC, the SCP transmits a new CWS that is equal to that chiller's front panel setpoint plus 15 F.

Note: The SCP will not apply more than 15 F reset to a unit's front panel chilled water setpoint.

Caution: To avoid damaging the SCP, never apply an analog input signal greater than 12.0 VDC to Terminals TB5-3 thru -8.

Figure 30
UCP695 Chiller Control Panel

Note: These controls are accessible without opening the control panel door.

Art No.
RF/CTV-1905

Drwg. 6400-0105
(Sheet 6 of 7)

Table 14
Unit Chilled Water and Current Limit Setpoints from Generic BAS Analog Inputs

Analog Input Voltage Signal (Vin) (1, 2)	Temperature Reset Added to Front Panel Chilled Water Setpoint	New Chiller Current Limit Setpoint (3)
0.0 < Vin < 1.5 VDC (or 0 - 3 mA)	No new CWS sent to unit.	No new CLS sent to unit.
1.5 < Vin < 2.0 VDC (or 3 - 4 mA)	New CWS = unit front panel CWS	New CLS = 100%
Vin = 2.1 VDC	Unit CWS + 0.188 F	99.25%
Vin = 2.5 VDC	Unit CWS + 0.938 F	96.25%
= 3.0 VDC	Unit CWS + 1.875 F	92.50%
= 3.5 VDC	Unit CWS + 2.813 F	88.75%
Vin = 4.0 VDC (or 8 mA)	Unit CWS + 3.750 F	85.00%
= 4.5 VDC	Unit CWS + 4.688 F	81.25%
= 5.0 VDC	Unit CWS + 5.625 F	77.50%
Vin = 5.5 VDC	Unit CWS + 6.563 F	73.75%
= 6.0 VDC (or 12 mA)	Unit CWS + 7.500 F	70.00%
= 6.5 VDC	Unit CWS + 8.438 F	66.25%
Vin = 7.0 VDC	Unit CWS + 9.375 F	62.50%
= 7.5 VDC	Unit CWS + 10.313 F	58.75%
= 8.0 VDC (or 16 mA)	Unit CWS + 11.250 F	55.00%
Vin = 8.5 VDC	Unit CWS + 12.188 F	51.25%
= 9.0 VDC	Unit CWS + 13.125 F	47.50%
= 9.5 VDC	Unit CWS + 14.063 F	43.75%
Vin = 9.9 VDC	Unit CWS + 14.813 F	40.75%
10.0 < Vin < 12.0 VDC (or > 20 mA)	New CWS = unit front panel CWS + 15 F	New CLS = 40%

Notes:

1. Analog input voltage values represented in this table include + 3%.
2. Whenever the analog input voltage is "2.0 < Vin < 10.0 VDC", the SCP sends the designated chiller a new chilled water (CWS) or current limit setpoint (CLS) based on these equations:

   a. New CWS = Unit Front Panel CWS + 15 F x ([Vin - 2] / 8)
   b. New CLS = 100% - 60 x ([Vin - 2] / 8)

3. The "new CLS" values in this column replace the designated chiller's front panel current limit setpoint if that unit is operating under AUTO/REMOTE control.

Unit Current Limit Setpoints. Another set of criteria (outlined below) is used to determine chiller current limit setpoints from the generic BAS analog input signals received at SCP Terminals TB5-9 through TB5-14. These new current limit setpoints are then sent to the appropriate chillers over the SCP/CenTraVac BCL.

Remember that chiller shutdown(s) may result if the values of the rate of change in the analog signal values issued by the generic BAS are great enough!

[ ] When the analog input voltage for a given unit is greater than 0 VDC but less than 1.5 VDC, the SCP will not transmit a current limit setpoint (CLS) to that unit.

[ ] If the analog input for a given unit is greater than 1.5 VDC but less than 2.0 VDC, the SCP will send that chiller a CLS that is equal to 100%.

[ ] The SCP uses this equation to calculate a new CLS for a particular unit when the analog input signal is greater than 2.0 VDC but less than 10.0 VDC:

$$\text{"New" CLS} = 100\% - 60\ \frac{(\text{Analog Input} - 2)}{8}$$

Current limit setpoints corresponding to various analog input voltages that range from 2.1 VDC to 9.9 VDC are included in Table 14.

[ ] Whenever the analog input voltage is greater than 10.0 VDC but less than 12.0 VDC, the SCP transmits a new CLS that is equal to 40% for the designated unit.

Caution: To avoid damaging the SCP, never apply analog input signals exceeding 12.0 VDC to Terminals TB5-9 thru -14.

Note: Besides modifying unit chilled water and current limit setpoints, a generic BAS can also initiate system-level free cooling via the SCP. See "Automatic Free Cooling: On/Off FC" in the SCP699 Operation section of this manual.

Condenser Limit Option

Note: This SCP option is intended to signal the cooling tower controller; it is not designed to control cooling tower operation!

The SCP's condenser control option is typically used to regulate cooling tower capacity by providing a 2-stage condenser limiting function. Specifically designed to maintain a minimum refrigerant pressure differential between each unit's evaporator and condenser, this control function also enables the chillers to operate over a broader range of operating conditions.

SCPs equipped with the condenser option include a "condenser water control/generic BAS analog interface" sideboard that is factory- (or field-) installed inside the SCP panel enclosure. See Figure 31. Notice that several sensor input and relay output electrical connections must be field-installed to make the sideboard operational:

1. Depending on the number of chillers connected to the SCP, up to 3 condenser refrigerant temperature sensors must be field-installed and -wired.

Refer to Figure 31. To ensure an accurate reading, each sensor (i.e., part no. 4533-1710-43A) must be epoxied to the condenser refrigerant line located between the unit's economizer and condenser. Do not install the sensor in the refrigerant line well! Remember that: (1) the tip of the thermistor must contact the bare metal of the refrigerant line; and, (2) the sensor and line must be wrapped with Armaflex insulation or equivalent.

The sensor leads are then routed into the low-voltage (upper) section of the UCP695 control panel, where they are connected to Terminals 1TB3-14 and -15. (These terminals are ordinarily designated for use with optional unit ambient temperature sensor 4RT6.)

Note: The SCP obtains evaporator refrigerant temperatures from each chiller control panel. Chiller sensor 4RT5 provides this data; it is factory-installed on all CVHE/B chillers with UCP695 control panels.

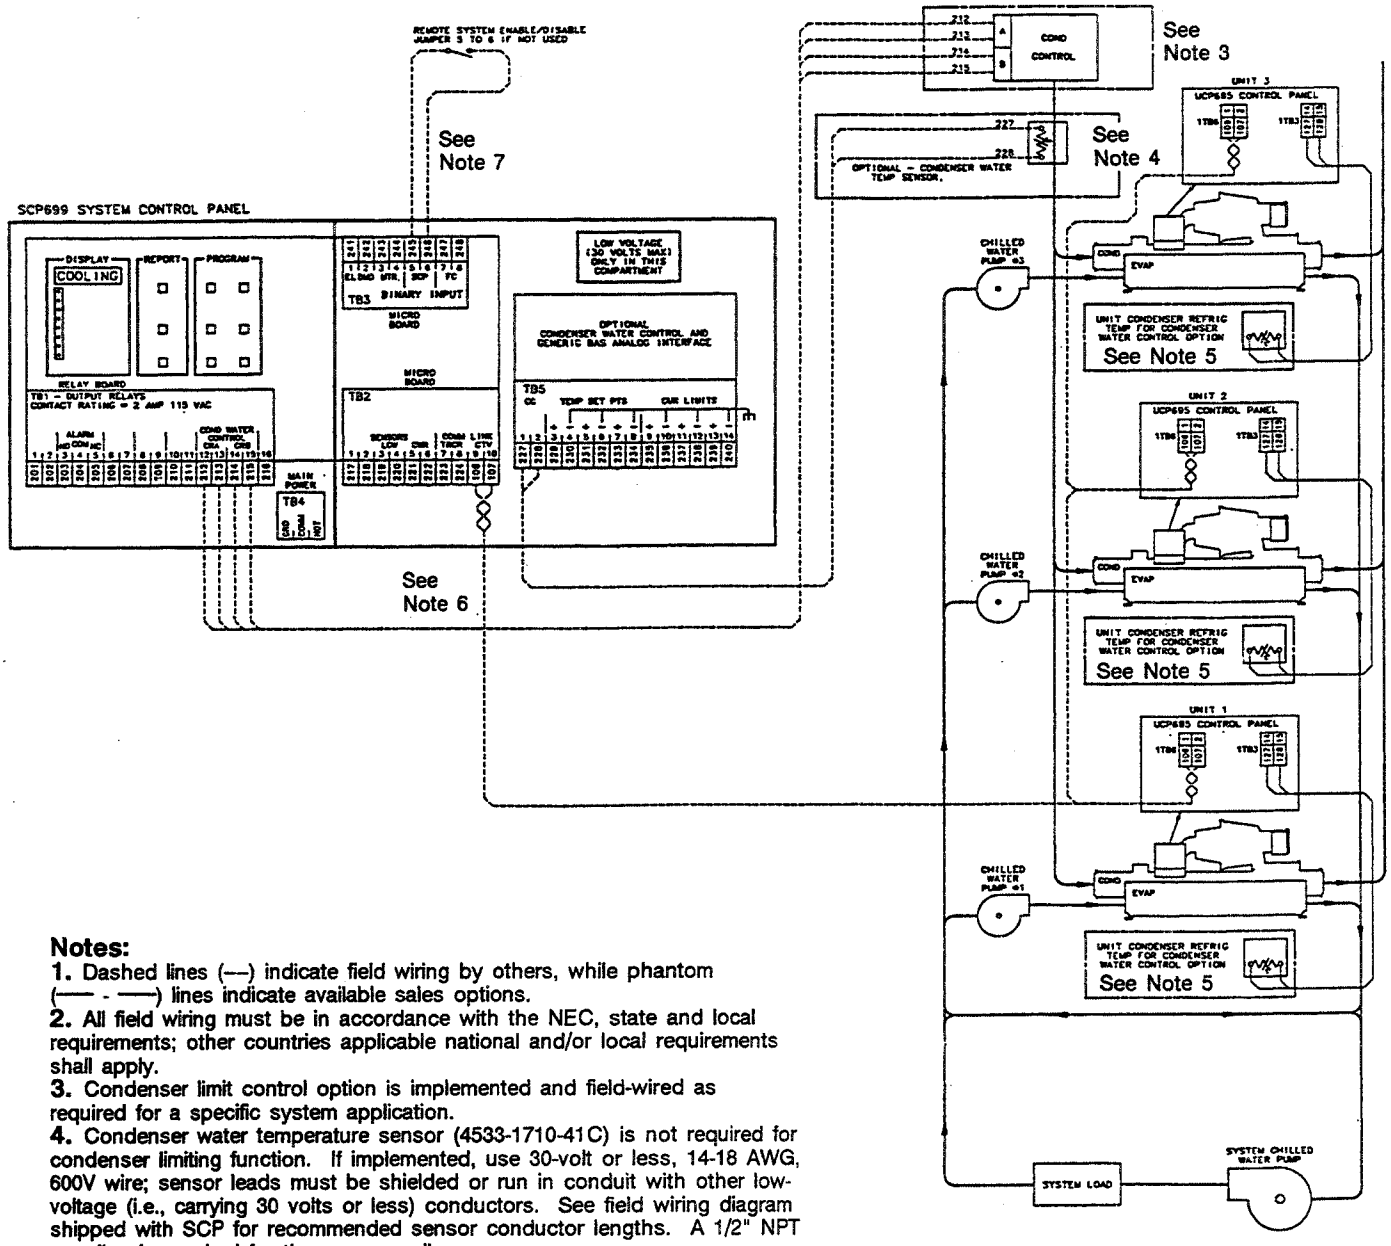
2. Two SCP condenser water control output relays--Relay A (CRA) and Relay B (CRB)--must be wired into the cooling tower control circuit. Connections at the SCP are made at Terminals TB1-12 and -13, and Terminals TB1-14 and -15, respectively. See Figure 31.

3. If desired, a condenser water temperature sensor (i.e., part no. 4533-1710-41C) may be installed in the common entering-condenser water pipe.

Note: The temperature input provided by this sensor is checked twice each second, and is used for display purposes only; it is not a part of the condenser limit control function. (See "'Report' Interface" in the SCP699 Operator Interface section of this manual.)

A "COND. SYS. TEMP = 0" entry appears in the SCP's system reports if the condenser system temperature sensor is not installed.

To enable the condenser limit function once these electrical connections are complete, DIP switch No. 1 on the sideboard (Figure 29) must be set at ON. In addition, 2 rotary switches--also located on the sideboard--must be adjusted to establish the desired "open" and "close" values for the condenser output relays.



Condenser Relays A and B are electrically-isolated, normally-open relay outputs that are "on" when the relay contacts are open. These contacts are designed to close--on a staggered basis--when the measured difference in refrigerant temperature between the evaporator and condenser rises to a specified level; "close" setpoint values for both relays range from 36 F to 64 F in increments of 4 F.

The relay contacts will reopen--again, at staggered levels--when the temperature differential drops sufficiently. Adjustment values for the relay "open" setpoints range from 24 F to 52 F in 4-degree increments. (Minimum condenser relay open time is 2 minutes.)

The SCP monitors the refrigerant temperature differential of each operating chiller, and uses the unit with the lowest differential to determine whether additional cooling tower capacity is required. Keep in mind that, once enabled, the condenser limit function is active whenever any of the system's chillers are running in the powered cooling mode.

Note: Condenser limiting is disabled during free cooling operation, and when all of the chillers are off.

Figure 31
SCP Field Wiring Connections for Condenser Limit Control Option

Notes:

1. Dashed lines (—) indicate field wiring by others, while phantom (—— - ——) lines indicate available sales options.
2. All field wiring must be in accordance with the NEC, state and local requirements; other countries applicable national and/or local requirements shall apply.
3. Condenser limit control option is implemented and field-wired as required for a specific system application.
4. Condenser water temperature sensor (4533-1710-41C) is not required for condenser limiting function. If implemented, use 30-volt or less, 14-18 AWG, 600V wire; sensor leads must be shielded or run in conduit with other low-voltage (i.e., carrying 30 volts or less) conductors. See field wiring diagram shipped with SCP for recommended sensor conductor lengths. A 1/2" NPT coupling is required for the sensor well.
5. Wiring included with sensor(s) (4533-1710-43A); field connection required.
6. Shielded, twisted-pair; use 30-volt or less, 14-18 AWG, 600V wire. Maximum conductor length is 5,000 feet. Do not run in conduit with circuits greater than 30V!
7. Use 30-volt or less, 14-18 AWG, 600V wire, and do not run in conduit with circuits exceeding 30V. Silver contacts (or better) are required; do not use series contacts!

WARNING
Disconnect electrical power supply to prevent injury or death due to electrical shock.

Caution
Use copper conductors only to prevent equipment damage (unless otherwise specified).

Drwg. 4533-1707B

Maintenance and Trouble Analysis

Periodic Maintenance

Weekly Checks

[ ] Review the SCP's "SCHEDULE" and "DAY/TIME" program entries; in particular, check the holiday list and update it as necessary for the upcoming week. (For program setup instructions, see "Program Interface: 'Day/Time' Program" in the SCP699 Operator Interface section of this manual.)

Note: Remember that "DAY/TIME" holiday designations are temporary. A day tagged as a holiday one week will return to its normal operating schedule the following week unless the SCP is programmed otherwise.

[ ] Check the SCP's present clock/calendar readout; correct it, if necessary.

Monthly Checks

[ ] Complete the weekly program entry checks.

[ ] Visually inspect the panel for loose or damaged parts or wiring; also check for any accumulation of dirt or moisture.

[ ] Review the SCP's preformatted System (Status), Schedule, System (Control Parameters), and Chiller reports.

Power Failures

In the event of a power failure an electrical backup system (i.e., capacitor) prevents loss of operator-programmed entries for up to 7 days.

A 9-volt, alkaline, transistor-type battery (field-supplied), mounted within the SCP panel enclosure, backs up the control panel clock function for a maximum of 8 hours. Be sure to replace it after extended power outages, or once annually, to ensure that the internal clock function continues to reflect the present time.

If a power failure occurs and the battery is either dead or not installed, scheduled system operation will not occur at the desired intervals since the SCP's internal clock no longer reflects the actual time of day. (That is, when power is restored, the SCP's clock function–i.e., day and time–will resume operation from the point of power interruption.

Trouble Analysis

Error Detection

As explained under "Report Interface", the SCP is designed to detect and record each of the system-level diagnostic conditions listed below:

- AA System Leaving Water Temperature Sensor
- DF Communications Failure
- D9 Power Loss w/Program Retained
- EF Power Loss w/Program Lost
- FF System Control Module (i.e., SCP self-check indicates a malfunction.)

Its CenTraVac bidirectional communication link (BCL) also allows the SCP to detect abnormal chiller operations and record "latching" diagnostic information from the UCP695 chiller control panels. (See Table 5 in SCP699 Operator Interface.)

Detection of a system-level (other than "D9") or "latching" chiller-level diagnostic condition causes the SCP to flash its alphanumeric display and energize its alarm relay (i.e., unless generic BAS is enabled). The display will continue to blink–and the alarm relay remain energized–until the "Display System Report/Alarm Reset*" button is pressed.

Note: "Latching" chiller diagnostics are defined as abnormal unit operating conditions that prompt the chiller to shut down and require manual reset at the UCP695 control panel before the chiller can be restarted.

Chiller-level diagnostic conditions are determined and reported by the SCP based on the following criteria:

1. If any chiller fails to respond to 2 consecutive communication attempts, the SCP considers that chiller to be nonexistent. When this occurs, the SCP alarms this loss of chiller communication with a DF diagnostic.

2. Operating parameters from any chiller that fails to communicate are not included in any of the SCP's preformatted status report displays.

3. All "latching" unit diagnostic conditions are reported at the SCP.

Note: While "latching" unit diagnostics are reported at the SCP when the generic BAS option is enabled, they are not alarmed.

If the chiller reports that the error or diagnostic condition no longer exists, the SCP considers it to be ready to operate.

The last entry of the System (Status) Report advises the most recent diagnostic condition detected and recorded by the SCP at the system or chiller level.

Once a system diagnostic is alarmed, it is important to remember that the SCP will not record a subsequent system error until the "Display System Report/Alarm Reset*" button is pressed.

Further, the SCP will not alarm a diagnostic condition with an error code that is the same as the last error code recorded. For example, if the last diagnostic code recorded in the SCP's memory is "DF" (i.e., communications failure)–and the SCP detects another communications failure, it will neither flash its display nor energize its alarm relay.

However, notice that the original "DF" error code will remain in the system status report either until: (1) another, different diagnostic (e.g., D9/power loss w/program retained) is detected and recorded; or, (2) the diagnostic register is cleared.

To remove the last recorded diagnostic code from the SCP's memory, simply press the "Display System Report/Alarm Reset*" key and hold it down while the system status report is displayed. After the "SYSTEM (and each UNIT) DIAG = " entry appears, the SCP generates a "CLEARED" message. (The current system operating status then returns to the display.)

Note: For your reference, a label listing the condition codes for system and unit diagnostics is affixed to the side of the SCP panel enclosure.

Keep in mind that the SCP will not be able to start a chiller if:

1. that particular unit is presently in a "latching" diagnostic mode. (In this situation, the SCP will attempt to start the next chiller in the start-up rotation order.)

2. that unit remains in a "nonlatching" diagnostic mode (i.e., b d9, b E2, b Ed or b F7; see Table 5) for 10 minutes. (At the end of this period, the SCP will attempt to start the next chiller in the start-up rotation order.)

3. that unit is in the restart inhibit mode (A 70). (The SCP will wait for the restart inhibit period to elapse rather than attempt to start the next chiller.)

Troubleshooting Charts

Note: Troubleshooting charts are provided solely as a guide for determining the cause of a mechanical failure or equipment malfunction. When operational problems do occur, be sure to contact a qualified service organization to ensure proper diagnosis and equipment repair.

Organization of the following troubleshooting chart is based on the possible 2-character system diagnostic condition codes that may be alarmed and displayed in the SCP's System (Status) Report at one time or another. Notice that these codes are arranged alphabetically, and that each is followed by a brief description of the diagnostic condition represented, along with the suggested action(s) for correcting the problem.

Note: When the SCP is "powered up", the "READY" system status message should appear on the alphanumeric display for at least 40 seconds unless a key is pressed. If any other message appears (e.g., "BAD RAM", "BAD ROM", "BAD MICRO", etc.), contact a qualified service technician.

Troubleshooting charts for chiller-level diagnostic conditions are included in the operation/maintenance manual that shipped with each CenTraVac unit. However, in the event that a chiller does not seem to function properly, always:

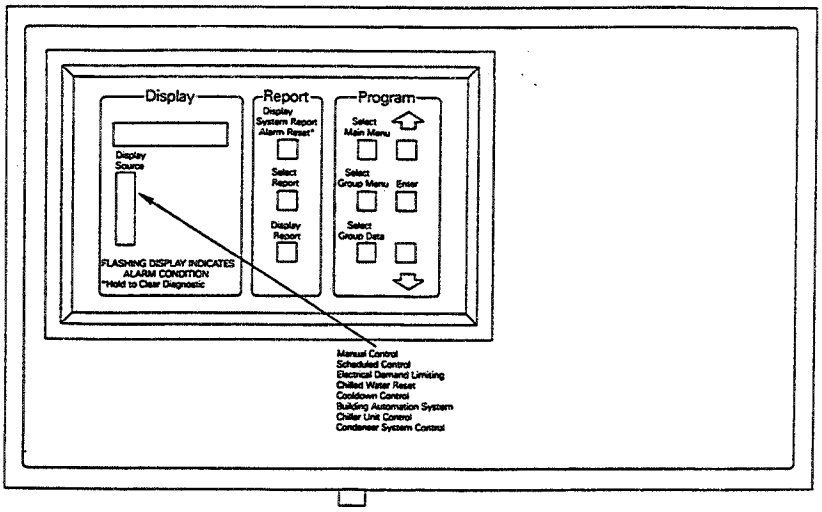
1. Ensure that the chiller switch (on the UCP695 control panel) is set at "Auto/Remote".

2. Check the SCP's chiller report for that unit. (This will verify that the unit is in communication with the SCP.)

3. Program manual unit chilled water and current limit setpoints at the SCP. (Use the SCP's "CHILLER" program menu.)

To verify that these commands were received at the UCP695 panel, check the UCP's status indicator lights when each setpoint is displayed at the UCP. If the setpoints were received, the "Remote Chilled Water Setpoint" and "Remote Current Limit Setpoint" lights should illuminate. (The pump relay(s) should then energize, and the unit should start.)

4. Single-Chiller System Applications Only. If the SCP's system leaving chilled water temperature sensor is not installed, verify that the chiller's address is "1". (See "UCP695 DIP Switch Setup" in the Start-Up section of this manual.)



WARNING: To prevent injury or death due to electrical shock, lock power supply disconnect open before removing SCP panel enclosure. It may be necessary to open several disconnects to remove all connected power from the SCP.

Troubleshooting Chart

Code	System Diagnostic Description	Recommended Action
AA	System Leaving Chilled Water Temperature Sensor	Contact a qualified service oganization; or, Check sensor connections at: (1) SCP Terminals TB2-3 and TB2-4; (2) sensor; and (3) intermediate points for open, shorted or loose connections. Repair wiring connections or replace sensor, as necessary. Note: This diagnostic only occurs if more than 1 chiller is connected to the SCP.
DF	Communications Failure	**WARNING: To prevent injury or death due to electrical shock, lock power supply disconnect open before removing SCP panel enclosure. It may be necessary to open several disconnects to remove all connected power from the SCP.** Secure all chillers, chilled water pumps, and connected equipment. Remove power from the UCP695 chiller control panels; then disconnect power from the SCP. Wait 1 minute; then restore power to the SCP and UCP695 control panels. If the "DF" diagnostic persists, contact a qualified service organization.
D9	Power Loss w/Program Retained	Clear the diagnostic. If the cumulative length of power outages exceeds 6 hours, replace the battery backup. Note: The battery's charge is depleted with each successive power loss; it is not recharged when power is restored to the SCP.
EF	Power Loss w/Program Lost	Clear the diagnostic and reprogram the SCP.
FF	System Control Module	**WARNING: To prevent injury or death due to electrical shock, lock power supply disconnect open before removing SCP panel enclosure. It may be necessary to open several disconnects to remove all connected power from the SCP.** Secure all chillers, chilled water pumps, and connected equipment. Remove power from the UCP695 chiller control panels; then disconnect power from the SCP. Wait 1 minute; then restore power to the SCP and UCP695 control panels. If the "FF" diagnostic persists, contact a qualified service organization.

Note: This troubleshooting chart is provided solely as a guide for determining the cause of a mechanical failure or equipment malfunction. When operational problems do occur, contact a qualified service organization to ensure proper diagnosis and equipment repair.

ST-MNL-5 "UCP2 – The Operator's Perspective"

INTRODUCTION

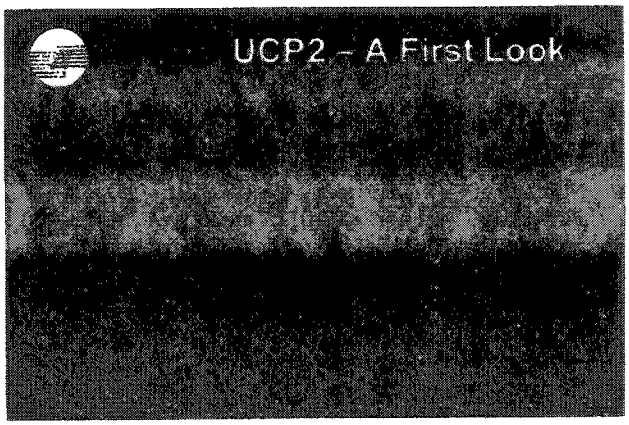

Figure 1

(Figure 1) The purpose of this manual is to introduce technicians and building owner operator personnel to the construction and operation of the Trane "UCP2" control system for heavy refrigeration chillers. This control system employs Trane's Enhanced Adaptive Control™ technology which has evolved from the Adaptive Control™ strategies used by the earlier UCP-695 control system.

UCP2 is not the first microcomputer-based control system used by Trane. It is, however, the most "intelligent" system available so far. This system can adapt to changing conditions in the HVAC system to keep a chiller running at "best" conditions and keep it producing chilled water in situations that would likely result in a shutdown using many other control systems.

The UCP2 system with Enhanced Adaptive Control™ is utilized on several Trane product lines. This course covers model CVHE and CVHF centrifugal chillers and RTHB helical-rotary chillers. These chillers range in capacity from 130 to 1,250 tons.

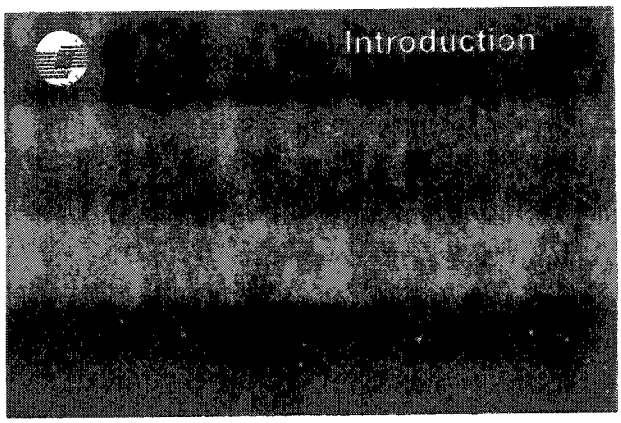

Figure 2

(Figure 2) This manual will show how Trane's UCP2, using Enhanced Adaptive Control™, has added flexibility, reliability and improved system performance to what was already the best chiller control system in the industry. It will show the overall physical organization of UCP2 system components and explain their functions. Finally, this manual will teach the reader how to use the UCP2 operator panel to access and utilize the unprecedented amount of data that UCP2 makes available.

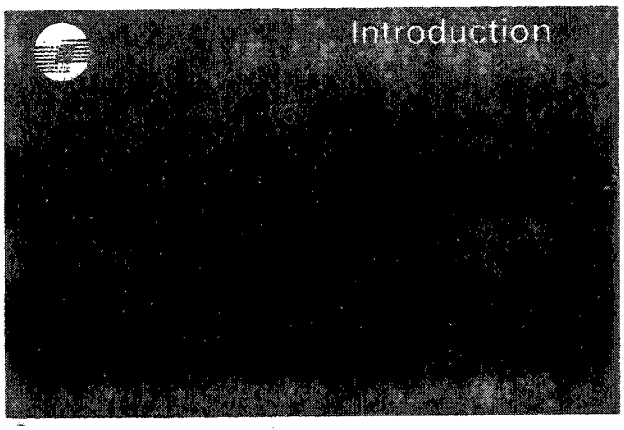

Figure 3

(Figure 3) The first generation Trane microprocessor chiller control system was officially designated UCP-695, although many people referred to it as the 'micro panel' because it was the first microprocessor control used on large centrifugal and helical rotary chillers. To simplify matters, this manual will refer to the older UCP-695 as the 'UCP1' and to the current system as 'UCP2'. This manual will examine the UCP2 control, first as an overall system, then its individual components. It will discuss the clear language display or CLD, which is the operator control panel for the system, and explain the benefits of the information this control can provide the chiller operator.

SYSTEM OVERVIEW

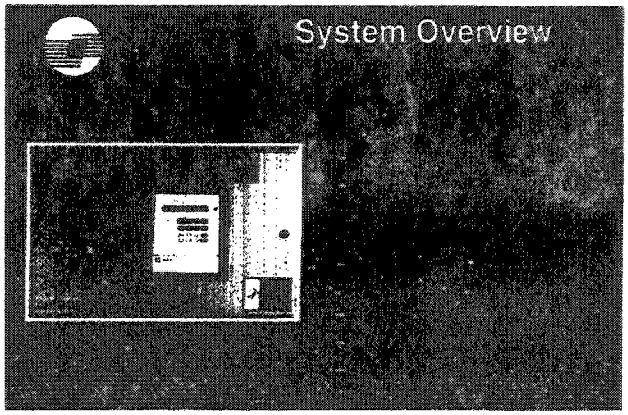

Figure 4

(Figure 4) UCP2 is the 2nd-generation microcomputer control system for Trane heavy-refrigeration water chillers. The acronym UCP2 simply stands for "unit control panel number two". UCP2 refers to the panel itself, all internal components and all peripheral devices (sensors, relays, communication links, etc.) needed for its proper operation. Some of these devices are not even located inside the panel.

UCP2 is the 'brain' of the chiller system. It evolved from UCP1 through customer feedback about what more they want a unit-level chiller control system to do. What they told us is that "a **good** chiller control system should":

- Produce chilled water at setpoint when needed
- Protect the chiller
- Keep the chiller on-line as long as possible during adverse operating conditions (This is where the term "Adaptive Control" comes in. The control system adapts chiller operation to changing conditions in the system to keep it performing.)
- Detect refrigerant loss - both long term leakage and catastrophic release

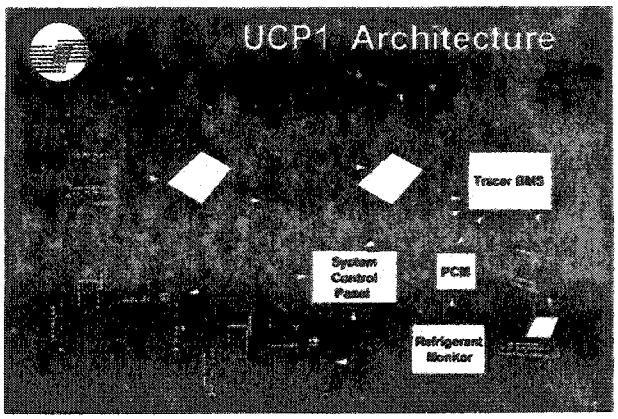

Figure 5

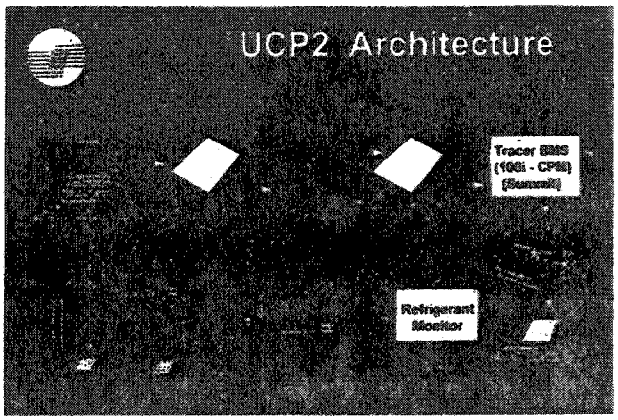

Figure 6

(Figure 5) (Figure 6) These two figures make a few basic system-level comparisons of UCP1 and the new UCP2:

UCP1 required a Trane SCP (System Control Panel) in order to communicate with higher-level devices such as the Trane Tracer or other building management systems (BMS). UCP2 communicates directly with the building management system.

UCP2 receives input directly from same-level or lower-level devices and reports to higher-level devices, such as a Tracer, through a direct communication link (no SCP needed). Also, UCP2 is backward and forward-compatible with all generations of Tracer equipment.

With UCP1, a programmable control module (PCM) was needed to allow device such as a equipment room refrigerant vapor level monitors to communicate with a Tracer or another BMS. UCP2 can accept equipment room refrigerant concentration level data directly from a refrigerant monitor and report the data back to the system level BMS.

Using UCP1, printed reports of chiller activity or refrigerant monitor data could only be generated at the system (BMS) level. The UCP2 can output reports directly to a printer within 50 feet of the chiller and/or to a printer at system level (Tracer) at a remote location.

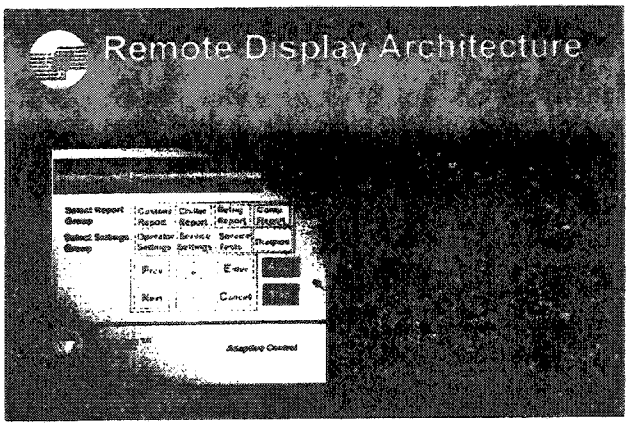

Figure 7

(Figure 7) In addition to its enhanced unit and system-level features, a "remote-control" version of the UCP2 operator panel is available that will control the chiller from as far away as 1,500 feet. This single low-cost panel will also control up to three additional UCP2-equipped chillers.

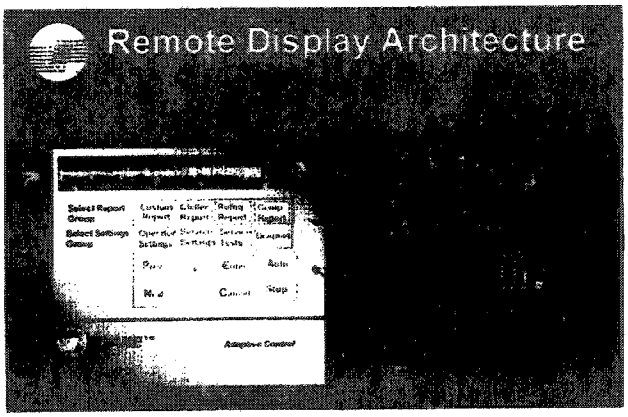

Figure 8

(Figure 8) The remote display can even communicate with different types of chillers, as long as they are equipped with a Trane UCP2 control system.

Remote control of multiple chillers is discussed in more detail later in this manual.

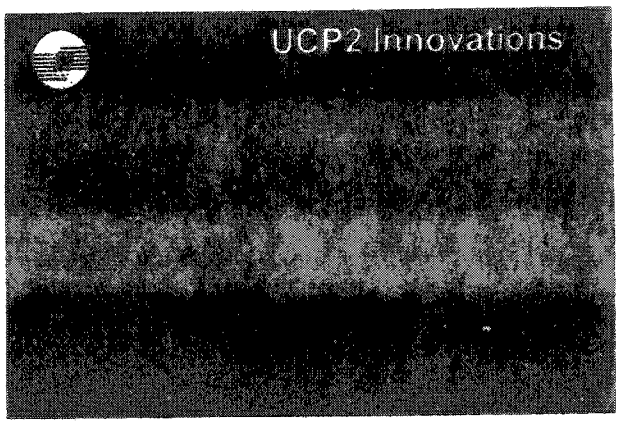

Figure 9

(Figure 9) The text items in these figures are color-coded. Yellow indicates standard equipment or features, while optional items are shown in aqua.

The UCP2 system design is modular by function. The chiller can be equipped with options that customize its control for the building system it is applied to. Also, the control system can be upgraded in the future as needed to meet changing building system or equipment room requirements. This also results in lower replacement parts costs, since individual modules are less expensive to replace than the old all-in-one UCM.

All data acquisition and chiller control are accomplished at the UCP2 operator control panel (i.e., clear language display). Information provided by the display is presented in clear language (i.e., English, French, German, etc.) rather than in code as with UCP1.

As previously mentioned, UCP1 needed a System Control Panel (SCP) to control chillers remotely or to access multiple chillers. UCP2 can be controlled by an inexpensive remote display panel or can talk directly to a Tracer.

Many features that were costly options for UCP1 are standard on UCP2. All that is required is that they be enabled from a menu. Most other optional features can be provided with the purchase of only one additional electronic module.

UCP2 brings a higher level of motor and compressor protection, including improved motor winding and oil pressure protection systems and simplified wiring between the motor terminal box and remote-mounted starter panels.

UCP2 has more precise capacity control. Stepper actuator motors for guide vanes and expansion valves do not use limit switches. The control system knows chiller loading condition at all times.

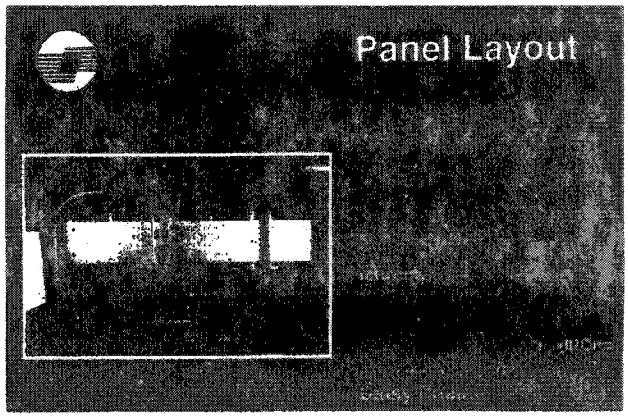

Figure 10

(Figure 10) The UCP2 panel will contain anywhere from four to eight electronic modules, depending on the type of chiller and features ordered. One module is mounted in the motor starter panel and one in the purge control panel on centrifugal chillers.

The Interprocessor Communications Link (twisted-pair wire) provides the communication path between modules. The Purifier Purge™ system used on low pressure chillers is also controlled and monitored at the UCP2 display panel.

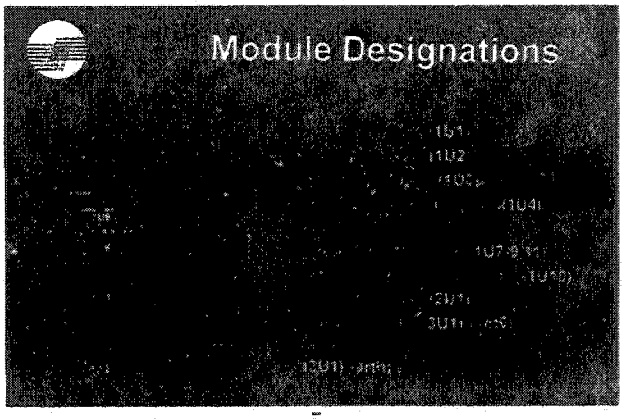

Figure 11

(Figure 11) The individual UCP2 electronic modules mounted in the panel are:

1U1 = Chiller Module;
1U2 = Circuit Module;
1U3 = Stepper Module;
1U4 = Clear Language Display;
1U5 = Options Module;
1U7 = Printer Interface Module;
1U8 = Tracer COM3 Interface;
1U9 = IPC Buffer;
1U10 = Input/Output Module;
1U11 = Tracer COM4 Interface

The clear language display (1U4) is mounted in the control panel door so that it is visible with panel door closed. All of the modules except 2U1 (the starter module) and 3U1 (the purge module) are located inside the UCP.

When RTHB units use a remote-mounted starter, a 3U1 module is mounted inside the motor terminal junction box on the chiller. On the RTHB, this 3U1 module is actually a phase sequence monitor for the compressor motor instead of a purge control device.

This is used because making the wrong electrical connections at the RTHB motor will cause reverse rotation of the compressor, resulting in immediate, catastrophic compressor damage.

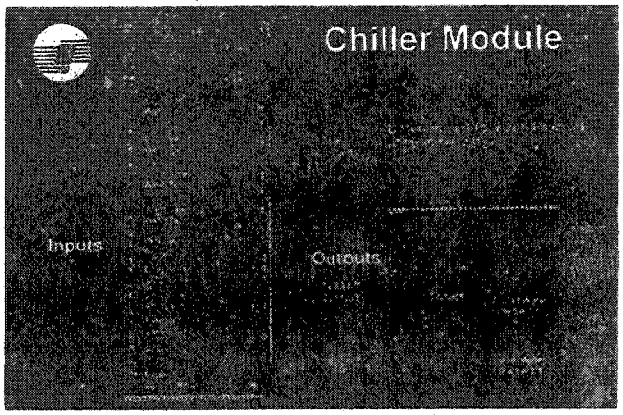

Figure 12

(Figure 12) The chiller module (1U1) is the "master module", collecting data, status conditions, diagnostic information, etc. from the other modules (over the IPC link) from sensors and remote contacts and in turn, communicating commands to other modules.

The chiller module performs leaving water temperature and limit control algorithms, trading off chiller capacity against various "limits" that the chiller may be working against.

It checks for valid setpoints and identifies the chiller type for the other modules. 1U1 also maintains all stored setpoints in non-volatile memory in the event of a power loss.

Chiller module electrical inputs and outputs are shown on the chiller control system wiring schematics.

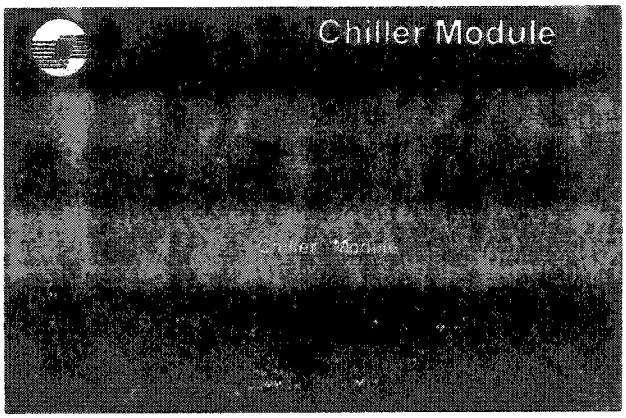

Figure 13

(Figure 13) During operation, the chiller module continuously "scans" the various modules for information over the IPC link. It completes a scan of the system about every two seconds.

This scan includes communication with any remote display used in the system and sending data to the local printer.

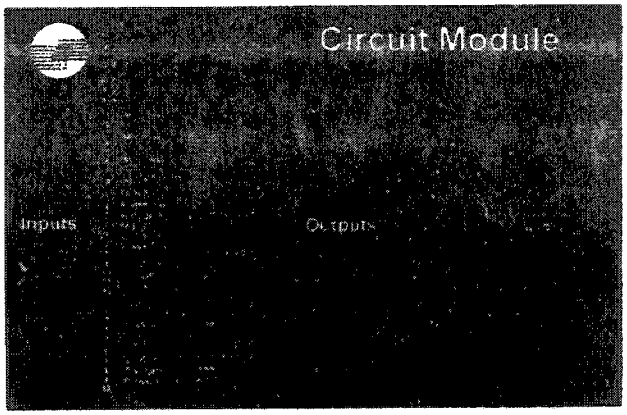

Figure 14

(Figure 14) The circuit module is assigned functions associated with compressor motor protection, the chiller lubrication system and refrigerant monitoring.

Circuit module electrical inputs and outputs are shown on the chiller control system wiring schematics.

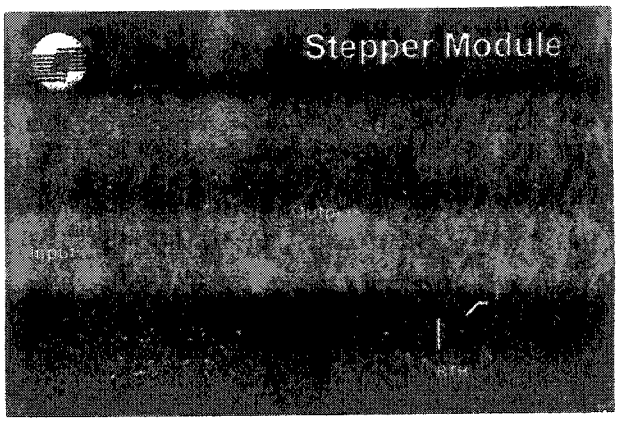

Figure 15

(Figure 15) The main function of the stepper module (1U3) is to drive the inlet guide vane stepper motor (CTV) or electronic expansion valve stepper motor (RTHB), in response to signals received from chiller module 1U1. This module also receives feedback on the actual open/closed position of the inlet guide vanes or the electronic expansion valve. The circuit module also monitors evaporator and condenser saturated refrigerant temperature and provides inputs for the discharge temperature and bearing temperature sensors. The module electrical inputs and outputs are shown on the chiller control system wiring schematics.

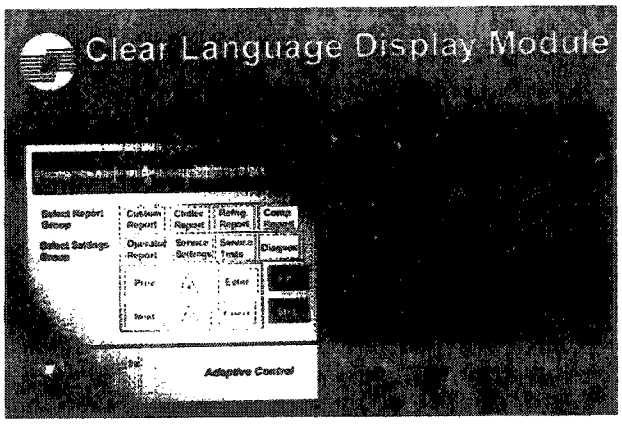

Figure 16

(Figure 16) The clear language display module, or CLD, is the operator panel for the UCP2 control system. It is the bridge between man and machine. Mounted in the control panel door, the CLD is viewed from the front of the panel. The module allows the operator to monitor system conditions as it displays chiller data, including chiller operating status, setpoints, operating conditions, unit configuration, purge conditions, service and diagnostic settings on the LCD screen. The operator controls chiller operation by pressing combinations of the keys provided on the panel. Electrical inputs and outputs are shown on the chiller wiring schematics.

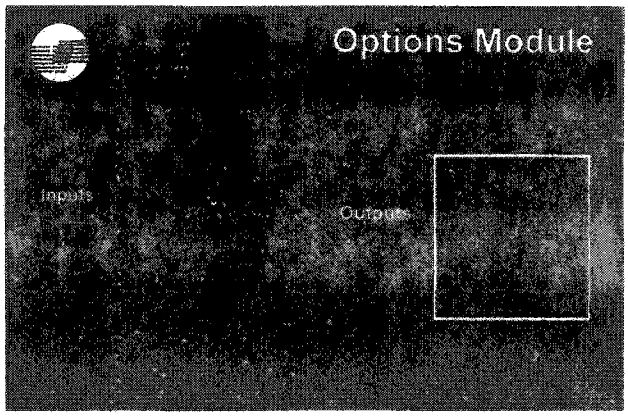

Figure 17

(Figure 17) As its name implies, the options module (1U5) provides the control or interface requirements for many of the options available with the UCP2. Some features provided by this module include ice-making, heat recovery, free cooling, head relief request and eternal chilled water setpoint, to name a few.

The options module electrical inputs and outputs are shown on the chiller control system wiring schematics.

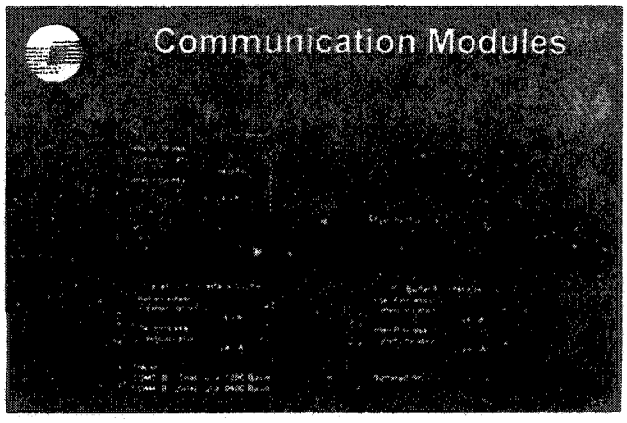

Figure 18

(Figure 18) The optional printer interface module (1U7) allows a preformatted chiller log to be output at a printer right at the chiller location. The UCP2 can be programmed using the CLD to print a chiller log on command, at the time of a diagnostic, or on a periodic basis.

There are two optional Tracer communication interfaces available, depending on which Tracer it will be communicating with. The Tracer COM3 interface module (1U8) provides an isolated, 1200-baud, bi-directional serial communication link to a Tracer 100/ Tracer i/Chiller Plant Manager or a generic BMS panel.

The Tracer COM4 interface module (1U11) provides a non-isolated, 9600-baud, bi-directional serial communication link to the Tracer Summit or Tracer i.

The IPC Buffer Module (1U9) is the communication interface needed between the UCP2 and any Remote CLD. If a remote panel is not used, this module is not required. It must be provided on any chiller (maximum of four) talking to a Remote CLD.

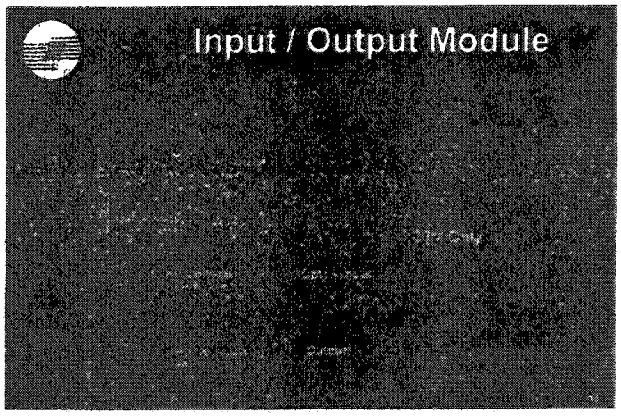

Figure 19

(Figure 19) The Input/Output module, (1U10) is provided only when a centrifugal chiller is equipped with the hot gas bypass (HGBP) option. This module operates the hot gas bypass valve on CVHE and CVHF units in response to signals from stepper module 1U3. The module also receives input on HGBP valve position from the HGBP valve end switch.

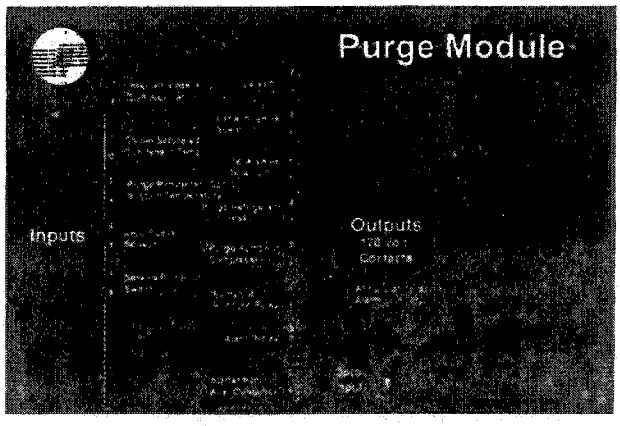

Figure 20

(Figure 20) The purge module (3U1) is provided with the Trane Model PGRC Purifier Purge used on CVHE and CVHF chillers. It is located in the purge control panel at the purge location. It provides all inputs and outputs for the UCP2 to control purge operation.

Purge module electrical inputs and outputs are shown on the chiller control system wiring schematics.

IMPORTANT: Although the RTHB chiller does not have a purge, it does utilize a device designated as 3U1 in certain cases. When the RTHB chiller uses a remote starter, a phase-sequence monitor (3U1) is mounted in the unit-mounted motor terminal junction box.

Proper phase-sequencing is critical to prevent reverse compressor rotation which will cause extensive damage almost instantly. Although the starter module provides this protection, if the starter is remotely mounted, it is possible to cross leads from the starter to the compressor motor.

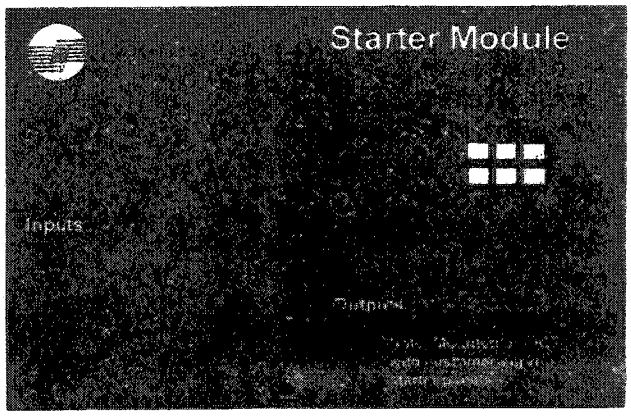

Figure 21

(Figure 21) The starter module (2U1) is present in all Trane-provided starter panels, whether unit-mounted or remote.

For centrifugal chillers, if no Trane starter is provided and the customer is providing the starter instead, 2U1 is mounted in an extension of the unit control panel. It is still designated as 2U1, however. For RTHB units, 2U1 is always located in the starter panel.

2U1 controls the starter when starting, running and stopping the compressor motor and provides an interface to all types of starters and AFD's (adjustable frequency drives). 2U1 provides compressor motor protection for running overload, phase reversal, phase loss, phase unbalance and momentary power loss.

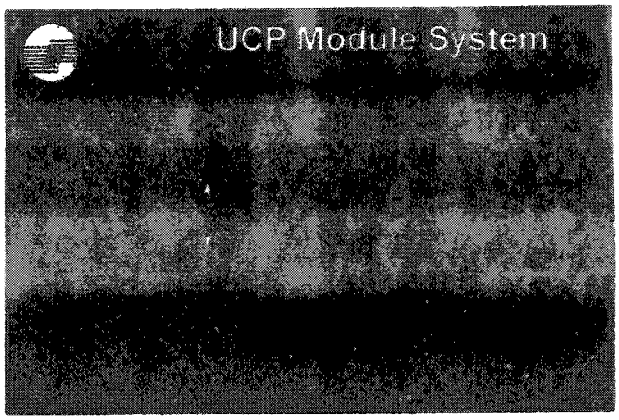

Figure 22

(Figure 22) This figure provides a summary of module organization and function. It also identifies their communication hierarchy (i.e., BMS level, System level, Unit level).

All UCP2 modules are at unit-level, either in the UCP2 panel, in the purge panel, starter panel or in the immediate vicinity of the chiller (i.e., a printer). A printer could also be located at the Tracer or other BMS level.

A remote clear language display would be considered to be located at system (i.e., chilled water system) level.

A Tracer or any other building management system and their communication links to unit control modules (UCMs) on HVAC or other types of equipment are on the BMS or building level. In addition to chillers, the BMS could be controlling air handlers, VAV systems, lighting and electrical equipment, etc.

CRUISING THE MENU

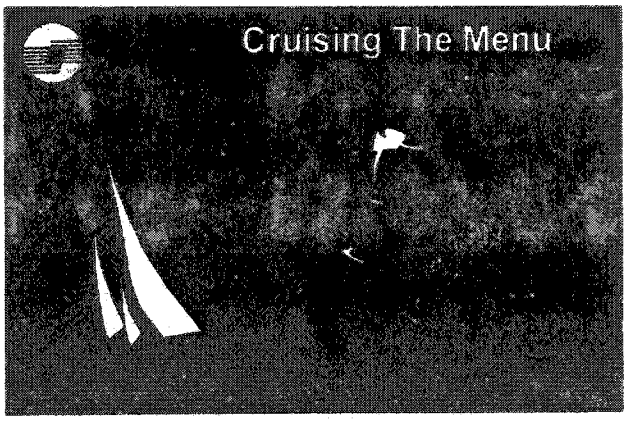

Figure 23

(Figure 23) The next portion of this manual examines the UCP2 menu structure and the functions of the clear language display and operator control keypad.

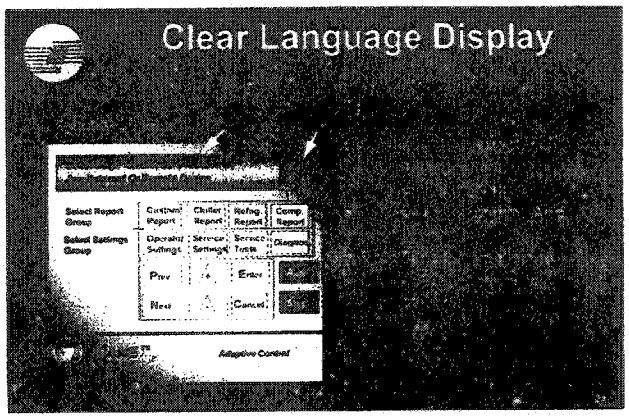

Figure 24

(Figure 24) The liquid crystal display screen and the sixteen-key membrane keypad together are referred to as the "Clear Language Display" or abbreviated as the "CLD". The CLD is mounted in the door panel of the UCP2. It is the designated as the "local" CLD. An identical, remote CLD is available also.

The chiller is controlled by pressing appropriate key combinations on the keypad. It provides access to control setpoints, and chiller setup information. All settings and adjustments are made from the menus in the CLD.

The two-line, forty-character liquid crystal display (LCD) screen will display the chiller data. The display screen backlights anytime a key is pressed. Chiller operators will be able to choose their preference of seven languages to display this information.

An "Alarm" light emitting diode (LED) is also located on the face of the CLD. The LED will flash if a diagnostic condition has locked out chiller operation that requires manual reset at the chiller (local) CLD. The LED will glow steadily when the control is in "Service Test" mode. This indicates that a service technician is running a service test procedure from the Service Tests menu.

Keyboard use can be locked out at the Service Setup Menu. If all keys are non-functional, contact a Trane service technician.

Note: Use this feature with caution. Locking out the keypad also prevents the operator from stopping chiller operation at the Stop key.

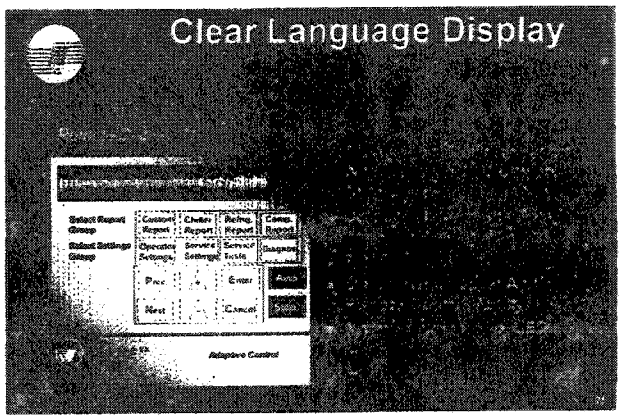

Figure 25

(Figure 25) As mentioned previously, a remote CLD is available that will communicate with and control any UCP2-based chiller by uploading and downloading data from the chiller module. The chiller(s) can be controlled at the local (chiller) CLD or from the remote CLD at any time.

The remote CLD will perform all of the functions of the local CLD except reset of certain latching diagnostics. The remote CLD can be located up to 1,500 feet away from the chiller(s).

All variable information such as temperatures and pressures, are updated on the screen every two seconds while it is being displayed.

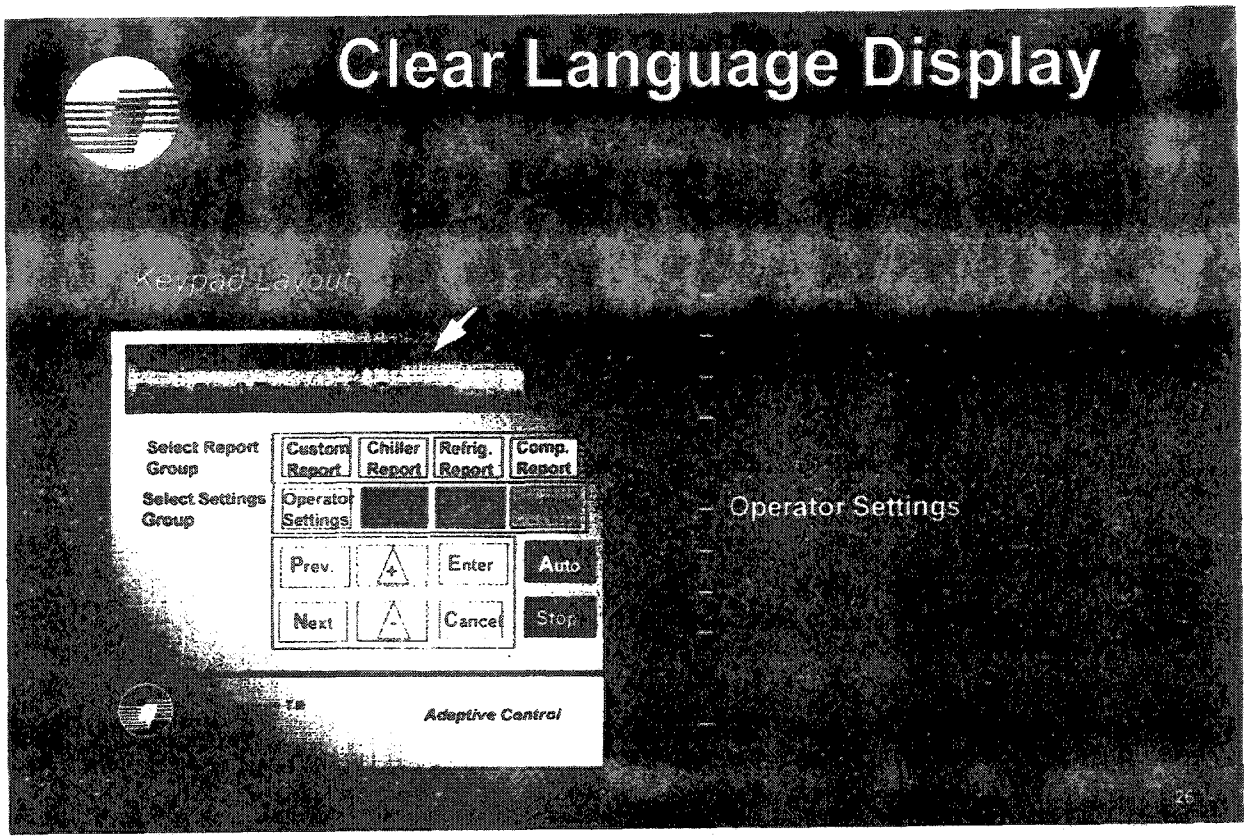

Figure 26

(Figure 26) The CLD displays all chiller operating data and provides access to controls, setpoints and setup and diagnostic information. The keys on the CLD keypad are arranged as follows:

REPORT GROUP KEYS

The top row of four keys are the Report Group Keys. Pressing one of these keys allows the operator or technician to view one of four "reports" available from the UCP2. These reports contain information on chiller operation, system setpoints and control settings. Access to these keys is usually not protected by a password. This allows the viewer to look at the data available but does not allow setpoints or control settings to be changed.

Custom Report Key

The Custom Report contains data that has been specifically selected to appear in this report. It can contain up to twenty items taken from the chiller, refrigerant and compressor reports.

Chiller Report Key

The Chiller Report contains current chiller operating status information, water temperatures and operating setpoints.

Refrigerant Report Key

The Refrigerant Report contains refrigerant-related data, including pressures, temperatures, purge and equipment room refrigerant monitor data.

Compressor Report Key

The Compressor Report contains all available compressor data, including total operating time, number of starts, oil system data, inlet guide vane position (CTV), bearing temperatures (CTV), and electrical data.

SETTINGS GROUP KEYS

The second row of four keys are the Settings Group Keys. Pressing one of these keys allows the operator or technician to not only view, but change chiller operating setpoints, and control and setup settings.

Operator Settings Key

Pressing the Operator Settings key accesses the Operator Settings menu, where the user may view and change operator-level chiller and purge operating setpoints.

Service Settings Key

Pressing the Service Settings key accesses the Service Settings menu where the user may view and change technician-level field setup data and factory chiller configuration settings.

Service Tests Key

Pressing the Service Tests key accesses the Service Tests menu which can be used by a technician to test or override chiller operation to conduct operating tests of certain chiller components.

Diagnostics Key

Pressing the Diagnostics key allows the technician to view a log of historical and active diagnostics and also allows the chiller operator to clear a diagnostic lockout condition and restore normal chiller operation.

DATA CONTROL KEYS

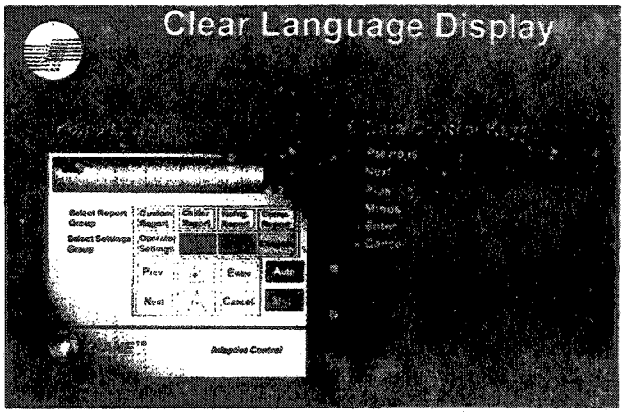

Figure 27

(Figure 27) The six Data Control keys are grouped together in the bottom two rows of the keypad. These keys are the Previous & Next, Plus & Minus and Enter & Cancel keys. They are used to manipulate the information that appears on the CLD screen.

Previous & Next Keys

These keys are used to scroll forward or backward through report items or menus. The screen will wrap back to the top or bottom of the menu when the end or beginning of the group is reached.

Plus & Minus Keys

Use these keys to change setpoints and control settings up (+) or down (-). This can only be done when viewing a "settings" menu where the second line of the screen is "Press (+) (-) to Change Setting".

Enter & Cancel Keys

Use the Enter key to enter a new setpoint or control setting into memory once it has been changed. Enter must be pressed to store any new setting into memory. Press Cancel if a new setting is inadvertently entered but should not be stored into memory. Again, this can only be done when in a "Settings" group or menu.

AUTO KEY

Pressing the AUTO key selects "automatic" chiller operation. This allows the chiller to start on a call for cooling at any time, based on the current differential-to-start setpoint. When in "auto" mode, the chiller stops when cooling load is satisfied. The chilled water pump continues to run, however, and the chiller module monitors leaving chilled water temperature to restart the chiller on a demand for cooling.

STOP KEY

Pressing the STOP key selects "manual" stop of chiller operation. The chiller still goes through its normal shutdown sequence, except that the chilled water pump stops also.

IMPORTANT: Pressing STOP two times within 5 seconds initiates an "emergency stop". The stop sequence is the same as a normal manual stop except that the compressor motor stops immediately and the chiller is not unloaded as it is during the normal stop sequence.

REPORTS

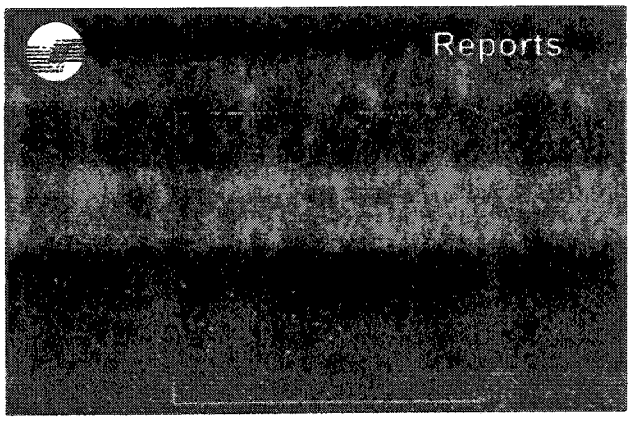

Figure 28

(Figure 28) As discussed previously, reports allow the chiller operator to view chiller operating conditions, settings and setpoints and provides a means of generating a report of selected information. There are four reports available. They are:

Custom Report
Chiller Report
Refrigerant Report
Compressor Report

Each individual point of any report can be viewed at the CLD at any time by pressing the desired report group key and using the Next and Previous keys to scroll through the report items.

The remainder of this manual will discuss the items contained in each of these reports and demonstrate how to access this information using the UCP2 clear language display.

Custom Report

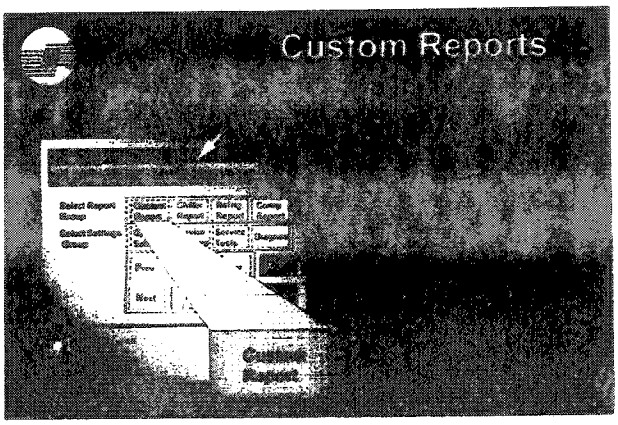

Figure 29

(Figure 29) The chiller operator can create a "Custom Report" by selecting individual points from the Chiller, Refrigerant and Compressor Reports. In this manner, data that is critical to the specific job can be viewed in one menu.

When the Custom Report key is pressed, the report heading will display as shown in Figure 29. If no items have been selected for this report, pressing Next or Previous will display:

"No Items Are Selected For Custom Report - See Operator's Manual to Select Entries"

To add an item to the Custom Report, enter the report that contains the item and using Next or Previous, scroll to the item. While viewing the item, press the (+) key. The item will be added to the Custom Report.

To view the item in the Custom Report, press the Custom Report key and scroll to the item. To remove an item from the Custom Report, view the item in the Custom Report and press the (-) key.

The Custom Report can contain up to 20 items. Use the Next and Previous keys to scroll through the items. If an attempt is made to add a 21st item to the report the display will indicate:

"Custom Report is Full, Report Not Added"

If an attempt is made to add an item already in the report, the display will indicate:

"Report Already in Custom Menu"

Chiller Report

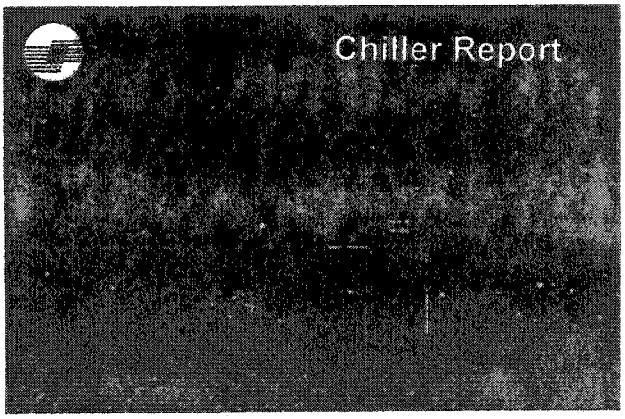

Figure 30

(Figure 30) The chiller report contains chiller operating data and setpoints such as current chiller operating mode and status, water temperatures and operating setpoints.

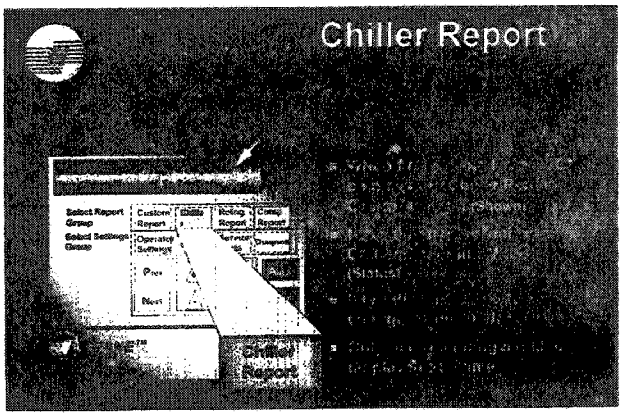

Figure 31

(Figure 31) The operator can view the chiller report by pressing the "Chiller Report" key. This will display the report heading:

"Chiller Status, Wtr Temps & Setpts - Press (Next) (Previous) To Continue"

The next screen will display the chiller operating "Mode" on one or both lines. There are many operating modes available. Examples of operating modes are:

"Auto–
Waiting For Evaporator Water Flow"
- or -
"Unit Is Running – Capacity Limited By High Condenser Pressure"

The operating mode message will indicate if the chiller is stopped, starting, running full load, running inhibited, locked out on a diagnostic condition, in free cooling, waiting for water flows, in hot gas bypass, ice making, shutting down, in extended unloading (RTHB), etc.

Continuing to press the Next key will scroll though the remaining chiller report items; system water temperatures and active chiller operating setpoints.

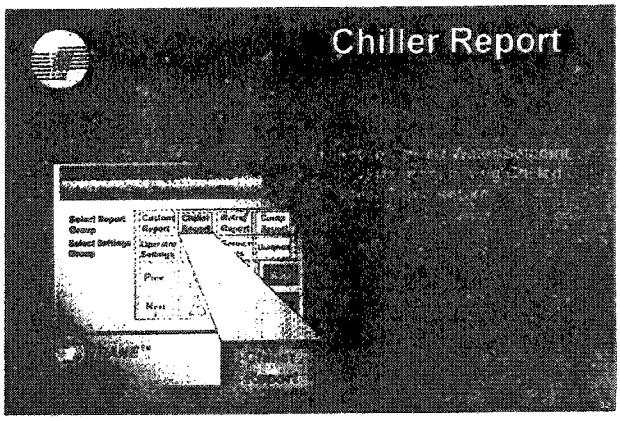

Figure 32

(Figure 32) The bulleted text items that are shown in Figures 32 through 51 are color-coded as follows:

- The items presented as yellow text are standard UCP2 features.
- Items presented as aqua text are options available with UCP2.

Only one of the items in Figure 32 can be displayed, depending upon chiller operating mode. Even if the chiller has one or both of the options (aqua) shown here, only one of these items can be displayed, depending on chiller operating mode.

When the chiller is in normal cooling operation, the "Active Chilled Water Setpoint / Evap. Leaving Water Temp." screen will be displayed. Setpoint temperatures are shown in degrees Fahrenheit or Celsius, depending on whether English or Metric (SI) display units have been selected from the Service Settings menu.

If the chiller is in "ice-making" or "ice-making complete" mode, then the "Active Ice Termination Setpoint / Evaporator Return Water Temperature" display will appear instead of "Active Chilled Water Setpoint / Evap. Leaving Water Temp."

If the chiller is in "Hot Water Control" mode, "Active Hot Water Setpoint / Condenser Entering Water Temperature" is displayed instead of "Active Chilled Water Setpoint / Evap. Leaving Water Temp."

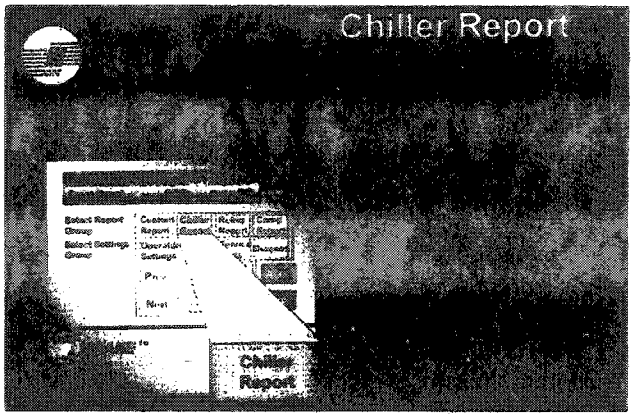

Figure 33

(Figure 33) At this point, the screen will display one of two items, depending upon current chiller operating mode: The active chilled water setpoint (CWS) is displayed on the first line, the setting source and the setting source setpoint on the second line;

or,

The active ice termination setpoint is displayed on the first line, the setting source and the setting source setpoint on the second line.

Possible setting sources for all setpoints are Front Panel, Tracer, Ice Building or External. In the event that the chiller module loses communication with the setpoint source, control will revert to the front panel setpoint.

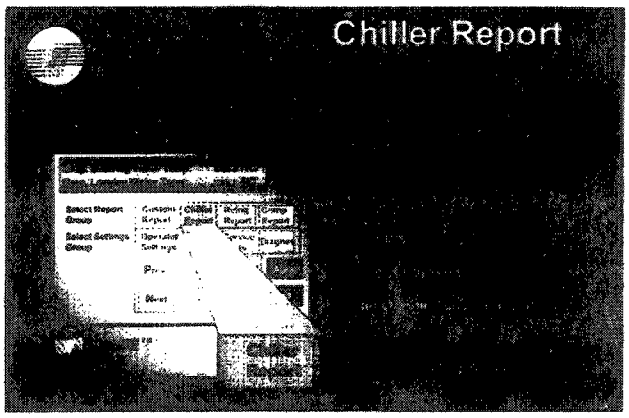

Figure 34

(Figure 34) Entering and leaving water temperature sensors are standard equipment for the UCP2 system. These sensors provide the inputs for the evaporator and condenser temperature differential calculations done by the chiller module.

Next, the CLD will display the active current limit setpoint, as a percentage of full load amps (nameplate). This setpoint indicates the point at which UCP2 will begin to prevent additional compressor loading due to overamperage draw by the compressor motor.

Current limit control is adjustable from 40 to 100 percent of compressor full load amps.

The differential water sensing option must be installed and enabled in order to display water flows and chiller tons. Water flows can be read in gallons per minute (gpm) or in liters per second (lps).

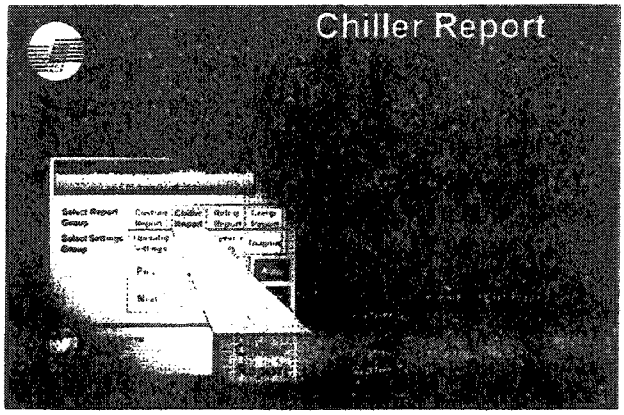

Figure 35

(Figure 35) The first screen in this figure displays the temperature being sensed at the optional outdoor air temperature sensor. The input for this sensor is located on the chiller module. This sensor is included with the Outdoor Based Chilled Water Reset option. This temperature is received by the CLD from the chiller module.

"Aux/Heat Rcvy" entering and leaving water temperatures will be displayed only if a heat recovery chiller is provided or if the chiller is equipped with an auxiliary condenser tube bundle.

The chilled water setpoint source can be a Tracer, the Local CLD or an external Building Management System. If the Tracer or an external source fails, the local CLD assumes control.

"Reset Condition" identifies the type of chilled water reset control being used. This is either outdoor air temperature or return chilled water temperature.

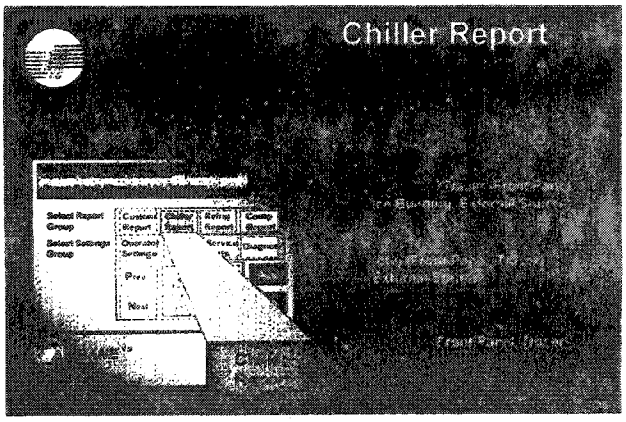

Figure 36

(Figure 36) The Current Limit Setpoint Source screen indicates where the current limiting signal is originating from. The current limit setpoint can originate from several locations or sources. These sources are:

Tracer
Front Panel (Local CLD)
Ice Building
External Source

The Hot Water Setpoint Source is only available on centrifugal chillers. It is displayed only if "Heat Pump Control" is enabled and the chiller is in "Hot Water Control" mode.

Heat Pump Control is used in rare cases where the CenTraVac is used to provide heating instead of cooling as a primary mission.

The Ice Termination Setpoint Source screen indicates where the signal to stop ice building is coming from. This signal can originate from a Tracer or the Chiller Front Panel (CLD).

Refrigerant Report

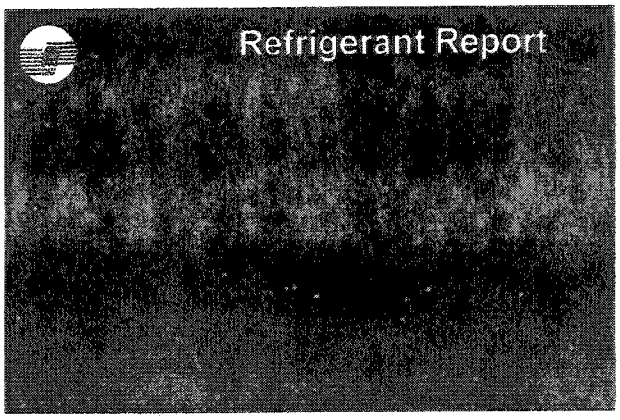

Figure 37

(Figure 37) The refrigerant report contains refrigerant-related information such as pressures, temperatures, purge operating data and equipment room refrigerant monitor log data.

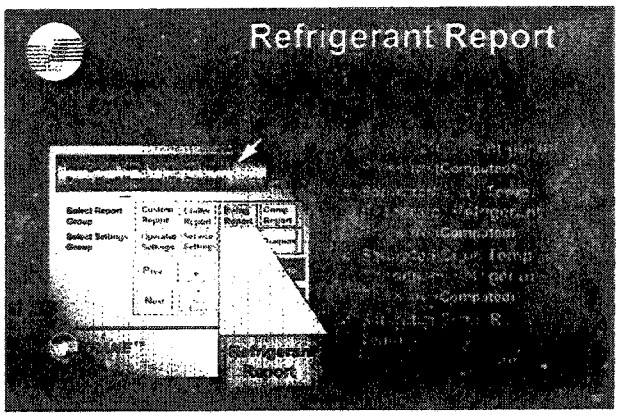

Figure 38

(Figure 38) The operator can view the refrigerant report by pressing the "Refrigerant Report " key on the CLD. This will display the report heading:

"Refrigerant Temp & Pressure Report-
Press (Next) (Previous) To Continue"

The next screens will display two report items each, one on each line. The first screen is:

"Evap. Rfgt Pressure: xxx.x psig-
Cond. Rfgt Pressure: xxx.x psig"

Refrigerant temperatures are provided by the factory-installed temperature sensors. Compressor discharge temperature sensing is standard on RTHB units because electronic expansion valve (EXV) control is derived from a combination of discharge superheat and chilled water temperature differential readings.

Continuing to press the Next key will scroll through the remaining refrigerant report items.

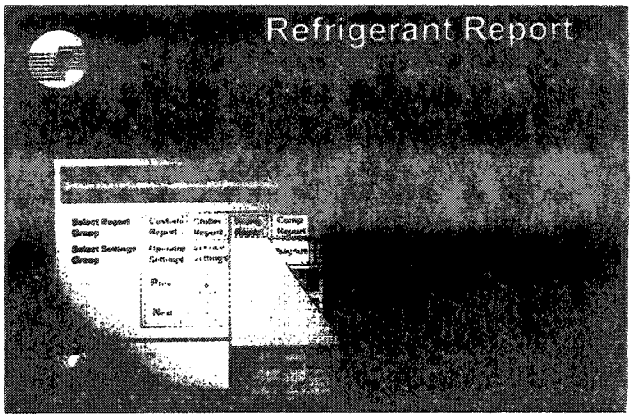

Figure 39

(Figure 39) The three items shown in this figure are displayed for RTHB chillers only, since these features are not provided on low pressure centrifugal chillers. The first screen compares the compressor discharge temperature with the available superheat available at that time.

Discharge superheat is computed from the compressor discharge temperature reading and the saturated condenser refrigerant temperature. Superheat is used to control electronic expansion valve operation to try to maintain the discharge superheat control point.

The second screen shows the discharge superheat control setpoint and the amount of superheat at that moment. The chiller should maintain superheat near the control point. If superheat is too high or too low for too long, the chiller will lock out on a latching diagnostic condition.

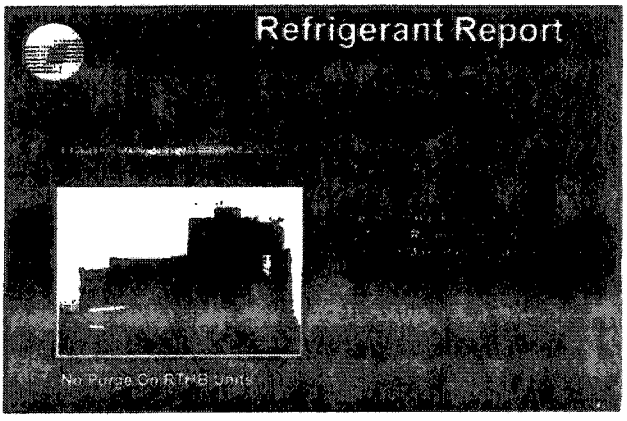

Figure 40

(Figure 40) The next message that appears on the CLD of a low pressure centrifugal chiller is the Purge Operating Mode screen shown here. The first line displays Purge Operating mode, the second is Purge Status. Operating mode is an adjustable setting, while status is just a condition report.

The next 12 screens following the Purge Operating Mode screen are purge-related. These screens are a report-only function that show how the purge is set to operate at this time and what it is actually doing. You cannot set the purge operating parameters in the Refrigerant Report; you can only view the existing purge operating status and settings.

The four purge operating modes are:

Stop
On
Auto
Adaptive

Purge operation mode is selected in the Operator Settings Group.

There are six possible purge status conditions. They are:

Idle
Running
Pumpout
Service Pumpout
Running Inhibited
Pumpout Maximum Rate Inhibited

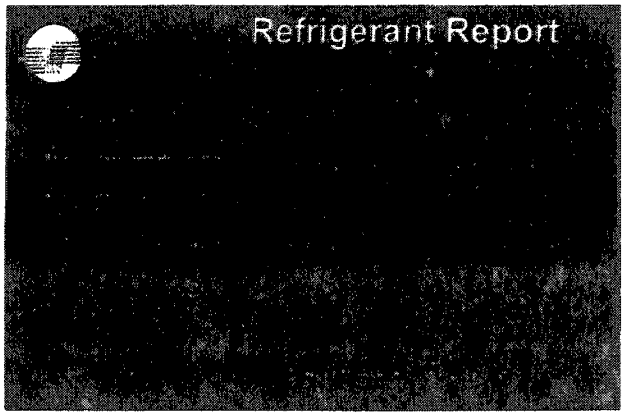

Figure 41

(Figure 41) The Purge Alarm Message screen is provided to inform the operator if non-latching purge diagnostics are occurring. The screen will look like one of the two shown here. The No Diagnostics Exist screen indicates there are no purge diagnostics stored in the diagnostic log at this time. A latching purge diagnostic will cause the purge to shut down and a warning screen to appear on the CLD. This automatically sends the display to the Diagnostic Settings menu so the fault can be viewed and cleared.

Purge Suction Temperature is the suction temperature of the purge air-cooled condensing circuit compressor. This temperature controls pumpout compressor operation, turning it on at 18 F and off at 22 F.

Chiller saturated condenser temperature (purge liquid temperature) is measured so that it can be used to prevent purge operation if the temperature is too low in the chiller condenser.

The top line of the Purge Pumpout Rate screen indicates how many minutes during the last 24 hours the purge pumpout compressor has operated. The maximum number of minutes per day for pumpout is set when the chiller is installed. The second line of this screen shows what the maximum setting is at this time.

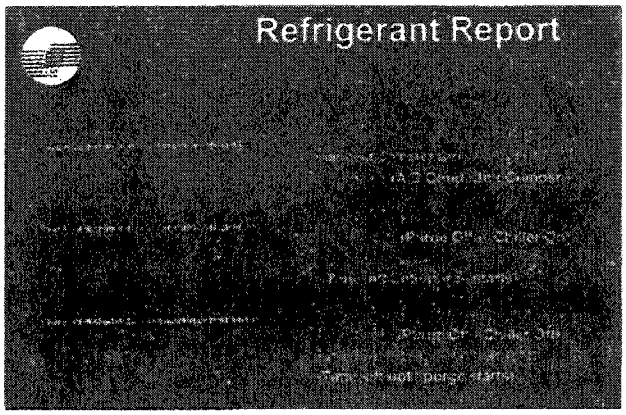

Figure 42

(Figure 42) The Purge Total Pumpout and Run Time screens provide information about the two purge compressors.

Purge Total Pumpout Time is a log of the total number of minutes that the pumpout compressor has operated during the life of the purge. Purge Total Run Time is a log of the total number of minutes that the air-cooled condensing compressor has operated during the life of the purge.

The Adaptive Cycle Time - Chiller On screen shows the length of the purge OFF cycle being used by the Adaptive Control mode with the chiller running and the amount of time left until the purge will restart.

The Adaptive Cycle Time - Chiller Off screen indicates the length of the purge OFF cycle being used by the Adaptive Control mode when the chiller is not running and the amount of time left until the purge will restart.

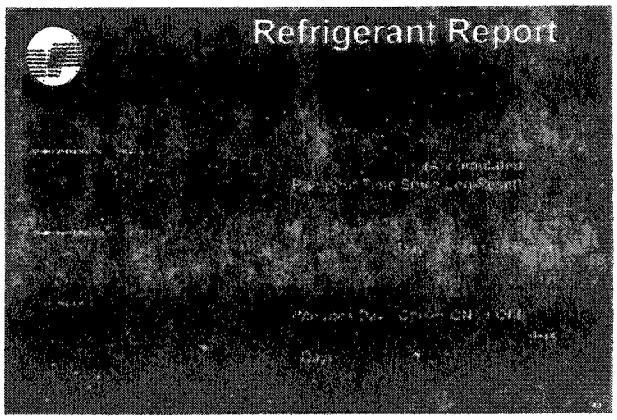

Figure 43

(Figure 43) The Purge Service Log is provided to help schedule purge service and maintenance procedures. The time on these two screens can be reset (zeroed) at any time from the Field Startup menu.

The first service log screen gives pumpout time accumulated since the log was last reset. This should be reset at the completion of purge service to help schedule service or maintenance based on pumpout time.

The second service log screen gives the number of days accumulated since the log was last reset. This should be reset at the completion of purge service to help schedule service or maintenance based on elapsed time or calendar days.

30-Day Summary Data

The last four purge-related screens show data that is accumulated over the previous 30-day period which is called 30-day summary data. Adaptive Control uses this data to automatically adjust purge operational settings.

The first of these is the 30-Day Purge Pumpout Average screen. This shows the average pumpout activity for each 24 hour period over the last 30 days and the Chiller Average Run Time screen which is a summation of chiller run time in hours divided by the number of days of available data.

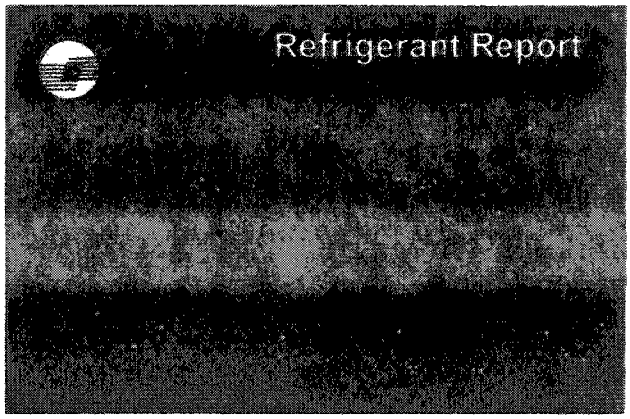

Figure 44

(Figure 44) The next 30-day summary screen is the 30 Day Pumpout Average - Chiller Running screen. This summary records all accumulated pumpout time for periods when the chiller is running. Large service pumpouts are not included if they occurred more than 7 days in the past.

Last 5 Cycle Pumpout Average, Interval From Shutdown To 3 Hours After Shutdown is a screen that gives the average pumpout time needed during the last five chiller shutdowns. Data is available for the last 30 calendar days of pumpout activity during the first 3 hours following chiller shutdown. Large service pumpouts are included. From this data, the average for the last 5 shutdown cycles is computed and shown on this screen.

The final purge screen in the chiller report is the 30 Day Pumpout Average, Interval From 3 Hours After Shutdown To Next Start screen. This summary includes all pumpout data for extended chiller shutdowns (beyond the 3 hour period covered above). Large service pumpouts are not included if they occurred more than 7 days in the past.

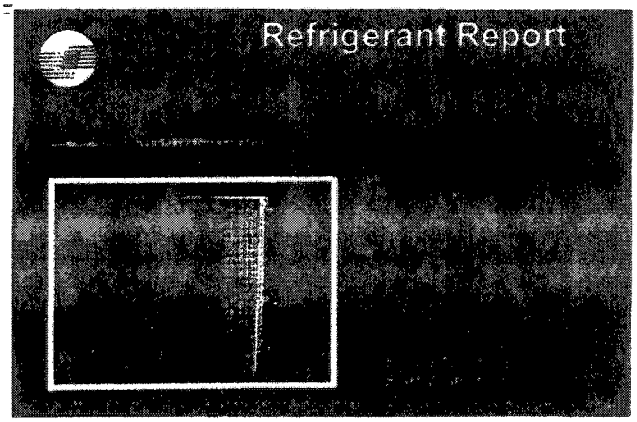

Figure 45

(Figure 45) The refrigerant monitor screens (CTV or RTHB) indicate the current equipment room refrigerant vapor concentration level reading (in parts-per-million), being taken by the refrigerant monitor. This screen will appear only if the refrigerant monitor option has been enabled from the Field Setup menu.

ASHRAE STD. 15-1992 is the current standard that specifies how equipment rooms should be laid out and ventilated and how the refrigerant systems in them should be piped and what safety devices should be provided. At the minimum, an oxygen deficiency monitor should be provided and a refrigerant monitor is recommended.

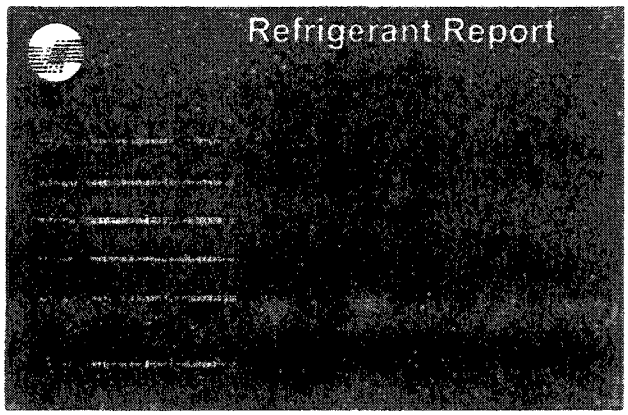

Figure 46

(Figure 46) The Trane Model RMWD digital refrigerant monitor provides more information to the operator than the older, analog monitor does. In addition to equipment room refrigerant vapor level readings, the RMWD shows the monitor's operating mode, case temperature, "bench" temperature and indicates the refrigerant type being read on the chiller's UCP2 display.

The display also indicates the current signal level (mA) being sent to the monitor auxiliary input. This monitor is also available mounted right on the chiller.

If a multiple channel refrigerant scanner is also provided, the display indicates which channel is currently being read and displays the last vapor level reading for each channel.

The monitor's auxiliary input can be used to accept a signal from an external device such as a oxygen level monitor.

The final screen in the CenTraVac Refrigerant Report displays the evaporator and condenser approach temperature readings (not used for RTHB). They are important chiller operating and diagnostic tools.

Compressor Report

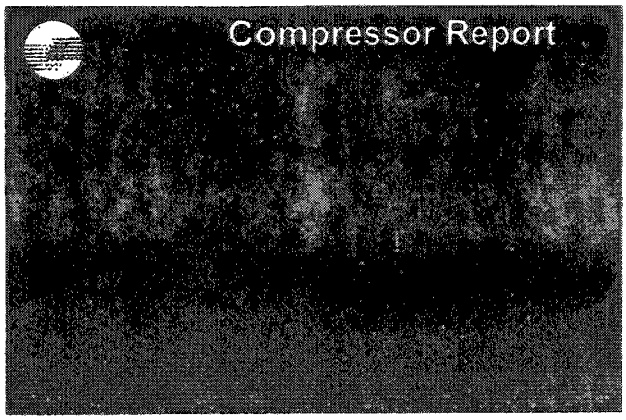

Figure 47

(Figure 47) The Compressor Report is the final Report Group. This report provides information on compressor operation, including oil system data, bearing information (CTV), inlet guide vane position (CTV), operating time and starts, electrical data and operating temperatures.

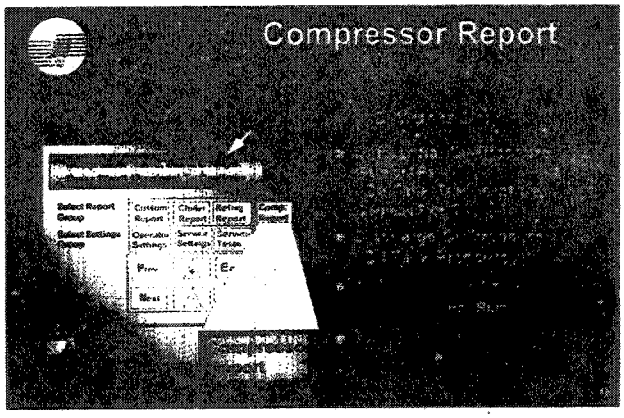

Figure 48

(Figure 48) When the Compressor Report key is pressed, the Compressor Report heading, shown in this figure will be displayed. Pressing Next will scroll through the report items that follow.

The first six compressor report screens shown here appear for CVHE and CVHF chillers only. The RTHB compressor report begins with the "Compressor Phase Currents - % RLA screen shown in Figure 49.

The Differential (Net) Oil Pressure reading is provided to assure the operator that oil is being supplied properly to the compressor bearings. This reading is equivalent to subtracting evaporator pressure from the oil supply pressure.

Normal operating Differential Oil Pressure reading is 12-18 psid. A minimum of 9 psid for 30 seconds is required for compressor start to take place. The 750-watt oil tank heater should maintain 140-145 F oil temperature during chiller operation. Oil tank temperature can be anywhere between 115-160 F with the chiller OFF.

The discharge oil and oil tank pressure screens show what oil pressure readings are being used to calculate the differential oil pressure.

The Adjustable Frequency Compressor Speed Command screen displays the compressor speed frequency and rpm for CVHE and CVHF only if the starter type is set at "adjustable frequency".

The Adjustable Frequency Boundary Pressure Coefficient and the Adjustable Frequency Pressure Coefficient are displayed for CVHE and CVHF only if the starter type is set at "adjustable frequency".

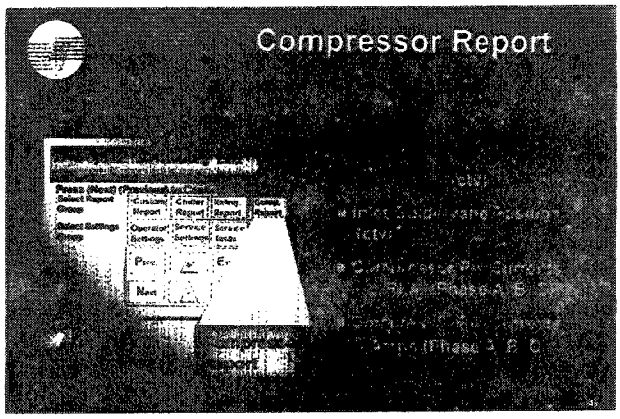

Figure 49

(Figure 49) The Adjustable Frequency Re-Optimization Time Remaining screen displays the amount of time left on the re-optimization timer. This is displayed for CVHE and CVHF only if the starter type is set at "adjustable frequency".

The Inlet Guide Vane Position screen shows the CVHE/F inlet guide vane position at any given time. Position is displayed in percent of full open and number of degrees open, based on inlet guide vane stepper motor position.

"Compressor Phase Currents – % RLA" is the percentage of Rated Load Amps (nameplate) being drawn at each compressor winding. "Compressor Phase Currents – Amps" is the total amperage being drawn at each compressor winding.

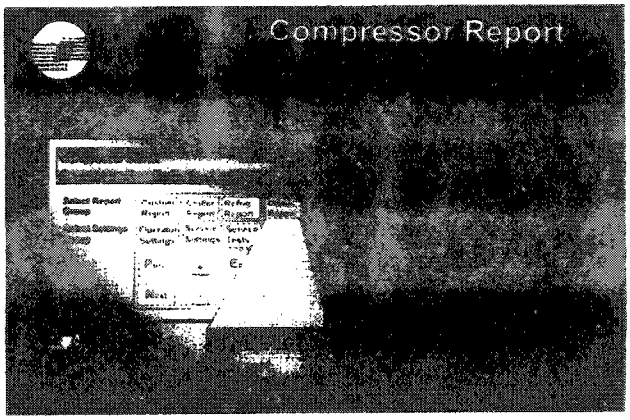

Figure 50

(Figure 50) "Compressor Phase Voltages" is the measured voltage present between Line Phases A-B, B-C and C-A respectively, of the incoming power supply.

"Compressor Power Factor" and "Compressor Kilo-Watts" readouts are options available for centrifugal chillers if:

- the Line Voltage Sensing Option (PTs) is installed;
- the starter type is not Adjustable Frequency Drive, and;
- "External KW" is not installed.

A RTD-type temperature sensor (W1, W2, W3) is buried in each phase winding of the compressor motor stator to detect motor overheating. The UPC2 monitors the resistance measured at each of the sensors, which varies in direct relation to the motor temperature.

A counter is provided to record the total number of compressor starts since chiller first startup. A digital hourmeter records total compressor run time since first chiller startup in hours, minutes and seconds.

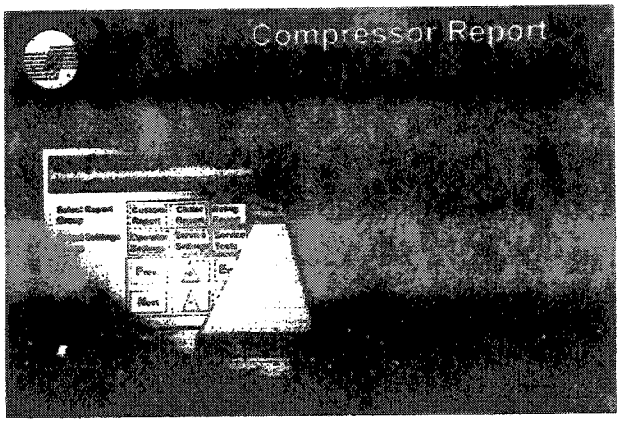

Figure 51

(Figure 51) Inboard and outboard bearing temperature protection is optional on CVHE/F centrifugal chillers. Fixed, high bearing temperature cutouts can be provided to generate a MMR diagnostic and shut down the chiller if temperature at either bearing exceeds 180 F (82.2 C).

Solid State Starter Heat Sink Temperature is displayed if the solid state starter option has been enabled from the Service Settings menus. UCP2 monitors this temperature to prevent chiller start when the starter heat sink temperature is too high.

Hot Gas Bypass Time is a readout of the total amount of time elapsed with chiller operating in hot gas bypass.

Extended Unloading Time indicates the total amount of time currently being allowed for an RTHB unit to operate in "extended unloading" condition. This is used to keep the chiller on line at minimum load by creating an artificial load on the evaporator (similar to hot gas bypass). When chilled water temperature differential falls to its lowest allowed point, UCP2 opens the EXV slightly, to allow more refrigerant to enter the evaporator.

SUMMARY

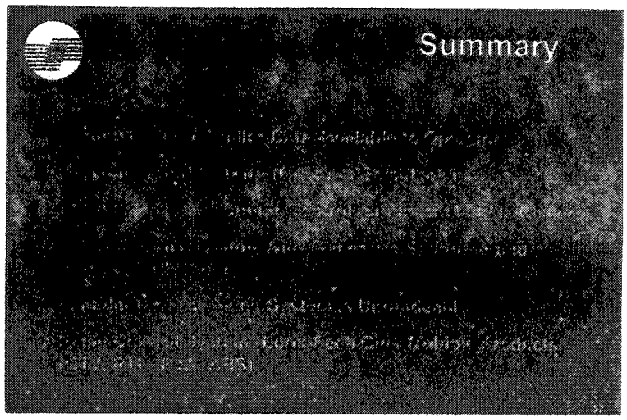

Figure 52

(Figure 52) The Trane UCP2 Enhanced Adaptive Control™ system provides chiller operating and maintenance personnel immediate access to all chiller operating status and setpoint data, pressure and temperature readings, electrical data, loading conditions, oil system information, and purge and refrigerant monitor data.

An operator can access critical information immediately by setting up a custom report for his particular application.

Chiller logs can be printed on demand, periodically, or in the instance of a diagnostic.

Multiple or single UCP2 chillers can be controlled remotely, using the Remote Clear Language Display and, all UCP2 chillers communicate directly with Tracer building management systems.

The UCP2 is so flexible that new features can be added to it at any time.

Finally, once an operator is familiar with UPC2 operation this familiarity will carry over to any other type of chiller using Trane's Adaptive Control technology.

SUMMARY 27

This manual is a companion to the Trane seminar of the same name. To order additional copies of this manual, contact:

Service Literature Department
The Trane Company
3600 Pammel Creek Road
La Crosse, WI 54601

Please specify literature order number ST-MNL-5.

The following related material is also available through Trane Service Literature:

ST-MNL-4 "UCP2 – A First Look"

The Trane Company, La Crosse, Wisconsin 54601-7599

INTRODUCTION

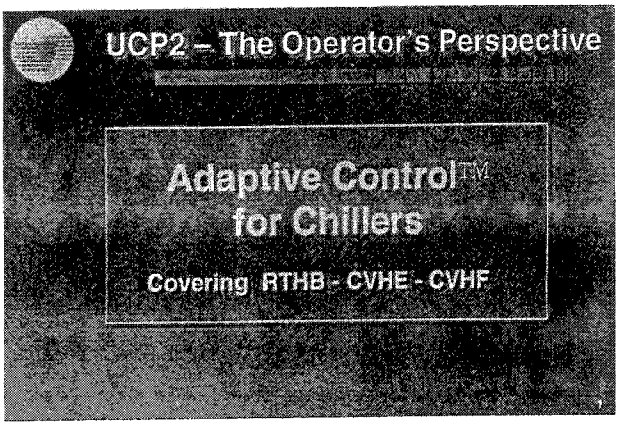

Figure 1

(Figure 1) This course is a continuation of the material contained in the companion training module to this one, ST-LG-4; "UCP2 – A First Look".

ST-LG-4 introduced the UCP2 and covered the clear language display's four report functions. This course picks up at that point, continuing with the UCP settings functions and concluding by discussing basic chiller operation using the control.

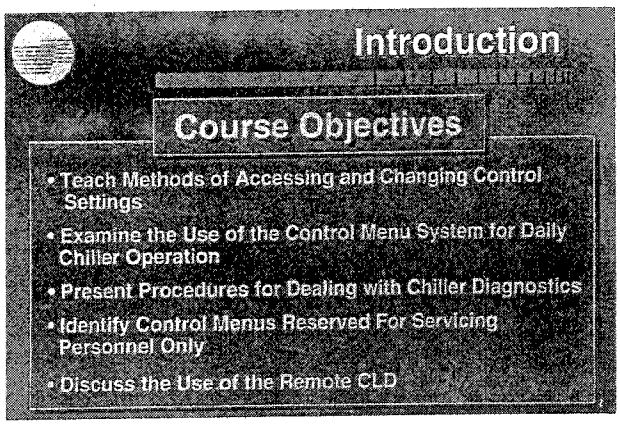

Figure 2

(Figure 2) The Adaptive Control™ System is presently available on these Trane products:

- Model CVHE 230-1250 ton CenTraVac® (3-stage centrifugal chillers)
- Model CVHF 650-1250 ton CenTraVac (2-stage centrifugal chillers)
- Model RTHB 130-450 ton Series R® CenTraVac (helical-rotary chillers)
- Model ABSC Absorber (single-stage absorption chillers)
- Model ABTE Absorber (2-stage absorption chillers)

This manual covers model CVHE and CVHF centrifugal and RTHB helical-rotary chillers equipped with Trane's UCP2 microprocessor control panel.

The manual will show how to use the control's menu system for daily chiller operation and how to deal with machine diagnostics and restore chiller operation. By studying this manual, the reader should learn how to access and use UCP2 control settings and become familiar with which ones chiller operating personnel would typically be expected to understand and set or change.

Finally, the reader will learn what control menus are reserved for service technician use and how to protect the chiller controls from unauthorized access.

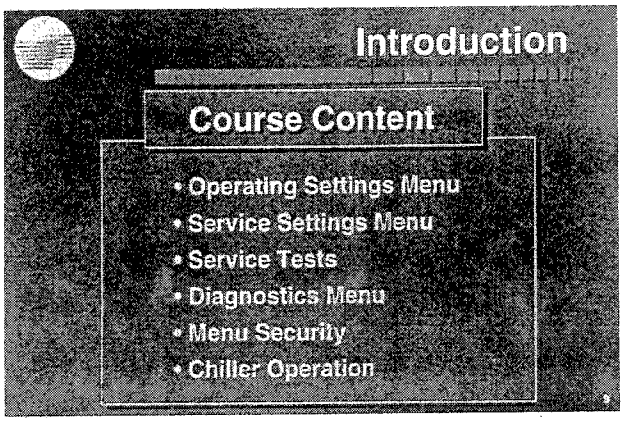

Figure 3

(Figure 3) With this course, we will continue discussion of the UCP2 clear language display. We begin with the four menus of the Settings Group, which are:

Operator Settings menu
Service Settings menu
Service Tests menu, and;
Diagnostics menu

We will also look at the UCP2 control system security measures. The course concludes with coverage of the UCP power-up and operational sequences, a discussion of chiller logging procedures, diagnostic handling routines and remote clear language display (CLD) operation.

SETTINGS GROUP KEYS

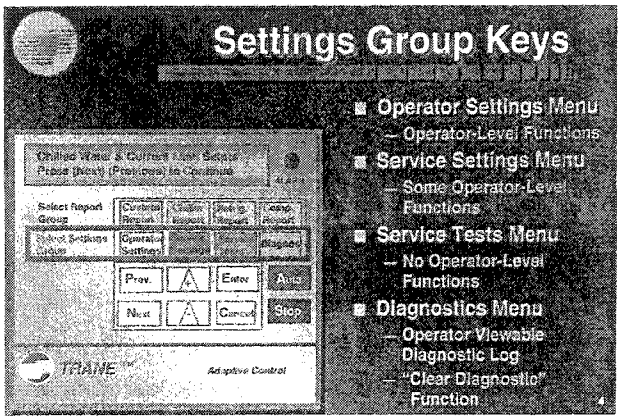

Figure 4

(Figure 4) As previously mentioned, the second row of four keys on the CLD is the settings group keys. They are used to access four menus of machine and system settings. They are:

Operator Settings Menu: It contains the majority of operator-level functions; no machine safety setpoints.

Service Settings Menu: Only the "Basic Setups" or top level settings of this menu are typically used by operating personnel.

Service Tests Menu: Use of this menu is reserved for qualified service technicians.

Diagnostics Menu: Operator views diagnostics log and clears diagnostics preventing chiller operation.

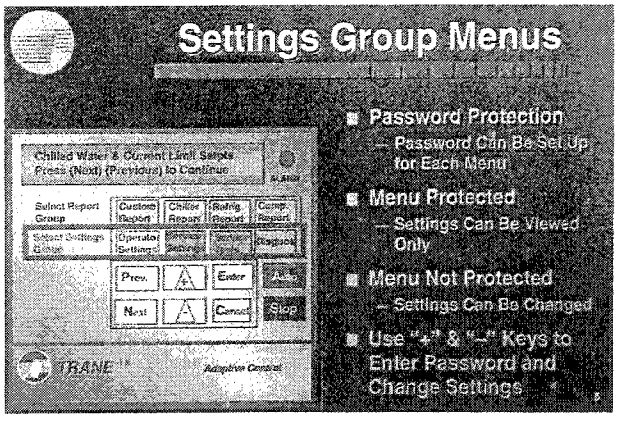

Figure 5

(Figure 5) Passwords can be set up for each menu. If menus are password protected, menu items can be viewed only, not changed. If menus are not protected, items can be both viewed and changed. Use the Previous and Next keys to scroll through menus. Use (+) and (–) keys to change settings. Use Enter key to enter changes into memory after each menu change.

Operator Settings

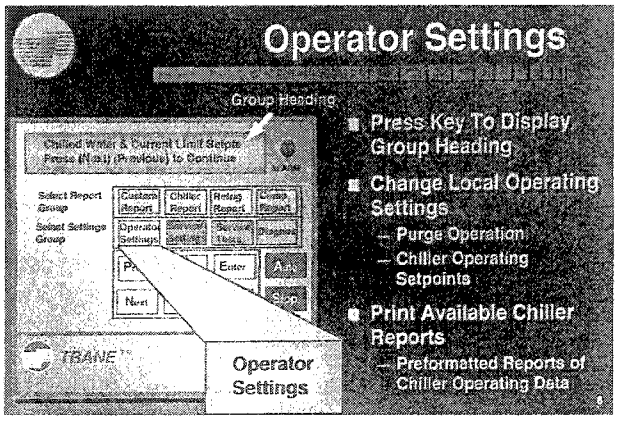

Figure 6

(Figure 6) Pressing the Operator Settings key displays the Operator Settings group or menu heading. If the group (menu) heading does not appear, the headings have been disabled. They can be restored from the Basic Setups area of the Service Settings menu.

Operator settings are used to set local chiller operating parameters and control purge operation (for CHVE/F units). The Operator Settings menu allows the operator to output the available printed reports also. Press Next to continue to the Menu Settings Password screen.

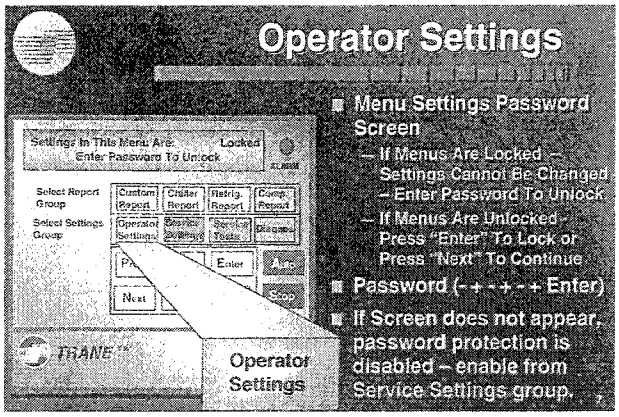

Figure 7

(Figure 7) This screen indicates that the settings in the menu are either locked or unlocked and displays the correct password on the second line for operator convenience. If settings are locked, the operator can unlock them by entering the Menu Settings password. The password is (– + – + – +) followed by Enter.

If the settings are already unlocked, then the operator can change the settings in this menu. Alternately, at this time, the operator can choose to lock the settings in this menu by pressing Enter or can continue on to the next screen by pressing Next.

Note: Any time you are entering a password with the (+) and (–) keys, up to 20 characters can be entered. The CLD uses the last six characters entered as the password, so in this case, the last six characters must be (– + – + – +) followed by the Enter key. So, up to 14 "nonsense" characters could be entered before keying in the correct password. If too many characters or an incorrect password are entered, the CLD will display "Incorrect Password".

If the screen in Figure 7 does not appear, then the menu settings display feature has been disabled from Field Startup menu of the Service Settings Group.

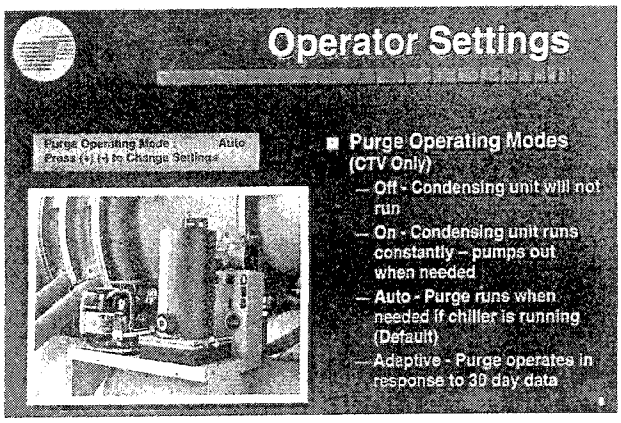

Figure 8

(Figure 8) This screen will not appear if "Stand Alone Purge" type has been selected from the Machine Configuration menu. The purge operating mode screen allows the operator to set one of the four purge operating modes. These modes are:

Off (Stop)

– Purge condensing unit will not operate.

On

– Purge condensing unit runs continuously. Pumpout compressor runs when needed to purge chiller.

Auto

– Condensing unit runs whenever needed if the chiller is running. This is the factory default setting.

Adaptive

– Purge operates in response to 30 day purge data accumulated from past operation.

Use the Plus / Minus keys to change operating modes. This can only be done when In "Settings" groups; the second line of this screen will be "Press (+) (-) to Change Setting".

Use the Enter/Cancel keys to enter new data into memory. Enter must be pressed to store any new setting in memory. If the menu is scrolled to the next item, without pressing Enter, the setting will be lost.

Use cancel if a new setting has been entered but should not be stored. This can only be done when in "Settings" groups. Remember, settings or sensed data are updated on the screen every 2 seconds.

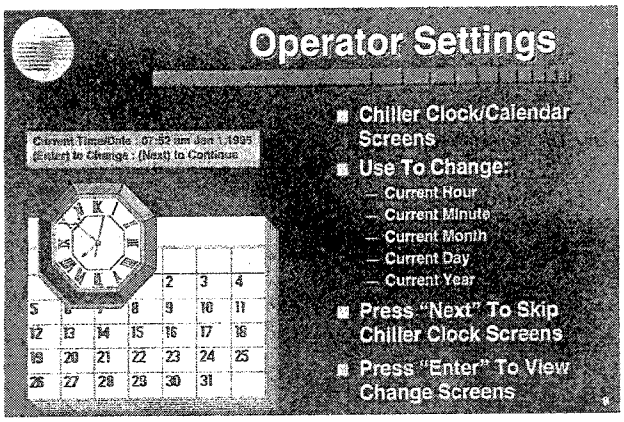

Figure 9

(Figure 9) The chiller Clock / Calendar screens are used to set the proper time and date on the chiller clock. It's important to have the correct time and date set on the chiller clock in order to perform time-related functions, print on time intervals and properly label printed reports.

When the Current Time / Date screen appears, the operator can choose to enter the screens that change the clock / calendar settings or not. To view these screens, press Enter. To skip the clock / calendar change screens, press Next.

When power is removed from the UCP, the clock does not continue to keep time. When the UCP is repowered, a Check Clock screen will display to remind the operator to reset the chiller clock.

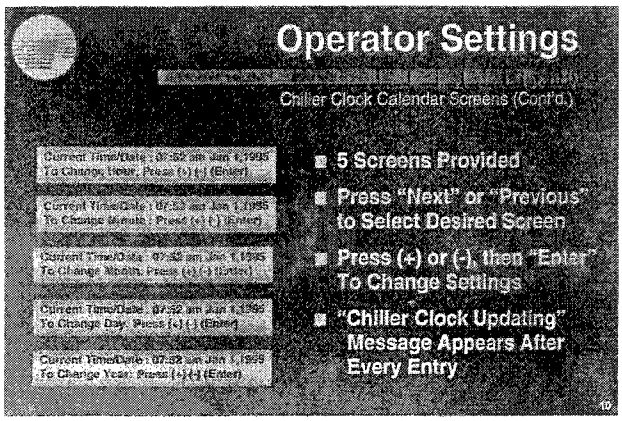

Figure 10

(Figure 10) There are five chiller clock settings screens.

Change Hour
Change Minute
Change Month
Change Day
Change Year

Press Next or Previous to scroll through the screens. Press (+) or (–), then Enter to change the value (remember, Enter must be pressed after each individual change). The Chiller Clock Updating screen will appear momentarily each time Enter is pressed.

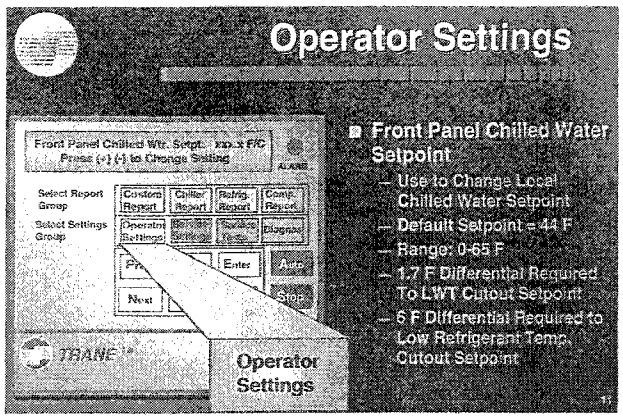

Figure 11

(Figure 11) The Front Panel Chilled Water Setpoint (CWS) is the primary chiller operating point. Press (+) or (–) to change displayed setpoint up or down (in degrees F or C). The programmed factory default setpoint is 44 F. The setting range is from 0 to 65 F.

It is necessary to maintain at least a 1.7 F differential between the CWS and the low water temperature cutout setting and a 6 F differential to the low refrigerant temperature cutout setting. When the Front Panel Chilled water Setpoint is within 1.7 F of the leaving water temperature cutout setpoint, or within 6 F of the low refrigerant temperature cutout setpoint, the second line of the display will read:

"Limited by Cutout Setpoint
Press (+) to Continue"

Plus / Minus Keys

Use to change all setpoints up (+) or down (–). This can only be done when in "Settings" groups. The second line of each screen in a settings menu will be "Press (+) (–) to Change Setting".

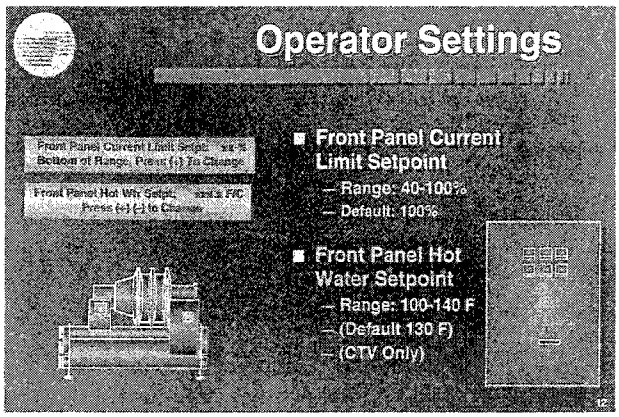

Figure 12

(Figure 12) The Current Limit Setpoint (CWS) is the point at which it is necessary to limit compressor loading because the compressor motor is drawing excessive amperage. This setpoint is set as a percentage of chiller nameplate full load amps (FLA). Press (+) or (–) to change displayed setpoint up or down (in degrees F or C). The factory default setpoint is 100%. Setting range is 40 to 100%.

If you try to establish a setpoint above or below the possible range, one of these two messages is displayed on the second line of the screen:

"Top of Range, Press (–) to Advance"
or;
"Bottom of Range, Press (+) to Continue"

When the chiller is in Hot Water Temperature Control operating mode, the hot water setpoint is the primary operating control point. This is used when heating (not cooling) is the primary mission of the chiller (rare application). In this situation, the UCP controls off leaving condenser water temperature instead of evaporator leaving water temperature.

Press (+) or (–) to change displayed setpoint up or down (in degrees F or C). The factory default setpoint is 100%. The setting range is 100 to 140 F.

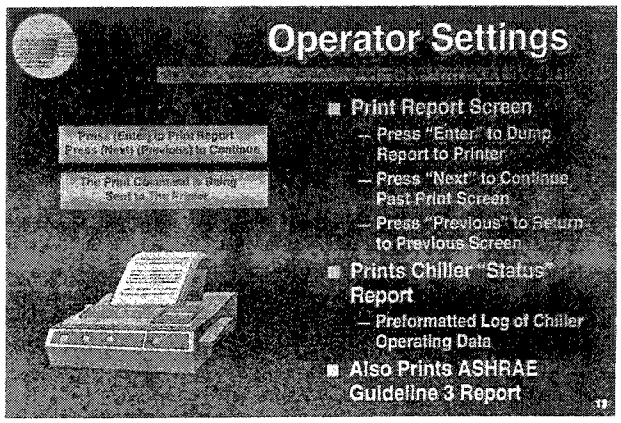

Figure 13

(Figure 13) The Print Report screen gives the operator the opportunity print out a chiller status or ASHRAE Guideline 3 report on demand. These reports can be printed on demand regardless of whether the UCP is configured to print reports at certain time intervals or on a diagnostic, too. To print reports, just press Enter. The Print Report Being Sent screen appears momentarily.

The chiller status report is a preformatted report of chiller data. The ASHRAE Guideline 3 report is a compilation of data from various UCP2 reports that ASHRAE recommends be monitored and logged daily to prevent refrigerant loss. Items in this report can be viewed at the second screen of the Chiller Report. This report is not found on earlier-model UCP2 panels. This is discussed again later in this manual.

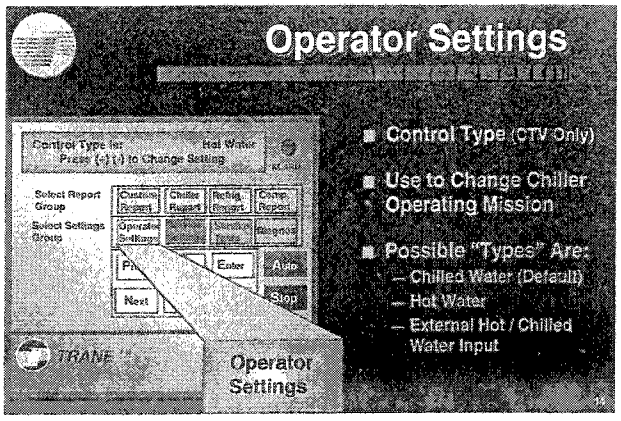

Figure 14

(Figure 14) This screen is used to switch the chiller operating control mode between chilled water control and hot water control. When the chiller is in Hot Water Temperature Control operating mode, the hot water setpoint is the primary operating control point.

This is used when heating (not cooling) is the primary mission of the chiller (rare application). The UCP controls off leaving condenser water temperature instead of evaporator leaving water temperature.

This screen will not appear unless this feature was installed from the Machine Configuration menu of the Service Settings group. The External Hot / Chilled Water Input is provided in the case where is it desirable to be able to switch between producing cold water and producing hot water from a Tracer location.

In this type of application the leaving evaporator water temperature is allowed to drift wherever it needs to be to satisfy the condenser heating load. The evaporator is normally piped into a lake, well or other source of constant temperature water for the purpose of extracting heat from it.

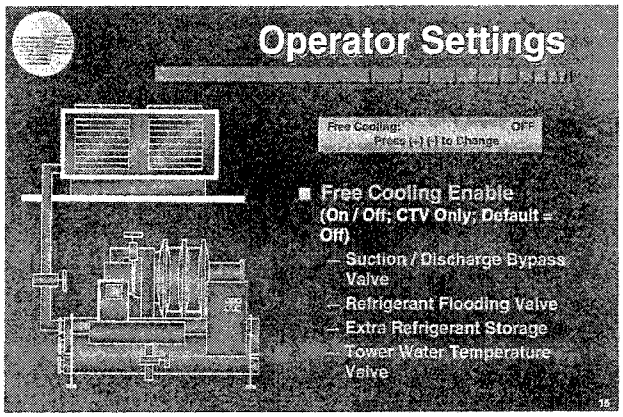

Figure 15

(Figure 15) This screen allows the operator to manually switch between normal powered cooling operation and free cooling. This can also be done automatically from a binary input on the options module or from a Tracer or Chiller Plant Manger (CPM).

Note: Free cooling has to be installed from the Machine Configuration menu of the Service Settings group.

Free cooling is a method to obtain up to 45% cooling without the running the compressor. In order to do this, first there must be a source of condensing water whose temperature is lower than the required chilled water temperature setpoint (i.e., you have an indoor load with low ambient outside air condition).

Free cooling requires a number of factory modifications to the chiller, including; installing a refrigerant gas line and liquid return line with automatic valves between evaporator and condenser, adding a liquid refrigerant storage vessel and providing extra refrigerant.

During free cooling, the water pumps operate and refrigerant circulates between the evaporator and condenser due to the pressure/temperature differential between them. The amount of cooling obtained depends on the magnitude of this differential. When the cooling load exceeds free cooling capacity or low temperature condenser water is no longer available, the operator manually switches back to normal cooling or this is done automatically via the input on the options module, a Tracer or Chiller Plant Manger (CPM).

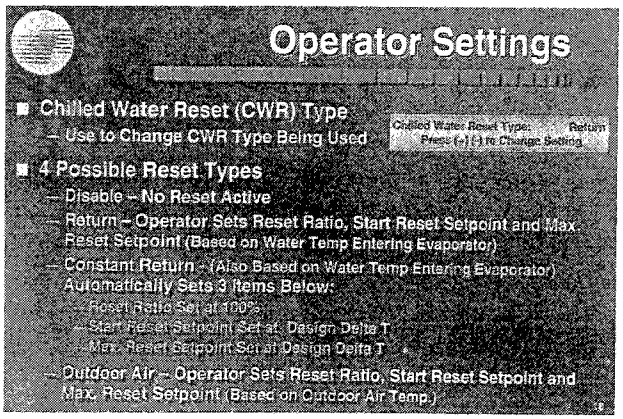

Figure 16

(Figure 16) Chilled water reset (CWR) is a means of reducing energy consumption during periods of the year when cooling loads are reduced. By resetting the chilled water setpoint upward as cooling load falls off, the chiller can satisfy the setpoint at lower load conditions, reducing electrical power consumption.

This screen allows the operator to select the type of chilled water reset to use or to disable reset altogether. The setpoint is based on a temperature such as return chilled water temperature (Return & Constant Return) or outside ambient air temperature (Outside Air). The most common use of chilled water reset is to provide a constant return chilled water temperature, so the settings for constant reset are the default settings.

If Constant Return is selected, then the reset ratio, start reset setpoint and maximum reset setpoint are set by the UCM. If chilled water reset is disabled or constant return is selected, the next three related subscreens will not appear (i.e., reset ratio, start reset setpoint and maximum reset setpoint). If chilled water reset type is set at return or outdoor air, then the next three related subcreens will follow. Then, it may be necessary for the operator to adjust the desired reset ratio, start reset setpoint and maximum reset setpoint (if the factory settings are not getting the job done).

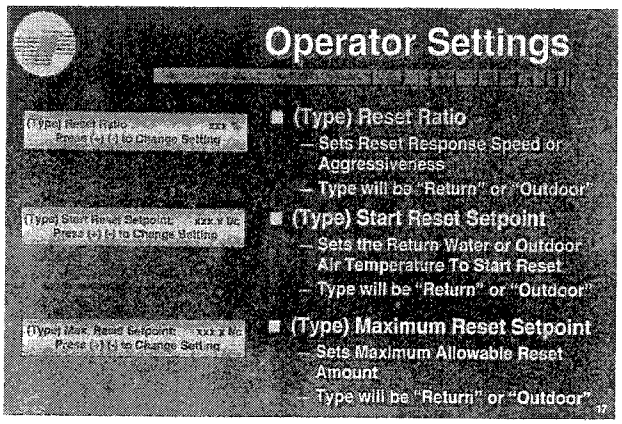

Figure 17

(Figure 17) Return and Outdoor reset setpoints can be calculated using the formulas provided in the chiller installation, operation and maintenance manuals.

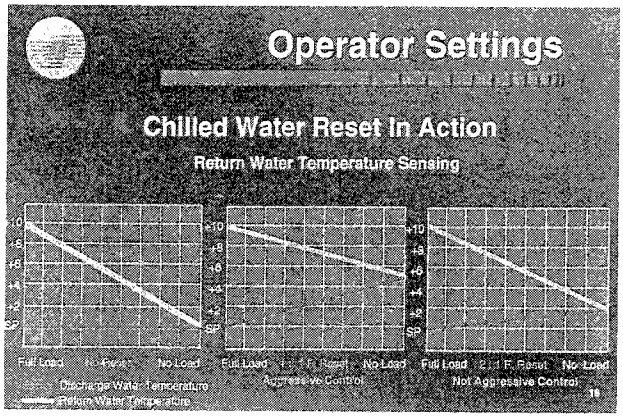

Figure 18

(Figure 18) In the "No Reset" example of the left chart, the chiller provides a constant discharge water temperature regardless of the return water temperature (return water temperature can drift anywhere).

In the "One-to-one" reset example of the middle chart, the UCP allows discharge water temperature (thus the chilled water setpoint) to raise at the same rate as return water temperature drops. This is considered aggressive reset control.

In the "Two-to-one" reset example in the right chart, the UCP raises discharge water temperature at only half the rate that the return water temperature drops. This is less aggressive reset control.

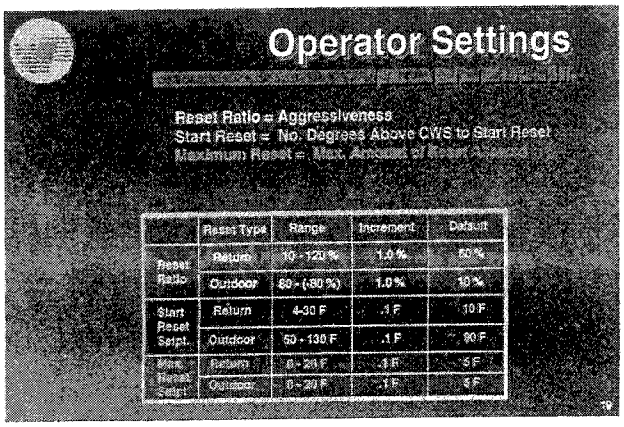

Figure 19

(Figure 19) Reset ratio is simply an arbitrary point that sets the rate of reset. Even though the default point is 50%, this will be set at the proper level for the job at the factory. If the operator feels that an increase or decrease in the reset rate (speed of reset) is needed, then the ratio must be adjusted up or down, accordingly.

At the default settings (reset ratio = 50%), when any chilled water reset is enabled, the UCP steps the chilled water setpoint toward the new (reset) setpoint at a rate of 1 F every 5 minutes until active chilled water setpoint matches the desired new setpoint.

When any type of reset is ordered, the setpoints are factory set for all chillers for the application. Resetting these values in the field is seldom necessary. If for some reason, the settings stored in memory were lost, then the default settings would take over. These setpoints are not lost when power is removed from the UCP.

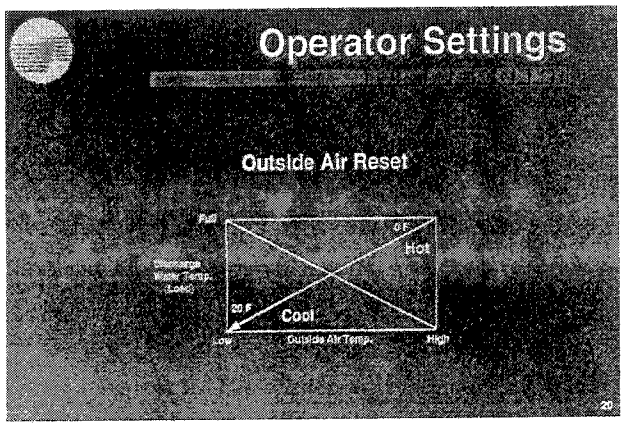

Figure 20

(Figure 20) For outside air reset, the chilled water setpoint is reset as outdoor temperature and cooling load decrease. In this example, maximum reset is set at 20 F.

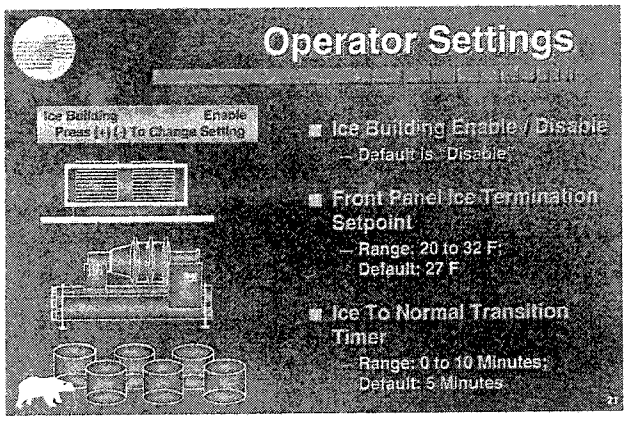

Figure 21

(Figure 21) Ice storage systems allow the chiller to operate at full load (build ice) during electrical off-peak periods (night) and use the stored ice as a cooling source during high electrical demand periods (day). During ice making operation, the chiller will be in "Ice-Building" operating mode.

Use the Ice Building Enable / Disable screen to select or turn off ice-making operation. Press (+) or (–) to change the setting. The Front Panel Ice Termination Setpoint is the return water (entering evaporator) temperature at which to stop making ice. Ice making can also be stopped by an external signal (Tracer) or opening of the External Ice Contact. The setting range is 20 to 32 F in 1 degree increments. The default setting is 27 F.

The transition timer is used when ice-making is terminated by a Tracer input or External Ice contacts to make the chiller run at minimum load for a set time period after the compressor unloads. The setting range is 0 to 10 minutes. The default setting is 5 minutes.

When ice-making is terminated, the chiller goes into "Ice-Making Complete" operating mode. If a CVHE/F operates in a surge condition for over 15 minutes, the chiller will shut down on the "Surge Shutdown: Ice Making" MMR diagnostic.

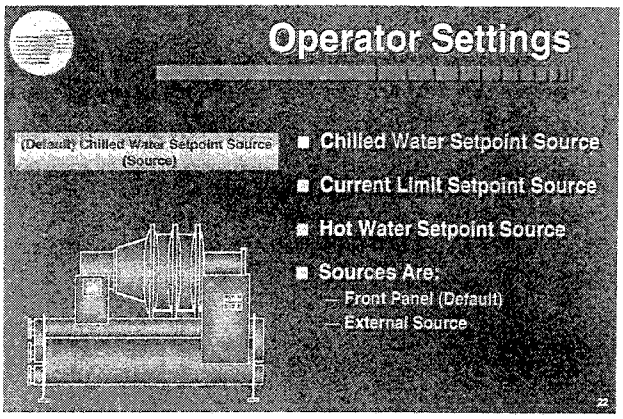

Figure 22

(Figure 22) The next five screens on the CLD (Figures 22 & 23) identify the sources for the present chilled water, current limit, hot water and ice termination setpoints and the setpoint override source and allow the operator to change the source if additional sources are installed. So, in order to change chilled water setpoint from the front panel to external source, the external chilled water setpoint inputs must be connected and that option installed from the Field Setup group.

Press (+) or (–) to change the displayed source. Possible sources are:

Front Panel (default)
External Source
Future 1, 2, 3 (Reserved for new sources options when available.)

The word "default" will appear at the beginning of all of the above source screens if the Tracer option is installed. If the Tracer does not provide a setpoint, then the default (front panel) is used. It is the valid setpoint source if there is no Tracer.

The Hot Water Setpoint Source screen will only display if the hot water control option is installed.

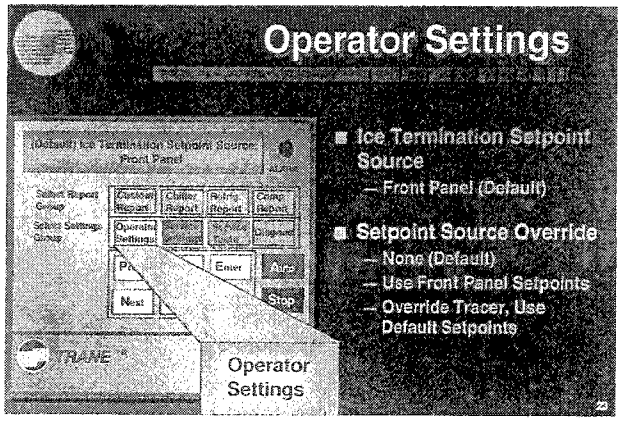

Figure 23

(Figure 23) The word "default" will appear at the beginning of the Ice Termination Setpoint Source screen if the Tracer option is installed. If the Tracer does not provide a setpoint, then the default (front panel) is used. It is the valid setpoint source if there is no Tracer.

The Setpoint Source Override screen allows the operator to override remote setpoints established by a Tracer or other generic input. Possible "sources" for this screen are:

None
Use Front Panel Setpoints
Override Tracer – Use Default Setpoints

"None" is the default setting.

Service Settings

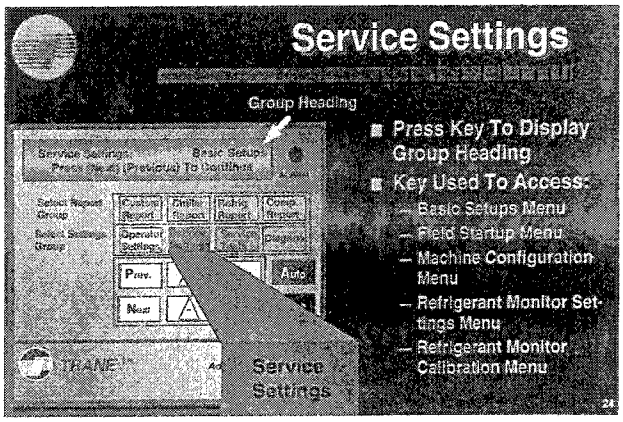

Figure 24

(Figure 24) The Service Settings Group consists of five separate menus. These are:

Basic Setups menu;
Field Startup menu;
Machine Configuration menu;
Refrigerant Monitor Settings menu;
Refrigerant Monitor Calibration menu

Each menu is protected by a different password, except for the Basic Setups menu. Although this menu does not have a password, the settings in it can be locked, just as in the previous menus we have discussed.

The Basic Setups menu consists of settings that would not often be accessed by the operator, and changes in them will not seriously affect the safety or reliability of the chiller.

The remaining password protected menus of this group are for changing parameters and settings for field commissioning, for setting fundamental protection of the chiller systems or for programming the UCP as to how the chiller was actually built in the factory.

Caution: Once these items are set they should never be changed again without specific knowledge of the effects these changes will have.

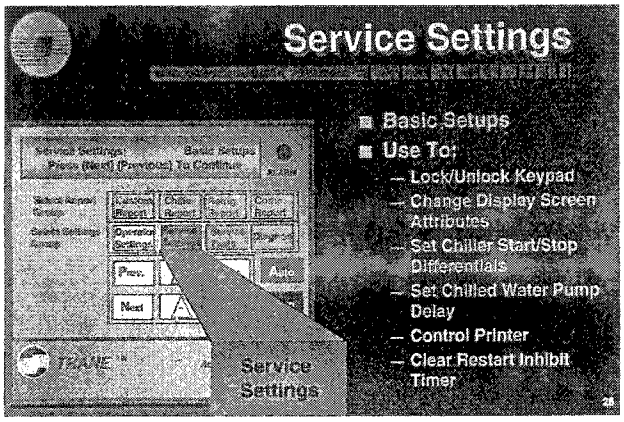

Figure 25

(Figure 25) Pressing the Service Settings key displays the Service Settings menu heading. If the group (menu) heading does not appear, the headings have been disabled. They can be restored from this settings menu. Press Next to continue to the Menu Settings Password screen. Service settings are used to set local chiller operating parameters and control settings.

Generally, the **Basic Setups** menu is used to:
– lock and unlock the keypad
– change display screen attributes (turn on / off group headings and menu setting password screens)
– set the chiller start and stop temperature differentials
– set the chilled water pump off time delay
– control printer operating settings
– clear the chiller restart inhibit timer

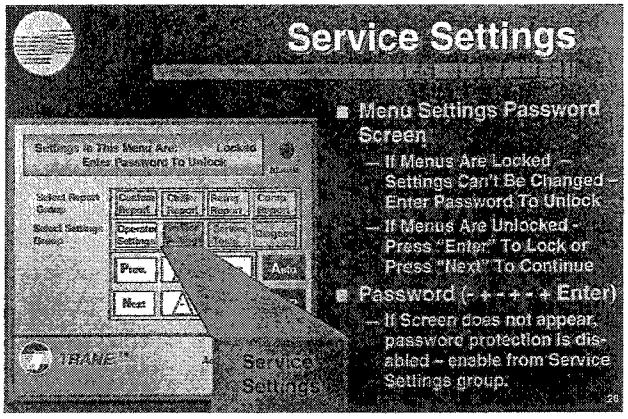

Figure 26

(Figure 26) This display screen indicates that the settings in the menu are either locked or unlocked and it displays the correct password on the second line for operator convenience. If the settings are locked, the operator can unlock them by entering the Menu Settings password. The password is (– + – + – +) followed by the Enter key.

If the settings are already unlocked, then the operator can change the settings in this menu. Alternately, at this time, the operator can choose to lock the settings in this menu by pressing Enter or can continue on to the next screen by pressing Next.

Note: Remember, any time you are entering a password with the + and – keys, up to 20 characters can be entered. The CLD uses the last six characters entered as the password, so in this case, the last six characters must be (– + – + – +) followed by the Enter key. So, up to 14 "nonsense" characters could be entered before keying in the correct password.

If too many characters or an incorrect password are entered, the CLD will display "Incorrect Password". If this screen does not appear, then the menu settings display feature has been disabled from Field Startup menu of the Service Settings Group.

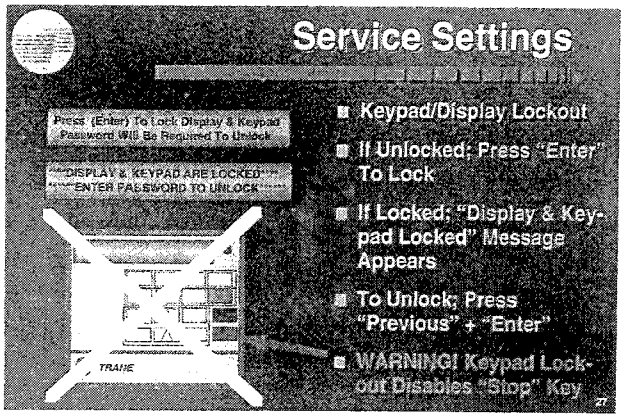

Figure 27

(Figure 27) If the Display and Keypad Are Locked, this screen appears when you attempt to use the UCP. Don't panic. Simply press the Previous and Enter keys simultaneously unlock the CLD.

If this screen does not appear, then the keypad lockout feature has been disabled from Field Startup menu of the Service Settings Group.

Locking out the keypad can be a dangerous thing to do, since this also disables the Auto and Stop keys. However, if the chiller is being controlled remotely from a remote CLD or Tracer, locking out the local keypad could be a good way prevent unauthorized personnel from inadvertently interfering with chiller operation.

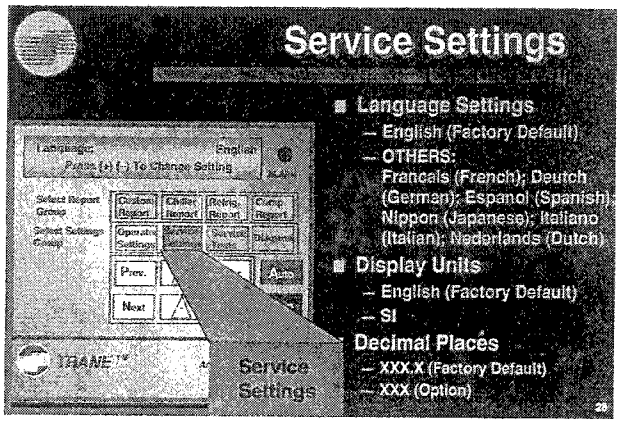

Figure 28

(Figure 28) The Language Setting screen is used to select the desired language for the CLD to use. The number of languages available depends on which software version is installed in the UCP. The factory default language is English. Press the (+) or (–) key and Enter to change languages.

The Display Units screen allows the operator to select to display data in either English or SI units. (i.e., temperatures in Fahrenheit or Celsius). The factory default units are English. Press the (+) or (–) key and Enter to change unit types.

Use the Decimal Places screen to select no decimal places displayed (i.e., 14) or tenths displayed (i.e., 14.0). The factory default is tenths displayed (i.e., 14.7). Press the (+) or (–) key and Enter to change the decimal display setting.

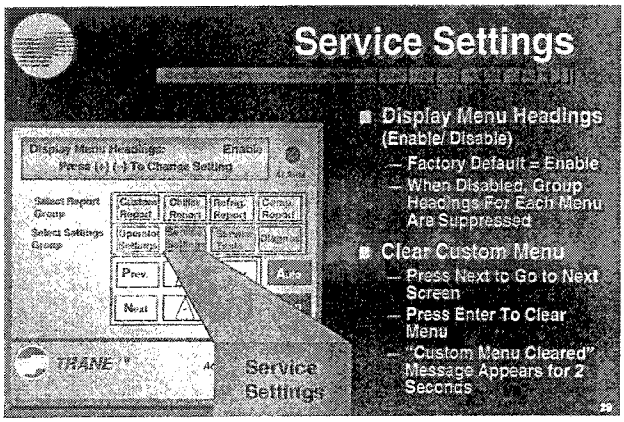

Figure 29

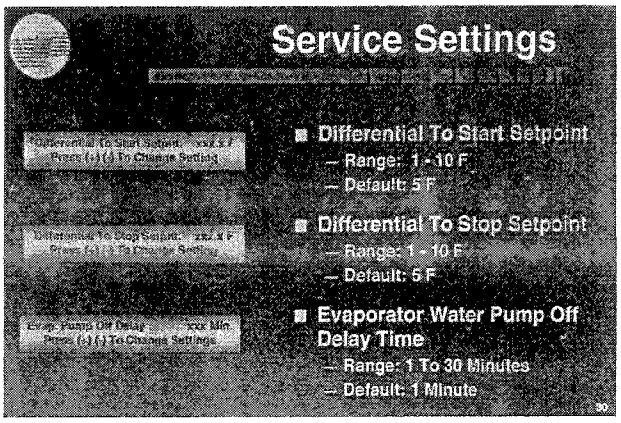

Figure 30

(Figure 29) The Display Menu Headings screen is where the group or menu headings are turned on and off. The operator has a choice of whether or not to view these headings as the first screen that appears when a menu key is pressed.

On one hand, turning off the headings saves the operator from having to scroll through this screen every time a new menu key is pressed. On the other hand, however, this screen verifies which menu the operator is accessing. It is easy to become confused and enter the wrong menu if these are turned off. The factory default is "headings enabled".

Press the (+) or (–) key and Enter to enable or disable the menu headings.

The Clear Custom Menu screen is a feature added at customer request. Pressing Enter at this screen clears all items from the Custom Report. With early versions of the UCP, the operator was required to enter the Custom Report menu and view each item individually in order to remove it from the report. There was no provision to allow the operator to totally clear the report of all items.

Press the Enter key to clear the Custom Report. Press Next to go to the next screen. If Enter is pressed, the Custom Menu Cleared screen will appear for two seconds.

(Figure 30) The Differential To Start Setpoint is the number of degrees above chilled water setpoint that return water temperature must drift before the chiller will start.

Press (+) or (–) to change the displayed setpoint up or down (in degrees F or C). The programmed factory default setpoint is 5 F. The setting range is 1 through 10 F.

The Differential To Stop Setpoint is the number of degrees below setpoint that supply water temperature must drift before the chiller will shut down. Press (+) or (–) to change the displayed setpoint up or down (in degrees F or C). The programmed factory default setpoint is 5 F and the setting range is 1 through 10 F.

The Evaporator Water Pump Off screen allows the operator to adjust amount of time that the chilled water pump will operate after compressor shutdown. Press (+) or (–) to change the displayed setpoint up or down (in minutes). The programmed factory default setpoint is one minute. The setting range is 1 through 30 minutes.

If you try to establish a setpoint above or below the possible range, one of these two messages is displayed on the second line of the screen:

"Top of Range, Press (–) to Advance"
or;
"Bottom of Range, Press (+) to Continue"

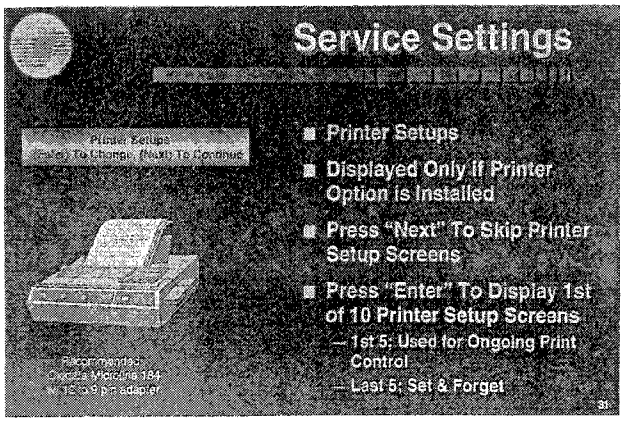

Figure 31

(Figure 31) If a printer is connected to the UCP (which requires the printer interface module), and the printer option has been installed from the Machine Configuration menu, the Printer Setups screen is displayed.

Press Next to go on to next Service Setting screen. Press Enter to view the ten printer setup screens.

The first five of these screens are used for ongoing control of the printer. The rest of the screens are used to set up the permanent printer configuration (as long as that particular printer is connected).

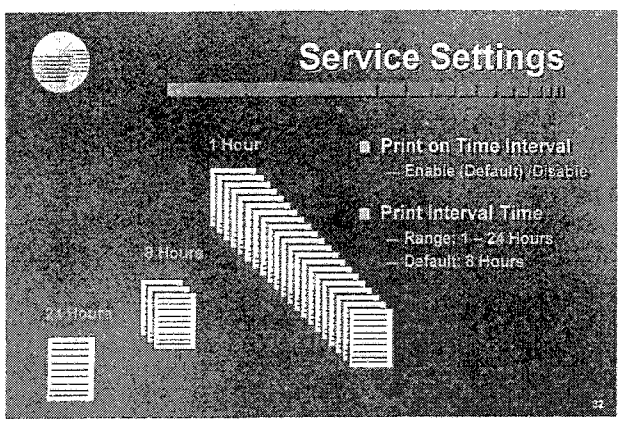

Figure 32

(Figure 32) As you will recall, a set of printed reports can be obtained on demand from the Print Report screen of the Operator Settings. The set consists of a chiller status report and an ASHRAE Guideline 3 report. These two screens allow the operator to select a set of printed reports at specific time intervals.

The operator uses the Print On Time Interval screen to enable or disable time interval report printing. The display will indicate whether this feature is enabled or disabled. Press (+) or (–) to change the setting.

The Print Interval Time screen allows the operator to choose how often the report set is printed. The time interval between printed reports can be set anywhere from 1 hour to 24 hours at one hour intervals.

If the operator sets the interval to 24 hours, then one report is printed every 24 hours. If the operator sets the interval to one hour, then 24 report sets would be printed in a 24 hour period. The default setting is eight hours, which results in the production of three printed report sets every 24 hours.

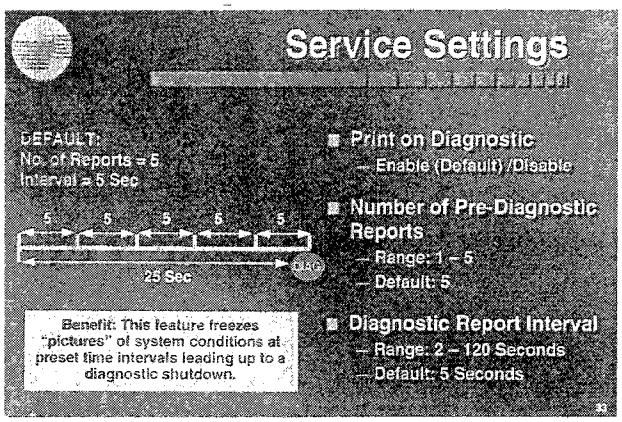

Figure 33

(Figure 33) The Print on Diagnostic screen is used to enable and disable diagnostic printing. The display will indicate whether this feature is enabled or disabled. Press (+) or (–) to change the setting.

These three screens allow the operator to select a specific number of printed report sets at specific time intervals whenever a diagnostic occurs. The Number of Pre-Diagnostic Reports screen allows the operator to choose to print between one and five reports each time a diagnostic occurs. The Diagnostic Report Interval screen lets the operator select the time interval between printed reports when a diagnostic occurs. This can be set anywhere from 2 to 120 seconds at two second intervals.

The default setting is one report every five seconds. The number of reports printed depends on the Number of Pre-Diagnostic Reports setting in the screen above.

The illustration in Figure 33 shows that at the default setting of 5 reports to be printed at 5-second intervals on a diagnostic, you would get a printout of system conditions covering a 25-second period before the diagnostic occurred.

The UPC2 is able to do this because, as we mentioned before, the chiller module is updating the CLD every two seconds, so the UCP is "freezing" a set of data every two seconds during operation.

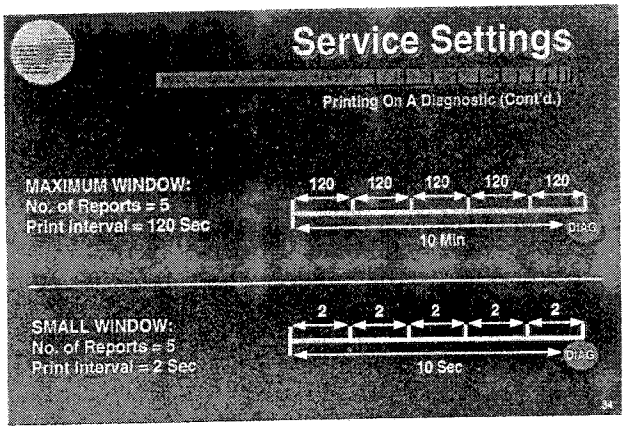

Figure 34

(Figure 34) The Maximum Window example in this figure shows the largest amount of time that can be covered before a diagnostic occurs. (Still using the maximum number of 5 reports).

This example shows that at a setting of five reports to be printed at the maximum 120-second (two minute) intervals on a diagnostic, you would get five printouts of system conditions covering a 10 minute period before the diagnostic occurred.

The Small Window example in Figure 34 shows the minimum amount of time that can be covered before a diagnostic occurs. (Still using the maximum number of 5 reports).

This example shows that at a setting of five reports to be printed at the minimum 2-second intervals on a diagnostic, you would get five printouts of system conditions covering a 10-second period before the diagnostic occurred.

By varying printed report output, the operator can pinpoint problems that may be developing that could cause diagnostics to occur.

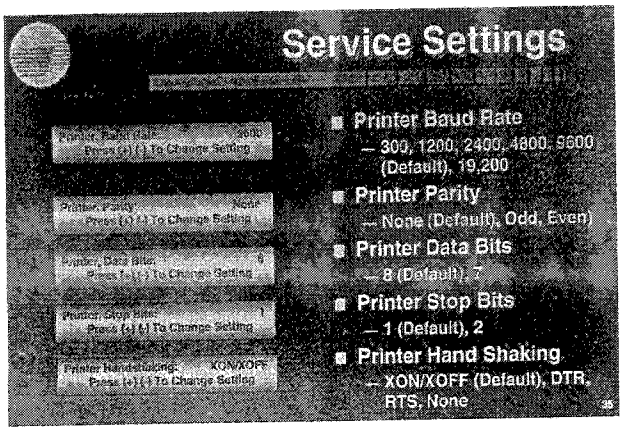

Figure 35

(Figure 35) The remaining printer setup screens are used to set printer configuration parameters that are permanent once they are set for the printer being used. These settings are printer baud rate, printer parity, printer data bits, printer stop bits and printer hand-shaking.

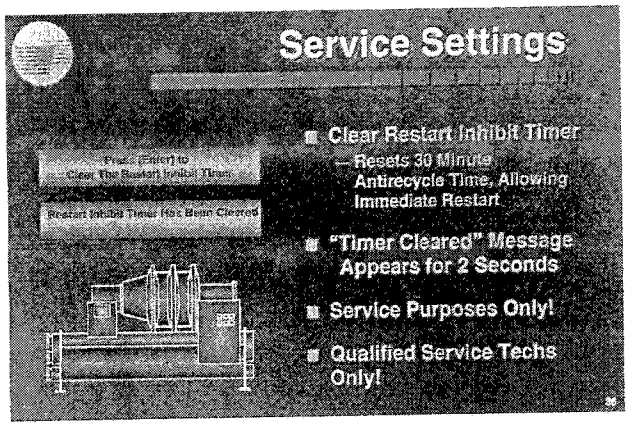

Figure 36

(Figure 36) The Clear Restart Inhibit Timer screen is provided to allow servicing personnel convenient access to a means of zeroing the restart inhibit timer so the machine can be restarted. To zero the timer, just press Enter when viewing this screen.

The restart inhibit timer protects the compressor motor and starter from damage that can be caused by short cycling (too frequent restarts). The amount of time on the timer varies with the type of chiller and size of compressor. Minimum time setting is 30 seconds for all chillers. Maximum is 8 minutes for RTHB and 60 minutes for CVHE/F units. This time can vary with each restart, because the timing also depends on motor temperature.

Service Tests

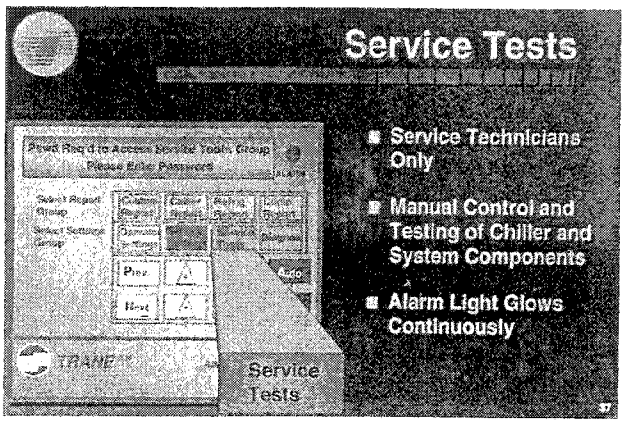

Figure 37

(Figure 37) The Service Tests menu, which is not discussed in detail in this course, provides a service technician the ability to manually control and test the functioning of the following components:

- Evaporator (chilled) water pump
- Condenser water pump
- CTV oil pump
- CTV inlet guide vanes
- RTHB electronic expansion valve
- RTHB slide valve
- Condenser and evaporator water flow switches

This menu, which is intended for use by qualified service personnel only, also allows the technician to test starter contactor integrity by performing a starter "dry run" test.

Note: The "Alarm LED" on the CLD will be lighted continuously when any service test procedure is being conducted.

Diagnostics

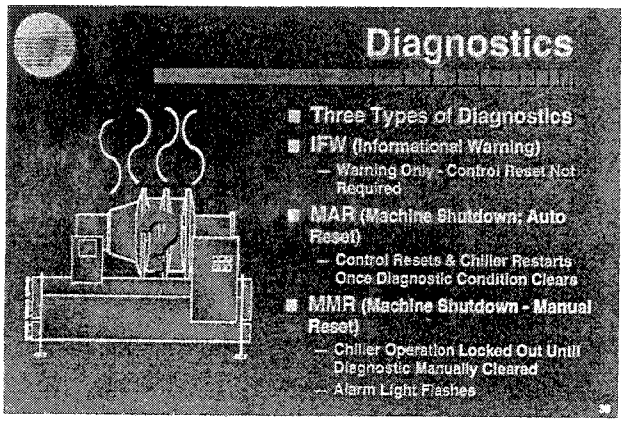

Figure 38

(Figure 38) The UCP2 recognizes three types or "levels" of diagnostics. The lowest level diagnostic, the informational warning (IFW) **does not** shut down the chiller. Both of the other two diagnostic types, MAR (machine shutdown / auto reset) and MMR (machine shutdown / manual reset) **will** shut down the chiller.

Only the highest level diagnostic, the MMR type, requires a manual reset of the control system to restart the chiller. MAR type diagnostics will allow the chiller to automatically continue operation once the diagnostic condition is corrected.

When an MMR occurs and the chiller shuts down, the alarm light on the face of the CLD flashes until the UCP is reset.

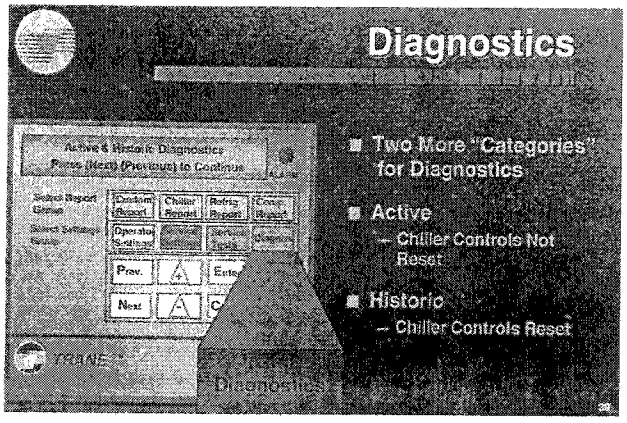

Figure 39

(Figure 39) Pressing the Diagnostics key displays the Diagnostics group or menu heading shown in this slide. If the group (menu) heading does not appear, the headings have been disabled. They can be restored from the Basic Setups area of the Service Settings menu.

The Diagnostic menu is used to view the diagnostic log and clear active and historic diagnostics from the UCP memory. Press Next to continue to the Menu Settings Password screen.

In addition to diagnostic types or levels, diagnostics are also categorized as being either "active" or "historic". Once active diagnostics are cleared, they become historic diagnostics.

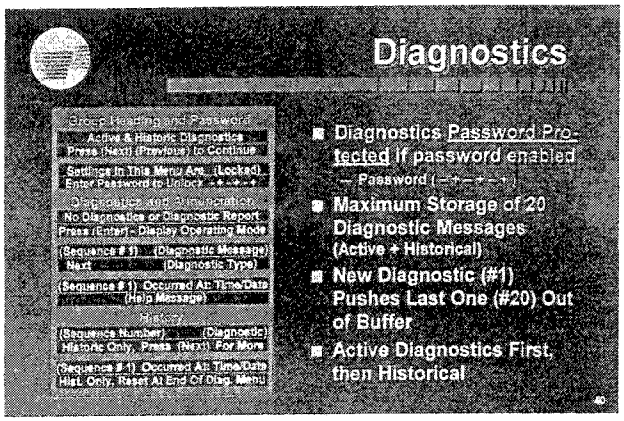

Figure 40

(Figure 40) Figure 40 shows the initial display screens and the organization of the diagnostic menu. As in all other menus, the Password Settings screen indicates that the settings in the menu are either locked or unlocked. If they are locked, the operator can unlock them by pressing (– + – + – +) followed by the Enter key.

Once unlocked, the operator can use the menu. If this screen does not appear, then the menu settings display feature has been disabled from Field Startup menu of the Service Settings Group. If there are no diagnostics present in the log, the only screen that displays is "No Diagnostics Present / Press (Next) Previous to Continue". If there are diagnostics in the log, the Diagnostic Report Follows / Press (Next) for More screen is displayed.

The next screen is "Press (Enter) to Display Operating Mode At Time of Last Diagnostic or (Next) for More". Pressing Enter displays the operating mode screen that was active when the diagnostic occurred. Pressing Next goes straight to the diagnostic log.

The log will display up to 20 **total** diagnostics (active + historic), in order of occurrence and are numbered one through 20. If the buffer is full, the last (#20) diagnostic is pushed out of the buffer when a new one is added.

In the log, active diagnostics are displayed on two screens. The first screen for each lists the diagnostic number, name and type. The second screen gives the diagnostic number, the time and date of occurrence and a help message, suggesting possible service procedures to consider.

Historic diagnostics are listed after active ones. If there are 20 active diagnostics, there can be no historics, since the log only holds 20 diagnostics. Historic diagnostics are also displayed on two screens. The first gives diagnostic number, type and shows that it is historic only. The second gives diagnostic number, the time and date of occurrence and shows that it is historic.

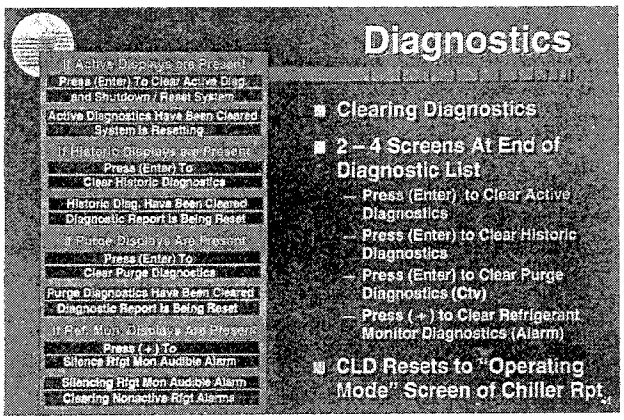

Figure 41

(Figure 41) Once the CLD is displaying the diagnostic log, the operator should scroll through the log, noting the types of <u>all</u> diagnostics present, the times that they occurred and any help messages displayed. This is recommended because once active diagnostics are reset they enter the history buffer. This may cause some entries already in the history buffer to be deleted before the operator could see them. All active diagnostics will be lost on a loss of power.

Note: All purge and refrigerant monitor diagnostics will be listed in the history buffer and they could be pushed out before the operator can view them.

All diagnostics can be cleared from the <u>local</u> CLD. The Clear Diagnostics screens are located at the end of the diagnostic log.

When the operator clears the active diagnostics they enter the Historic buffer and the Cleared / Resetting screen appears for 2 seconds. When the operator clears the historic, purge or refrigerant monitor diagnostics, the Cleared / Resetting screen appears for 4 seconds. Once diagnostics have been cleared, the CLD reverts to the Operating Mode screen of the Chiller Report menu.

Note: If the condition that caused the diagnostic to appear is not corrected, the diagnostic will be re-established.

MENU SECURITY REVIEW

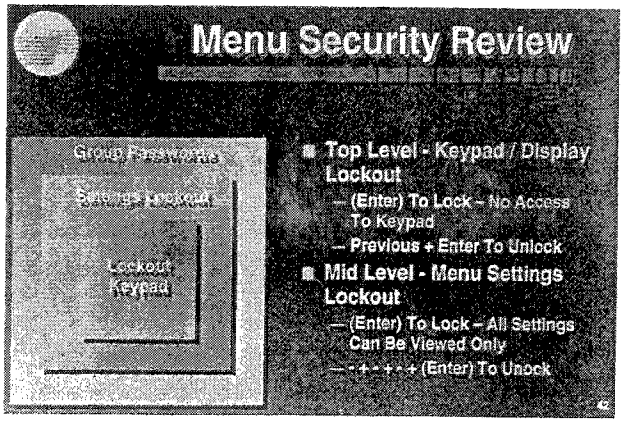

Figure 42

(Figure 42) Figures 42 and 43 provide a review of the UCP2 menu security system. At the top level of security, the whole keypad can be locked out. NO KEYS FUNCTION!

Remember:

The keypad is locked from one of the first screens in the Basic Setups of the Service Settings group. To unlock a locked keypad, press the Previous and Enter keys simultaneously.

Locking out the keypad disables the Auto and Stop keys.

At the next level, the settings in any settings menu can be locked by enabling the Menu Settings Password screens.

Remember:

The menu settings password protection is enabled (and disabled) from the Field Setup menu of the Service Settings group. (This enables the menu settings password screen for all menus at once. You can have all enabled or disabled but not just certain ones.)

The settings for each menu can be locked or unlocked at the second screen of each menu if this feature has been enabled.

Press Enter to lock or press (– + – + – +) and Enter to unlock.

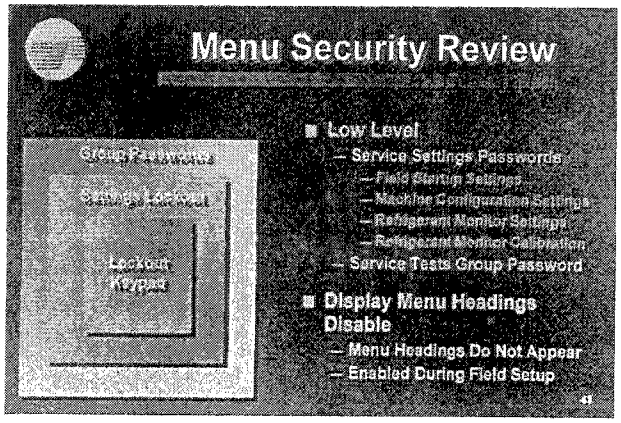

Figure 43

(Figure 43) At the lowest level, certain individual menus have specific passwords. They are:

- **Service Settings Passwords**
  - **Field Startup Settings**
  - **Machine Configuration Settings**
  - **Refrigerant Monitor Settings**
  - **Refrigerant Monitor Calibration**
- **Service Tests Group Password**

These passwords are provided in the chiller IOM manual.

Although not really intended as part of the menu security scheme, the ability to prevent the menu headings from being displayed could be used to discourage unauthorized UCP use, since it is likely more difficult for an person unfamiliar with the menu system to use the clear language display without the menu headings.

OPERATING WITH UCP2

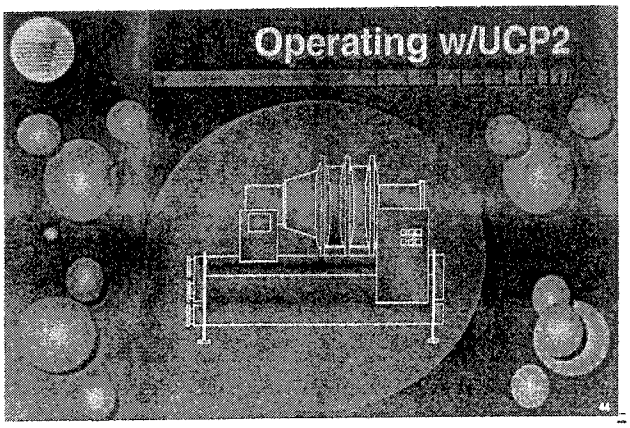

Figure 44

(Figure 44) The final section of this manual describes basic chiller operation, including specific operating sequences; auto operation and the chiller stop sequence. It also discusses routine chiller logging procedures, report printing duties, briefly reviews what to do when diagnostic shutdowns occur and how the remote clear language display is used.

Power-Up Sequence

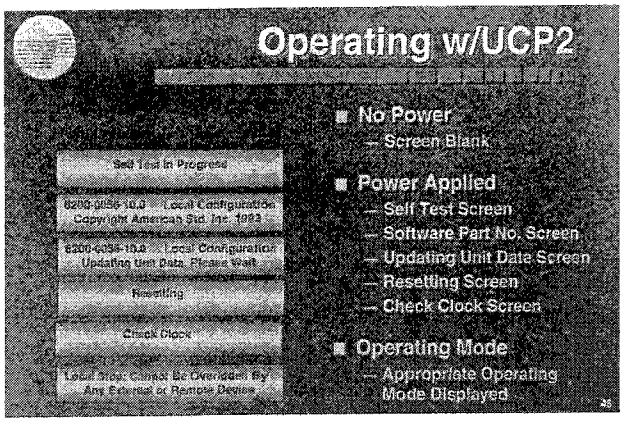

Figure 45

(Figure 45) When electrical power is off, the CLD screen is blank as shown in the first screen of Figure 45. When power is first applied, the UCP goes through a "power up" routine. The power up sequence takes 20 seconds before the CLD enters the Stop operating mode. During power up, the UCP performs a series of self-diagnostics (Self-Test screen).

The Software Part No. screen is the identifier of the software version that is installed in the UCP.

The Check Clock screen is a reminder to be sure that the chiller clock is set correctly. It doesn't keep time when power is removed from the UCP.

While the Updating Unit Data screen is displayed, the CLD is retrieving all available data from the chiller module memory about unit configuration and setup.

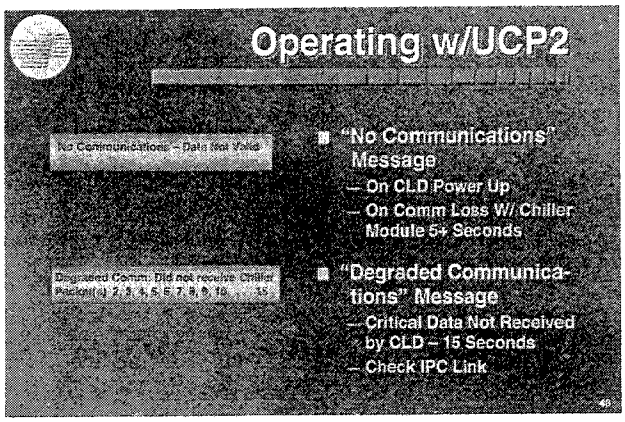

Figure 46

(Figure 46) The settings used by the chiller are stored in the chiller module, not in the CLD. The chiller module contains the non-volatile memory that stores these settings when power is removed. It also has to verify that none of the settings in memory have been corrupted. If any have, it will substitute default settings instead.

The CLD just stores copies of settings so it can display and change them. The original settings in the chiller module are not changed until Enter is pressed after making a change.

If upon power up, there is no communication with the chiller module, the No Communications screen is displayed. This screen will reappear any time that all chiller module communications are lost for more than five seconds.

Note: If certain critical data is not received by the CLD from the chiller module every 15 seconds, an IFW diagnostic (Degraded Communications screen) is generated. The chiller can run in this condition, using setpoints already in memory. Check the IPC link wiring and connections. The CLD will return to normal once communications are re-established.

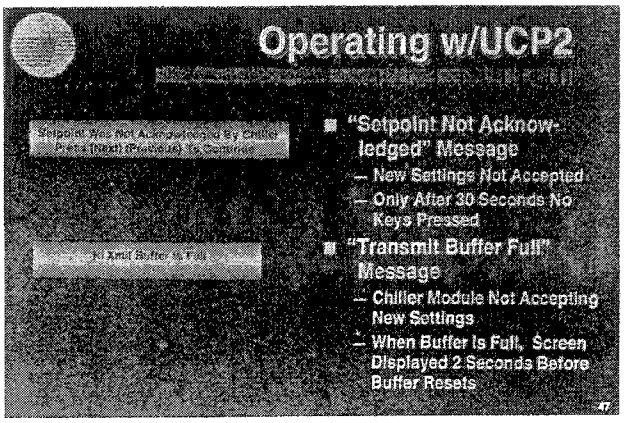

Figure 47

(Figure 47) During operation, if a settings change is made and communicated to the chiller module, but is not accepted after 30 seconds of no key activity on the CLD, the Setpoint Not Acknowledged screen is displayed at the end of the chiller report.

If you enter a lot of settings changes (send them to the chiller module) that are not acknowledged by the chiller module, then the CLD transmit buffer will become full of data and won't be able to take any more changes. If this happens, the Transmit Buffer Full message is displayed for two seconds before the CLD clears the buffer and all the changes are lost. If you get this message, there is a problem between the chiller module and the CLD.

Auto Key

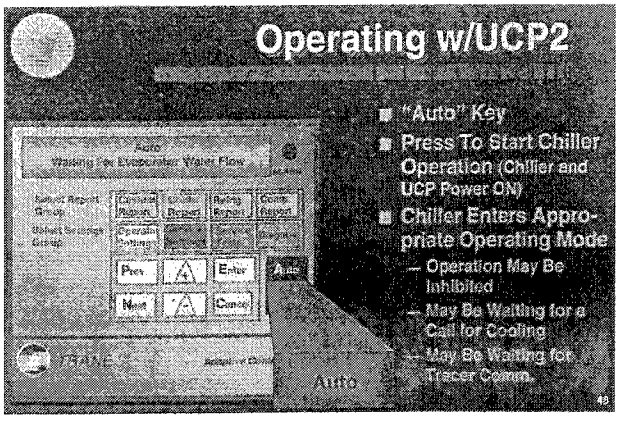

Figure 48

(Figure 48) To start the chiller from a power up or from a Stop condition after a normal shutdown, press the Auto key. Whether or not the chiller starts, depends upon many variables, including differential to start condition, whether the restart inhibit timer is timed out, whether or not Tracer communications have been established, etc. The CLD will indicate what is happening by displaying the appropriate operating mode screen.

Chiller Operating Sequence

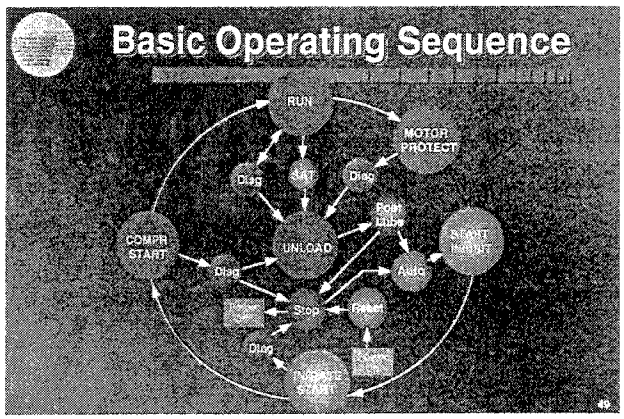

Figure 49

(Figure 49) As we have just seen, from a Power Off condition following a normal shutdown, the UCP goes through a power up (reset) sequence that performs self diagnostic tests and resets the control system for renewed operation.

Once this procedure is complete, the control enters a Stop condition (operating mode) and waits for a start command. Then the restart inhibit timer begins timing out and on CenTraVacs, the inlet guide vanes are driven closed for 50 seconds to insure that the compressor starts unloaded. Also during this time, inlet guide vane operation is tested. This is done on all control resets and on a call for cooling after 24 hours of no cooling.

When operating mode is set to Auto by pressing the Auto key, the chilled water pump starts. Chilled water flow must be proven in 3 minutes. If the UCP has received a call for cooling and 30 seconds or less remain on the restart inhibit timer, the UCP will enter the Initiate Start mode, starting the condenser water pump. Condenser water flow must be proven in 3 minutes.

On CenTraVacs, the oil pump starts also. 9 psid oil pressure must be proven in 3 minutes. On entering Initiate Start for RTHB units, the master oil line solenoid is energized, the oil heater is turned off and the unload solenoid valve is energized for 30 seconds to insure an unloaded compressor start. At the end of the restart inhibit time period, the UCP performs a starter test.

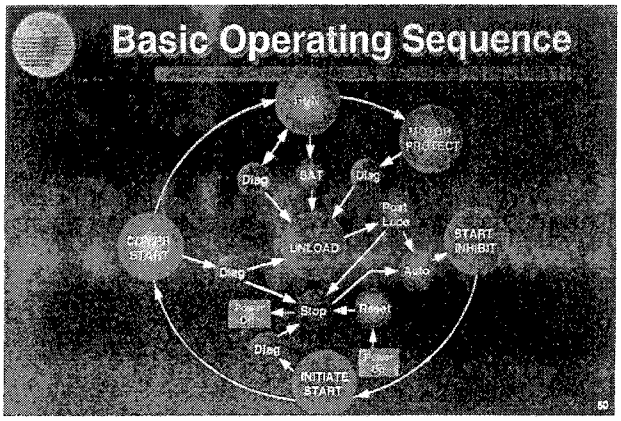

Figure 50

(Figure 50) After a successful starter integrity test, the UCP sends a start signal to the compressor motor. The motor starts in Wye configuration and the maximum acceleration timer starts timing out. On CenTraVacs, the vent line solenoid valve closes temporarily. Once the compressor has accelerated and maximum phase current drops below 85% of name-plate RLA for 1.5 seconds, the starter initiates transition to Delta configuration. Proof of transition must occur within 2.5 seconds of transition initiation. During compressor start, diagnostics can occur that will cause the compressor to unload or unload / stop. Once compressor is running normally, inlet guide vanes (CTV) or unloader slide valve (RTH) are modulated to satisfy the chilled water setpoint. During operation, numerous diagnostics can occur that will cause the compressor to unload or unload / shut down. Also, the compressor may stop due to the fact that the cooling load is satisfied. During normal operation, motor protection devices are active that can generate diagnostics that will unload or unload and shut down the compressor.

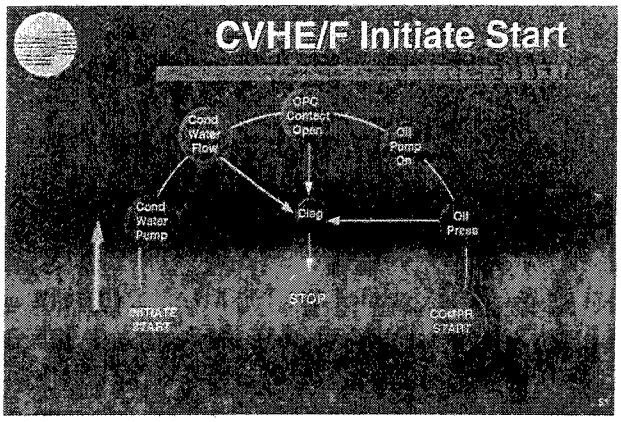

Figure 51

(Figure 51) Initiate Start mode begins when the UCP issues a call for cooling and less than 30 seconds remain on the restart inhibit timer. If the chiller is in a Stop mode, the chilled water pump starts when the Auto key is pressed. If the chiller is already in Auto mode and has shut down because cooling load is satisfied and is just restarting due to a need for cooling, the chilled water pump will have been operating continuously.

For CenTraVac units, when Initiate Start mode begins, the condenser water pump starts. Condenser water flow must be proven within 3 minutes or a diagnostic is generated that sends the chiller into a Stop condition. Also, the UCP checks for an open oil pump start contact. An open contact will result in a diagnostic that sends the UCP back to a Stop condition.

Then the oil pump is started. The UCP must verify nine psid oil pressure for 30 contiguous seconds before compressor start. If not, a diagnostic is generated that sends the chiller back to a Stop mode.

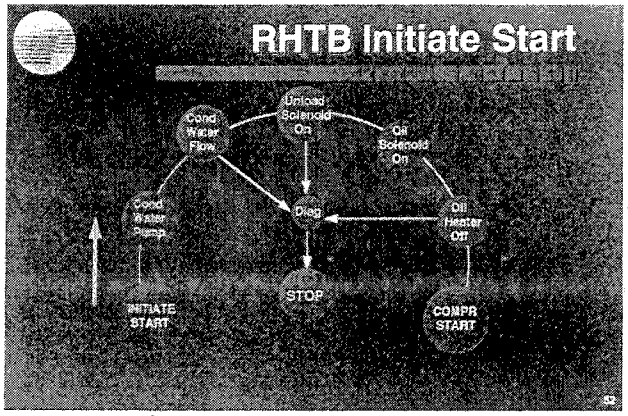

Figure 52

(Figure 52) When Initiate Start mode begins for RTHB units, the condenser water pump starts. Condenser water flow must be proven within 3 minutes or a diagnostic is generated that sends the chiller into a Stop condition. The master oil line solenoid valve is energized, the oil sump heater is turned off and the slide valve unload solenoid valve is energized for 30 seconds to make sure the compressor starts unloaded.

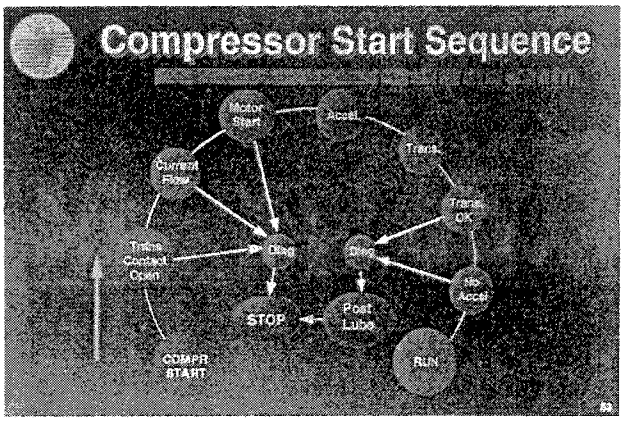

Figure 53

(Figure 53) Compressor Start begins with a UCP test to insure that the transition-complete contact is open. If it is closed, a diagnostic is generated and the chiller enters a Stop condition. The UCP then checks the start (Y-Delta only) and shorting (all starters) contactors for No Current. Current at either contactor generates a diagnostic and the chiller enters a Stop condition.

As previously described, after the starter integrity test, the UCP sends a start signal to the compressor motor. The motor starts and the acceleration timer starts timing out. Once the compressor has accelerated, the starter initiates transition to Delta configuration. Proof of transition must occur within 2.5 seconds of transition initiation. If the compressor motor does not accelerate to proper speed within the limit of the maximum acceleration timer (5 seconds for RTHB, 27 seconds for CVHE/F), a diagnostic is generated and the chiller enters a Stop condition. Then, on CVHE/F units, the vent line solenoid valve opens back up.

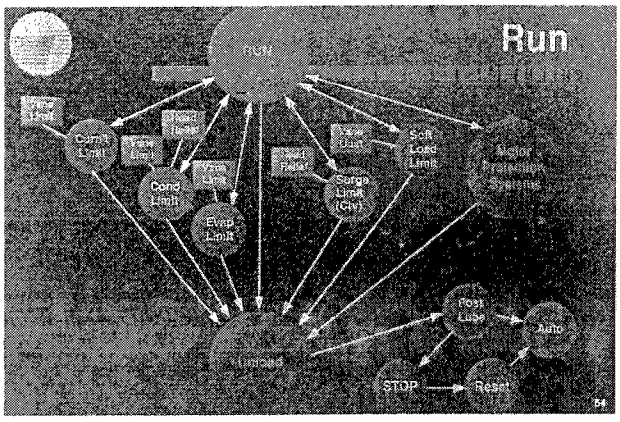

Figure 54

(Figure 54) Once the compressor runs normally, the inlet guide vanes (CTV) or unloader slide valve (RTH) are modulated to satisfy the chilled water setpoint.

Again, during operation, numerous diagnostics can occur that will cause the compressor to unload or unload and shut down. Also, the compressor may stop due to the fact that the cooling load is satisfied.

During normal operation, various motor protection devices are active that can generate diagnostics that will unload or unload and shut down the compressor Once in Run mode, the chiller can operate in various load-limiting sub-modes, depending on system and chiller conditions. These include Current Limit, Evaporator Limit, Condenser Limit, Surge Limit, Softloading, etc. During limit conditions, the UCP utilizes a vane (CTV) or slide valve (RTH) limit function that prevents loading or unloads the compressor as the condition increases. The objective is to keep the chiller on line and avoid a shutdown.

Stop Sequence

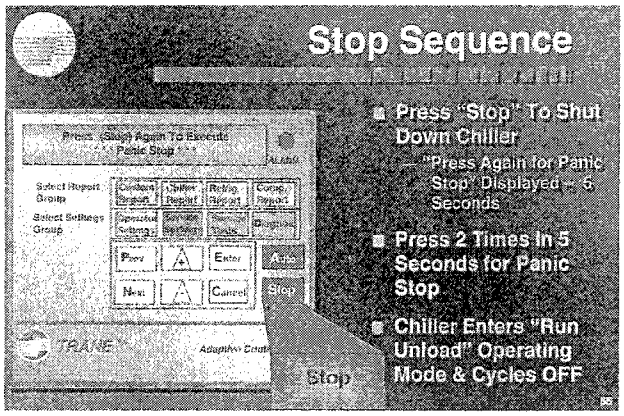

Figure 55

(Figure 55) Press the Stop key to shut down chiller operation. The Press (Stop) Again screen will appear for five seconds, giving the operator a chance to perform a Panic Stop.

If the operator presses the Stop key again while this screen is displayed, the chiller will enter a "Panic Stop" condition. On the other hand, if the Press (Stop) Again screen is allowed to pass, the chiller will enter the "Run Unload" operating mode and shut down normally.

Once shutdown is complete, the CLD reverts to the appropriate Operating Mode screen. This may be the group heading or menu password screen if they are enabled. If not, the CLD will show an actual operation mode. If shutdown is due to an MMR or MAR, a diagnostic warning screen will appear.

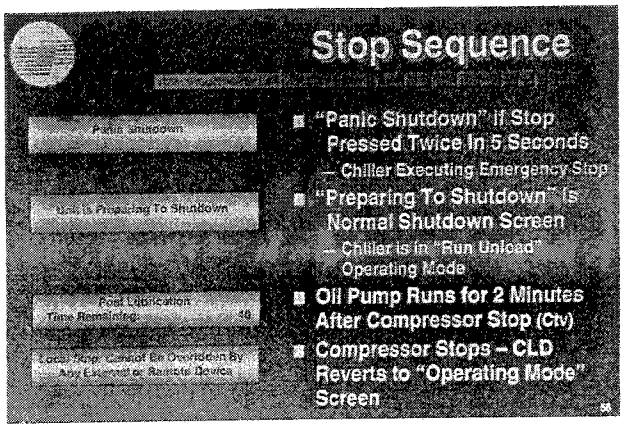

Figure 56

(Figure 56) If the operator selected panic stop, a Panic Shutdown screen appears while panic stop sequence is executed. If the chiller is allowed to shut down normally, it will enter "Run Unload" operating mode and display Unit Is Preparing to Shutdown. If the chiller is shutting down because the cooling requirement has been satisfied, then it goes directly into "Run Unload" mode without displaying the Press Again for Panic Stop screen. The chilled water pump continues to run.

CVHE/F Stop Sequence

During "Run Unload" mode, the compressor is gradually unloaded by closing the inlet guide vanes. Once fully unloaded, the compressor stops, condenser water pump turns off, and the chiller enters "Post Lube" mode (Figure 56). The screen shows the amount of time left for continued oil pump operation. Once the two-minute post lube function times out, CLD reverts to the appropriate Operating Mode screen. The chilled water pump shuts off after the delay timer times out.

RTHB Stop Sequence

During "Run Unload" mode, the unload solenoid energizes (20 seconds) and the load solenoid deenergizes. The compressor continues to run. The slide valves move away from the rotors, unloading the compressor. After 20 seconds, the compressor turns off, the master oil line solenoid turns off, the crankcase heater turns on and the condenser water pump turns off. The electronic expansion valve travels to full open and the CLD reverts to the appropriate Operating Mode screen. The chilled water pump shuts off after the delay timer times out.

Panic vs. Normal Stop

A panic stop differs from a normal stop in that, during a panic stop, the compressor stops immediately without unloading.

Chiller Logging

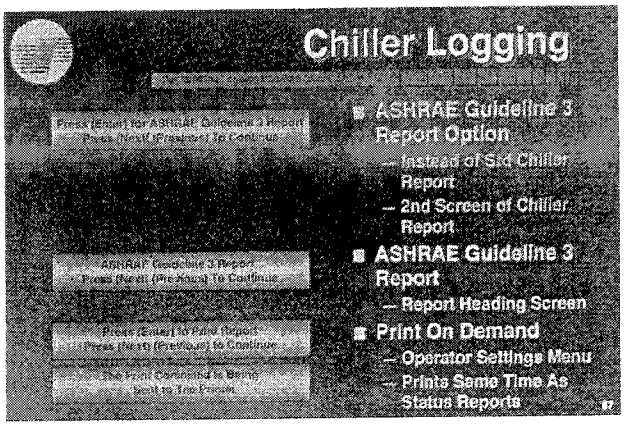

Figure 57

(Figure 57) One of the primary reasons for logging a chiller is to keep a running record of refrigerant and oil usage. In 1995, a new feature was implemented in the Chiller Report to allow an operator to view an ASHRAE Guideline 3 Report (See Note below).

This report is a compilation of data points from various UCP2 reports that ASHRAE recommends be monitored and logged daily to prevent refrigerant loss. This recommendation applies specifically to centrifugal and large positive displacement (medium and high pressure) systems.

This report is accessed at the second screen of the chiller report. At that point, the operator has to decide whether to view the standard UCP2 chiller report, or view the ASHRAE Guideline 3 report. If Enter is pressed, then the ASHRAE Guideline 3 report heading appears. Then press Next to view the report items.

In addition, the "Guideline 3" report can be added to the UCP Custom Report **as a single item**, which greatly increases the number of data points available in it.

The ASHRAE Guideline 3 report can be useful for maintaining proper records for a refrigerant management program. This report will be printed any time that a chiller status report is sent to the printer. If the printer is set up to print on a time interval or on a diagnostic, then the ASHRAE report will print also. Remember, that the print on demand screen (shown above) is located in the Operator Settings menu.

Note: The ASHRAE Guideline 3 report is not found on earlier-model UCP2 panels. This means that on those panels, the operator can view only the normal chiller report and print out only the chiller status report.

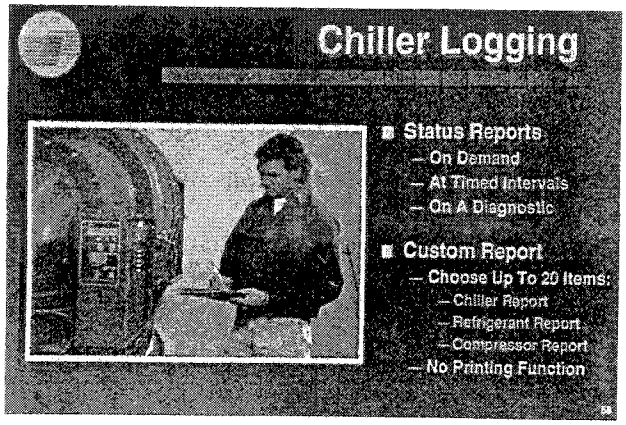

Figure 58

(Figure 58) This slide should be entitled "Chiller Logging Made Easy", because that's one of the biggest benefits of UCP2.

It's standard operating procedure to maintain a regular log of chiller operating conditions. Even with UCP1, this was a laborious procedure, requiring the operator to access each coded item on the UCP display and record it, measure water flows and pressures separately and record them, etc.

With UCP2, nearly all the data you need to view in order to log the chiller is available through your custom, chiller, refrigerant and compressor reports.

If a printer is installed, then your job is even easier. Chiller "Status" and "ASHRAE Guideline 3 Reports" are available whenever you need them. They can be printed on demand, at timed intervals and also any time a diagnostic occurs.

Remember, the "print-on-demand" function is found in the Operator Settings menu and the "print-at-intervals" and "print-on-diagnostics" are set up in the Basic Setups of the Service Settings menu. That's a lot of printed data available at your fingertips without ever having to enter the Chiller, Refrigerant or Compressor Reports.

If you could possibly still need any additional items of data that are not included in the printed reports, you can set up 20 additional items to show up in your Custom Report. The only drawback this is that the Custom Report can't be printed.

Diagnostic Shutdown Recovery

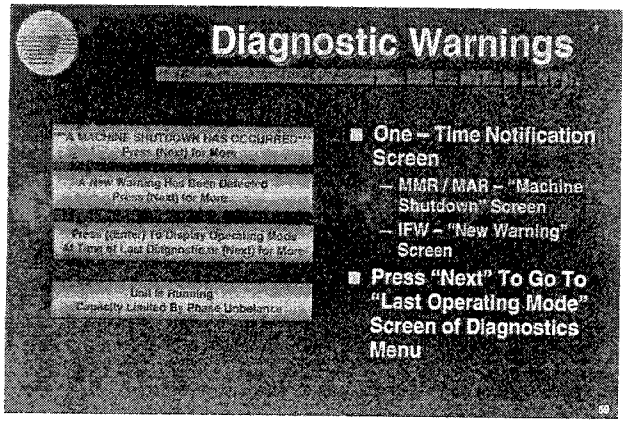

Figure 59

(Figure 59) What happens when a diagnostic occurs? It depends on the kind of diagnostic. If it's a "show-stopper", meaning an MMR (Machine Manual Reset) or an MAR (Machine Auto Reset) type, then the chiller will shut down and the CLD will display the first screen shown above:

"A Machine Shutdown Has Occurred"

Remember, in the case of the MAR, the condition that caused the shutdown may clear itself and the chiller will restart. If not, then the machine will restart once the condition is corrected.

An MMR, however, requires that the operator manually "clear" the diagnostic to reset the system controls before the chiller can restart.

If the diagnostic is an IFW (Informational Warning) type, then the A New Warning Has Been Detected screen is displayed but the chiller does not shut down.

When one of these screens is displayed, the operator must press the Next key. This will take the operator to the 3rd screen shown in this slide which is part of the diagnostics menu:

"Press (Enter) To Display Operating Mode At Time of Last Diagnostic or (Next) for More"

The Operator will press Enter to view the last screen shown on this slide which indicates what operating mode the chiller was in when the diagnostic occurred. The operator can choose to press Next instead, which skips this screen and advances straight to the diagnostic log.

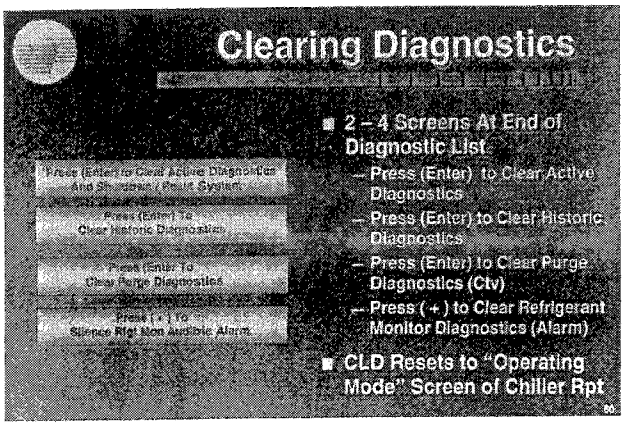

Figure 60

(Figure 60) Once the CLD is displaying the diagnostic log, the operator should scroll through the log, noting the types of diagnostics present, the times that they occurred and any help messages displayed.

The Clear Diagnostics screens are located at the end of the diagnostic log. When the operator clears active diagnostics, the Cleared / Resetting screen appears for 2 seconds. When the operator clears historic, purge or refrigerant monitor diagnostics, the Cleared / Resetting screen appears for 4 seconds. Once diagnostics have been cleared, the CLD reverts to the Operating Mode screen of the Chiller Report menu.

Note: If the condition that caused a diagnostic to appear is not corrected, the diagnostic will repeat.

Remote CLD

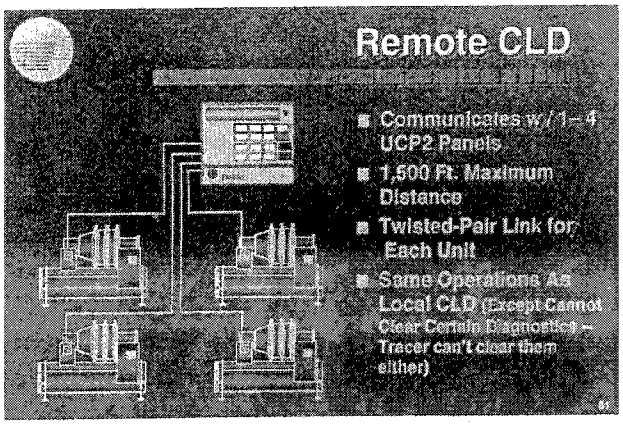

Figure 61

(Figure 61) The last four figures in this manual are a quick review of the remote clear language display (CLD) capabilities and a brief discussion of how the displayed information varies from the screens of the chiller-mounted CLD.

Each UCP2 panel can support two clear language displays, one on the chiller and a remote-mounted one. The remote CLD can be as far away as 1,500 feet from the chiller. The communication link is a simple twisted-pair wire.

The remote CLD will communicate with up to four UCP2 chillers if an optional board is added to it. The chillers do not have to be the same type (CVHE/F, ABS, RTHB). Each chiller must have the optional IPCB (interprocessor communications buffer) module in order to communicate with the remote CLD.

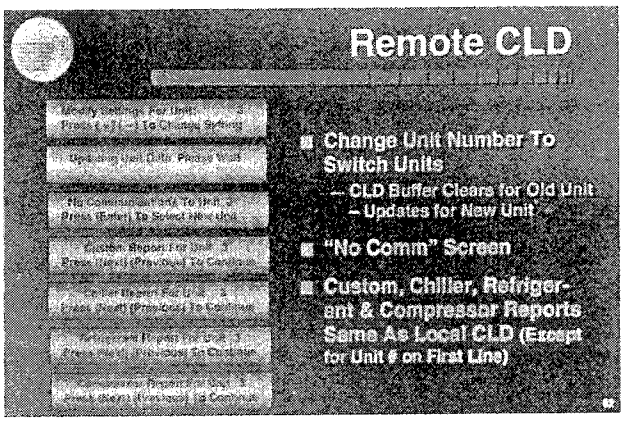

Figure 62

(Figure 62) The displays that appear at the remote CLD are identical to the ones on the unit-mounted CLD except when the "multiple unit" option board is installed. This option enables the remote CLD to communicate with multiple chillers.

When this option is present, the second screen in each group is the Modify Settings for Unit # screen. The operator must enter the number of the chiller being accessed. When the "unit number" is entered, the CLD clears its buffer of data for any other chillers and updates it with the new data.

The Updating Unit Data screen will appear for 5 seconds or until the data is updated, whichever comes first. If data is not received in 5 seconds, the No Communication ... screen appears. Pressing Enter at this time, sends the display back to the first screen above.

When each report or settings group key is pressed, the Report for Unit # or Settings for Unit # screen will be the second screen followed by the Updating Data screen.

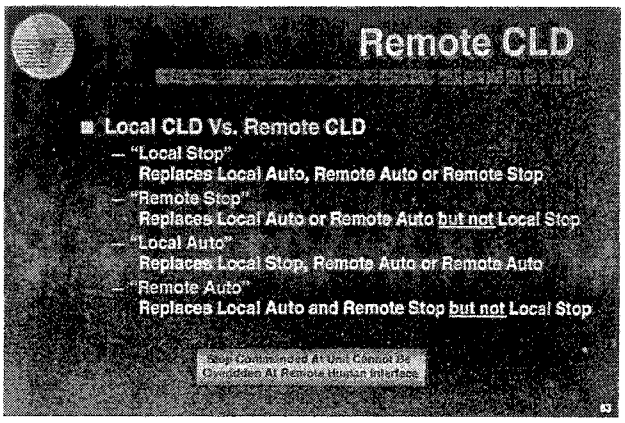

Figure 63

(Figure 63) This slide is provided as a quick review of the UPC2 operating priorities. This is how the UCP determines when an Auto or Stop command will be accepted and stored into memory. The chiller module stores the source of the current Auto or Stop command. If an Auto command is given from the remote CLD when the chiller is "stopped" from the local CLD, the Stop Command at Unit Cannot Be Overidden ... screen shown in this slide is displayed. Local and Remote Stop are highest priority.

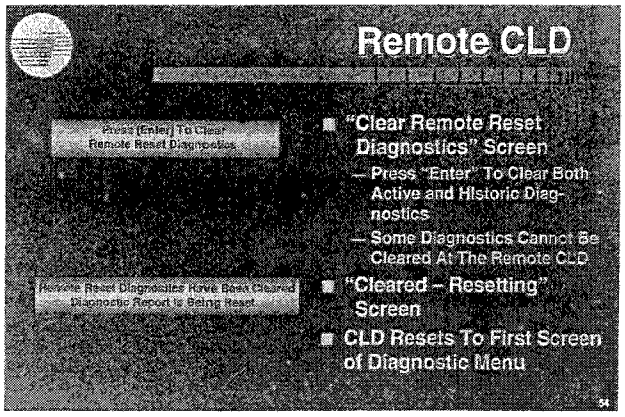

Figure 64

(Figure 64) When using the "clear diagnostic" function at the Diagnostic Menu of the remote CLD, the Press Enter to Clear Remote Diagnostics screen appears. When Enter is pressed, the Remote Reset Diagnostics Have Been Cleared screen appears momentarily, and the display reverts back to the top of the diagnostic menu.

All functions of the chiller-mounted CLD can be accomplished with the remote CLD except for the clearing of certain MMR (manual reset) diagnostics that must be reset at the local CLD on the chiller. Refer to the chiller installation, operation and maintenance manual for a complete list of these diagnostics.

SUMMARY

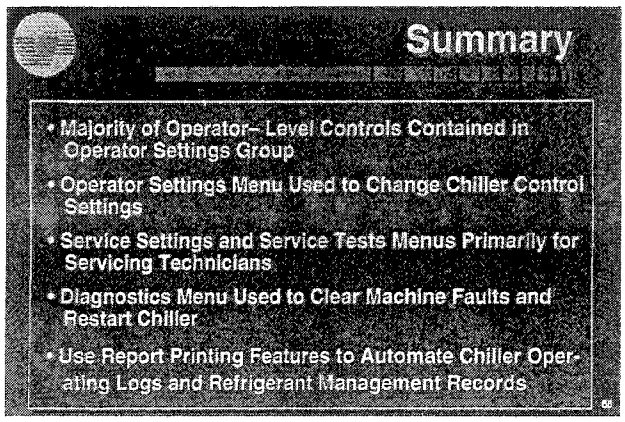

Figure 65

(Figure 65) Most of the control functions that an operator will deal with are located in the Operator Settings menu. There will, of course, be times that it will be necessary to use other portions of the control system. At those times, it will probably be necessary to refer to the IOM literature or consult a service representative.

Factory setup personnel use the Machine Configuration menu of the Service Setting group to establish settings for factory required categories according to the chiller order and design criteria. Once on the job, the setup technician will use the Field Setup menu to tailor the machine to the job.

The only portion of the Service Settings group that the operator will use more or less routinely, is the Basic Setup menu, where the operator can lock and unlock the keypad, change how the CLD displays headings and security menus, set the chiller start and stop differentials, set the chilled water pump delay time, control printer operation and clear the restart inhibit timer.

The operator will have to access the Diagnostic menu in order to look at and clear diagnostics and keep an eye on purge and refrigerant monitor operation.

Finally, with a printer connected, the report printing features of the UCP2 can be used to help keep machine logs, refrigerant usage records, and help pinpoint potential machine problem areas.

Literature Change History

CVHE-CLD-1 (February 1995)

Application of the Clear Language Display to the UCP2 Centravac

CVHE-CLD-1A (June 2000)

Updated information and incorporated FastPak™ items.

About This Manual

This manual describes the application of the Clear Language Display (CLD) to the UCP2 Centravac. It describes its use as a machine-mounted human interface.

A description of the UCP2 reports and message displays are provided along with additional "Help Notes" to clarify the display messages. In addition, a Diagnostics section is also included.

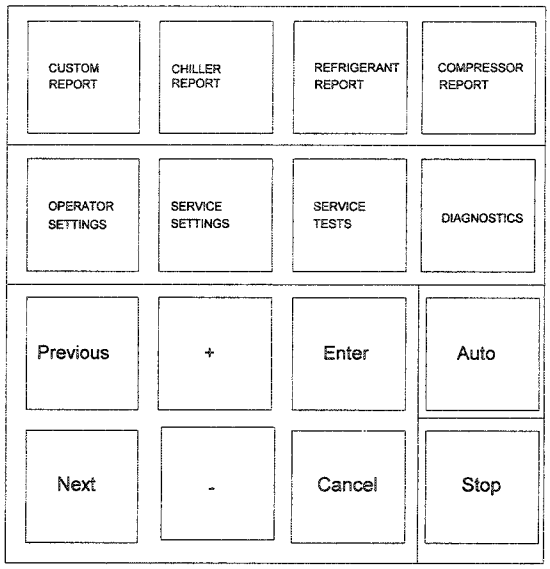
LCD Display

The display on the Clear Language Display is a 2-line by 40-character liquid crystal display (LCD). Upper and lower case alphabetic characters can be displayed, along with numeric and special characters.

LCD Backlight

The LCD display has an LED backlight so it can be read in low light conditions.

Keypad



A sealed dirt-proof keypad is used on the unit mount Clear Language Display. Metal dome switch actuators respond when any key is pressed. See *Figure 1* .

Important! *FACTORY DEFAULT SETTINGS: Menu items that are programmable using the keypad may have a selectable choice that is listed as Factory Default. This Factory Default setting is the software default that is initially factory-programmed for a new module assembly and may NOT be the correct setting for a specific operating chiller. Always review all settings when any module is replaced to verify that the settings agree with the desired settings that were selected at initial startup or programmed at the factory.*

LED Alarm

In addition to the alpha-numeric LCD display, there's a single discrete LED on the human interface. The red LED flashes on-off whenever a latching diagnostic is present and a manual reset is required to restore full unit operation. The LED is also used to indicate that a function or control has been set to manual from within the ***Service Test*** Menu. If a control has been set to manual, the LED is on and non-flashing. A diagnostic supersedes a manual operation. As a result, the unit could have a manual mode set and be in a latching diagnostic. In this case the LED would flash on-off. The LED is off otherwise.

Figure 1
Keypad Matrix

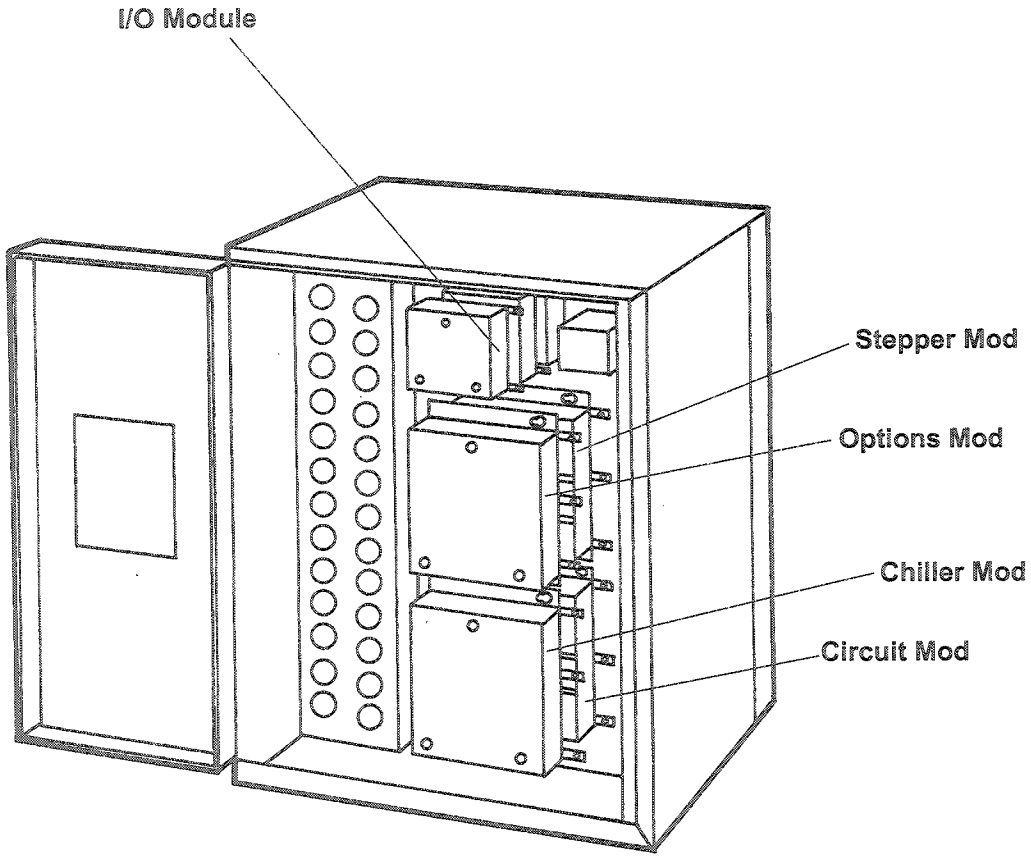
Local Clear Language

The Local CLD "Clear Language Display" resides at the Chiller providing display of chiller data and access to operator/service controls, setpoints, and chiller set-up information. All information is stored in non-volatile memory in the Chiller module. The Local CLD and the Chiller module work together to display and store information requiring non-volatility.

Control System

Unit Control Panel

Safety and operating controls are housed in the UCP2 unit control panel, the starter panel, and the purge control panel.



The UCP2 control is a modular design partitioned by major function or group of functions. All modules (see *Figure 2*) communicate with each other through the Interprocessor Communication Circuit (IPC).

Major components within each control group are shown in the figure.

Unit-mounted temperature sensors, pressure transducers, and functional switches provide analog and binary inputs to the various modules.

The microcomputer-based modules are illustrated in the figure. All wiring to the modules are to pluggable terminal blocks.

Figure 2
UCP2 Control Panel

Custom Report

Custom Report Group

Reports are added to the custom report group by pressing the <+> key when the desired report is being displayed from its normal report location. Reports are removed from the custom report group by pressing the <-> key when the desired custom report is being displayed. The Custom report group can contain a maximum of 20 reports. When adding a report to the Custom Report, if the <+> key is pressed when the Custom Report already contains 20 reports, a message, "Custom Report Is Full, Report Not Added," indicating that the Custom Report is full, will be displayed for 2 seconds. If an attempt is made to add a report to the Custom Report that is already in the Custom Report, a message, "Report Already In Custom Menu", will be displayed for 2 seconds.

The Custom Report sequence is as follows:

Report Heading

User Defined Custom Report
Press (Next)(Previous) To Continue

If no entries are selected for the Custom Report, see Empty List Display.

Empty Display List

If no entries are selected for the Custom Report, the second entry is:

No Items Are Selected For Custom Report:
See Operators Manual To Select Entries

The report then wraps around to the report heading when <Next> is pressed.

If there are items selected for the Custom Report, then the empty list display is not used. Instead, the report heading and the selected items are displayed sequentially as <Next> or <Previous> are pressed.

ASHRAE Guideline 3 Report

Press (Enter) For ASHRAE Guideline 3 Rpt
Press (Next)(Previous) To Continue

If <Enter> is pressed the ASHRAE Guideline 3 Report Menu is entered, shown at the end of the Standard Report below. Otherwise, If <Next> is pressed the Standard Report is entered. The ASHRAE Guideline 3 Report Entry screen may be added to Custom Report by pressing the <+> key. Adding it to the Custom Report allows the user to access the ASHRAE Guideline 3 Report from the Custom Menu.

The following are the Standard Report screens, e.g. not part of the ASHRAE Guideline 3 Report.

ASHRAE Guideline 3 Reports

Time Of Day/Refrigerant Type

Current Time/Date HH:MM xm Mon,XX XXXX
Refrigerant Type: [type]

Possible values for refrigerant type are: R11, R123, R12, R134a, R22, R113, R114, R500, or R502.

Chiller Operating Mode

The chiller operating modes display comes up first in the standard report:

[Operating mode line 1]
[Operating mode line 2]

Line 1 (and 2 if needed) indicates a current condition of the unit as shown in the following table *(Table 1)* . In some cases, an associated timer or system parameter will be displayed that assures the transition to an expected mode is in progress, particularly during the unit start-up sequence.

Table 1

```
Active Current Limit Setpoint: xxx %
[settings source] CLS:          xxx %
```

Settings source will be one of the following: Front Panel, Tracer, External Source, or Ice Building.

Refrigerant Monitor

The following item will be displayed if the Analog Rfgt Monitor is installed.

```
Refrigerant Monitor: xxx.x PPM
Press (Next)(Previous) To Continue
```

The following item will be displayed if the IPC Rfgt Monitor option is installed.

```
Refrigerant Monitor: xxxx PPM R-YYYY
Press (Next)(Previous) To Continue
```

Where (Y) can equal 123, 11, 22, 134a, or 12.

Purge Pumpout Rate/Purge Max Pumpout Rate

The following screen(s) does not appear if the selected Purge Control/Type is "Stand-Alone Purge."

```
Purge Pumpout Rate: xxx.x Min/24Hrs
Purge Max Pumpout Rate: xxx.x Min/24Hrs
```

Purge Total Pumpout Time/ Purge Total Run Time

The following screen(s) does not appear if the selected Purge Control/Type is "Stand-Alone Purge."

Purge Total Pumpout Time: xx,xxx.x Min
Purge Total Run Time: xx,xxx.x Hrs

Purge Operating Mode/Purge Status

The following screen(s) does not appear if the selected Purge Control/Type is "Stand-Alone Purge."

Purge Operating Mode: [Mode]
Purge Status: [Status]

Possible values of [Mode] are: Auto, Stop, On, or Adaptive.

Possible values of [Status] are:

Idle	*(Condensing Unit is Off)*
Running	*(Condensing Unit is On)*
Pumpout	*(Temperature initiated Pumpout)*
Service Pumpout	*(Pumpout initiated by the service switch)*
Running - Pumpout Inhibited By Low Temp.	*(Pumpout inhibited by low liquid temp)*
Pumpout Maximum Rate Disabled	*(Max. Pumpout Rate alarm disabled)*

Saturated Evap Temperature/Evap Refrigerant Pressure Compressor Discharge Temp

Compressor Discharge Temperature shown only if discharge temperature is installed.

Saturated Evap Rfgt Temp: xxx.x f/c
Compressor Discharge Temp: xxx.x f/c

Compressor Starts and Running Time

The starts and hours counters are displayed as follows:

Compressor Starts: xxxxx
Compressor Running Time: HRS:MIN:SEC

Discharge Oil Pressure, Oil Tank Pressure

This screen is only displayed if the "Oil Pressure Protection" setpoint is set to "Transducer" or "Xducer & Switch."

Discharge Oil Pressure: xxx.x psig
Oil Tank Pressure: xxx.x psig

Differential Oil Pressure, Oil Temperature

This screen is only displayed if the "Oil Pressure Protection" setpoint is set to "Transducer" or "Xducer & Switch."

Differential Oil Pressure: xxx.x [units]
Oil Tank Temperature: xxx.x f/c

' Differential Oil Pressure: xxx.x [units]' is only displayed if the "Oil Pressure Protection" setpoint is set to "Transducer" or "Xducer & Switch." If 'Switch' is selected as the setpoint, then ' Differential Oil Pressure Switch: [Status]' is displayed where Status is open or closed.

For FastPak, Differential Oil Pressure: xxx.x [units], this screen is only displayed if the "Oil Pressure Protection Setpoint" is set to "Diff Xducer" If 'Switch' is selected as the setpoint, then ' Differential Oil Pressure Switch: [Status]' is displayed where Status is open or closed.

The Possible value for [units] is "psid" or "kPa" dependent upon whether English or SI units are selected.

Bearing Temperatures #1 and #2

The following will be displayed only if the Bearing Temp Sensors Option is Installed.

Bearing Temperature 1: xxx.x f/c
Bearing Temperature 2: xxx.x f/c

Evaporator Entering and Leaving Water Temperatures

Evap Entering Water Temp: xxx.x f/c
Evap Leaving Water Temp: xxx.x f/c

Saturated Evap Temperature/Evap Refrigerant Pressure

Saturated Evap Rfgt Temp: xxx.x f/c
Evap Rfgt Pressure: xxx.x psig

Evaporator Approach Temp.

Evaporator Approach Temp.: xx.x f/c
Press (Next) (Previous) To Continue

Evaporator Entering/Leaving Water Pressure

The following will be displayed only if the low pressure (< or = to 150 psig) Differential Water Pressure Sensor Option is Installed.

Evap Entering Water Pressure:xx.x psid/kPa
Evap Leaving Water Pressure: xx.x psid/kPa

Evaporator Differential Water Pressure

The following will be displayed only if the Differential Water Pressure Sensor Option is Installed.

Evap Differential Wtr Press: xx.x psid/kPa
Press (Next) (Previous) To Continue

Evaporator Water Flow

The following is displayed only if the Differential Water Sensing Option is installed.

Approx Evaporator Water Flow:xxx.x gpm/lpm
Press (Next) (Previous) To Continue

The possible values for units are "gpm" or "lpm."

Chilled Water Flow Switch Status

The following will be displayed only if the Differential Water Sensing Option is not installed. This screen displays the status of the chilled water flow switch status at the input to the UCM.

Chilled Water Flow Switch Status:
[y]

Possible values for [y] are: Flow Switch is Open/No Flow or Flow Switch is Closed/Flow.

Chiller Tons

The following will be displayed only if the Differential Water Sensing Option is installed.

Approximate Chiller Capacity: xxxx Tons/KW
Press (Next) (Previous) To Continue

The possible values for units are "Tons" or "KW."

Cond Entering and Leaving Water Temps

Dashes will be displayed for condenser entering or leaving water temperature if the corresponding input is open or shorted.

Cond Entering Water Temp: xxx.x f/c
Cond Leaving Water Temp: xxx.x f/c

Saturated Cond Temperature/Cond Refrigerant Press

Saturated Cond Temp: xxx.x f/c
Cond Rfgt Pressure: xxx.x psig

Condenser Approach Temp.

Condenser Approach Temp.: xx.x f/c
Press (Next) (Previous) To Continue

Condenser Entering/Leaving Water Pressure

The following will be displayed only if the low pressure (< or = to 150 psig) Differential Water Pressure Sensor Option is Installed.

Cond Entering Water Pressure:xx.x psid/kPa
Cond Leaving Water Pressure: xx.x psid/kPa

Condenser Differential Water Pressure

The following will be displayed only if the Differential Water Pressure Sensor Option is Installed.

Cond Differential Wtr Press: xx.x psid/kPa
Press (Next) (Previous) To Continue

Condenser Water Flow

The following will be displayed only if the Differential Water Sensing Option is installed.

Approx Condenser Water Flow: xxx.x gpm/lpm
Press (Next)(Previous) To Continue

The possible values for units are "gpm" or "lpm."

Condenser Water Flow Switch Status

The following screen is displayed only if the Differential Water Pressure Sensor Option is not Installed. This screen displays the status of the condenser water flow switch status at the input to the UCM.

Condenser Water Flow Switch Status:
[y]

Possible values for [y] are Flow Switch is Open/No Flow or Flow Switch is Closed/Flow

Aux. Bundle or Heat Recovery Temps

The following will be displayed only if either the Heat Recovery Option or Aux Condenser Option is installed.

Aux/Heat Rcvy Ent Wtr Temp: xxx.x f/c
Aux/Heat Rcvy Lvg Wtr Temp: xxx.x f/c

Chiller Report

The Chiller Report sequence is as follows:

Chiller Status, Water Temps & Setpts

Chiller Operating Mode

The chiller operating modes display comes up first in the standard report:

[Operating mode line 1]
[Operating mode line 2]

Line 1 (and 2 if needed) indicates a current condition of the unit as shown in the preceding table *(Table 1)* . In some cases, an associated timer or system parameter will be displayed that assures the transition to an expected mode is in progress, particularly during the unit start-up sequence.

Active Chilled Water Setpoint/Evap Leaving Water Temp

Active Chilled Water Setpoint:xxx.x f/c
Evap Leaving Water Temp: xxx.x f/c

If the chiller is in the Ice Making or Ice Making Complete state, the following display is substituted for the above display:

Active Ice Termination Setpoint: xxx.x f/c
Evap Entering Water Temp: xxx.x f/c

If the chiller is in the hot water control state, the following display is substituted for the above display:

Active Hot Water Setpoint: xxx.x f/c
Cond Leaving Water Temp: xxx.x f/c

Active Chilled Water Setpoint/Chilled Water Setpoint Source

Active Chilled Water Setpoint: xxx.x f/c
[settings source]CWS: xxx.x f/c

Settings source will be one of the following: Front Panel, Tracer, External Source, or Duplex Control.

Active Ice Termination Setpoint/Ice Termination Setpoint Source

The following will be displayed only if the Ice Building Option is installed.

Active Ice Termination Setpoint: xxx.x f/c
[settings source] ITS: xxx.x f/c

Settings source will be one of the following: Front Panel or Tracer.

Active Hot Wtr Setpoint/Hot Wtr Setpoint Source

The following will be displayed only if the Hot Water Control Option is Installed.

Active Hot Water Setpoint: xxx.x f/c
[settings source] HWS: xxx.x f/c

Settings source will be one of the following: Front Panel, Tracer, or External Source.

Evaporator Entering and Leaving Water Temperatures

Evap Entering Water Temp: xxx.x f/c
Evap Leaving Water Temp: xxx.x f/c

Cond Entering and Leaving Water Temps

Dashes will be displayed for condenser entering or leaving water temperature if the corresponding input is open or shorted.

Cond Entering Water Temp: xxx.x f/c
Cond Leaving Water Temp: xxx.x f/c

Active Current Limit Setpoint

Active Current Limit Setpoint: xxx %
Press (Next)(Previous) To Continue

Active Current Limit Setpoint/Current Limit Setpoint Source

Active Current Limit Setpoint: xxx %
[settings source] CLS: xxx %

Settings source will be one of the following: Front Panel, Tracer, External Source, or Ice Building.

Evaporator Water Flow/ Condenser Water Flow

The following will be displayed only if the Differential Water Sensing Option is installed.

Approx Evaporator Water Flow:xxx.x gpm/lpm
Approx Condenser Water Flow: xxx.x gpm/lpm

The possible values for units are "gpm" or "lpm."

Chiller Tons

The following will be displayed only if the Differential Water Sensing Option is installed.

Approximate Chiller Capacity: xxxx Tons/KW
Press (Next)(Previous) To Continue

The possible values for units are "Tons" or "KW."

Outdoor Temperature

If the outdoor air temperature input is open or shorted and neither Outdoor Air Reset nor Low Ambient Lockout is enabled, display "------" in place of "xxx.x F." Otherwise the temperature received from the chiller module is displayed.

Outdoor Air Temperature: xxx.x f/c
Press (Next)(Previous) To Continue

Aux. Bundle or Heat Recovery Temps

The following will be displayed only if either the Heat Recovery Option or Aux Condenser Option is installed.

Aux/Heat Rcvy Ent Wtr Temp: xxx.x f/c
Aux/Heat Rcvy Lvg Wtr Temp: xxx.x f/c

Chilled Water Setpoint Source

Chld Wtr Setpt Source: [settings source]
Reset Condition: [reset condition]

Settings source will be one of the following: Front Panel, Tracer, or External Source.

Reset condition will be one of the following: None, Outdoor Temp, or Return Wtr Temp.

Current Limit Setpoint Source

Cur Lim Setpt Source: [settings source]
Press (Next) (Previous) To Continue

Settings source will be one of the following: Front Panel, Tracer, External Source, or Ice Building.

Hot Water Setpoint Source

The following will be displayed only if Hot Water Control is Installed.

Hot Water Setpt Source: [settings source]
Press (Next) (Previous) To Continue

Settings source will be one of the following: Front Panel, Tracer, or External Source.

Ice Termination Setpoint Source

The following will be displayed when/if remote computer is installed.

Ice Termn Setpt Source: [settings source]
Press (Next) (Previous) To Continue

Settings source will be one of the following: Front Panel or Tracer.

Last 5 Cycle Pumpout Avg, Interval From Shtdn To 3 Hrs After Shtdn: xxx.x Min

30 Day Pumpout Avg, Interval From 3Hrs After Shtdn To Next Start: xxx.x Min

Refrigerant Monitor

The following item is displayed if the Analog Refrigerant Monitor option is installed.

Refrigerant Monitor: xxx.x PPM
Press (Next)(Previous) To Continue

The following items are displayed if the IPC Refrigerant Monitor option is installed.

The following screen is displayed if the refrigerant monitor scanner is installed:

Refrigerant Monitor Mode: [Mode]
Scanner Channel X XXXX PPM [Rfgt Type]

The following screen is displayed if the channel scanner is not installed:

Refrigerant Monitor Mode: [Mode]
XXXX PPM [Rfgt Type]

Possible values of Mode are: Warmup, Ready, Monitor Check, Trouble.

If the PPM is out of range low or high "-Err" and "++++" respectively are displayed. If the concentration has not been determined, or the refrigerant monitor is in "Monitor Check" mode, "-----" is displayed.

The following is displayed if the channel scanner option is installed.

Last Rfgt Conc Chan1 Chan2 Chan3 Chan4
PPM [Rfgt Type] XXXX XXXX XXXX XXXX

If the PPM is out of range low or high "-Err" and "++++" respectively are displayed. If a channel is inactive, "-----" is displayed.

Refrigerant Monitor Case Temp: XXX.X F
Refrigerant Monitor Bench Temp: XXX.X F

The following is displayed if the IPC Refrigerant Monitor Auxiliary input option is installed.

Rfgt Mon Auxiliary Input: XX.X mA
Press (Next) (Previous) To Continue

Approach Temperature

Evaporator Approach Temp: XXX.X F
Condenser Approach Temp: XXX.X F

Compressor Report

The Compressor Report Group sequence is as follows.

Report Heading

Compressor Hours, Starts & Amps
Press (Next)(Previous) To Continue

Differential Oil Pressure, Oil Temperature

Differential Oil Pressure: xxx.x [units]
Oil Tank Temperature: xxx.x f/c

The possible value for [units] is "psid" or "kPa" dependent upon whether English or SI units are selected.

Discharge Oil Pressure, Oil Tank Pressure

Discharge Oil Pressure:	xxx.x psig
Oil Tank Pressure:	xxx.x psig

AF Compressor Speed Command

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator and Adaptive Speed Control Algorithm is Enabled.

AF Compressor Speed Command:	xx Hz
AF Compressor Speed Command:	xxxx RPM

Range of values is 2520 to 3600 rpm in increments of 1 rpm. Factory default is 3600 rpm.

AF Boundary Pressure Coefficient/AF Press. Coefficient

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator and Adaptive Speed Control Algorithm is Enabled.

AF Boundary Press Coefficient:	x.xxx
AF Pressure Coefficient:	x.xxx

Note: This is a Report only for Troubleshooting purposes.

AF Re-Optimization Timer Time Remaining

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator and Adaptive Speed Control Algorithm is Enabled.

AF Re-Optimization Time Remaining:xx:xxHrs
Press (Next) (Previous) to Continue

Note: This is a Report only for Troubleshooting purposes.

Inlet Guide Vane Position

This screen does not appear if "Inlet Guide Vane Output" is set to "Pulsed."

Inlet Guide Vane Position xxx.x % Open
Inlet Guide Vane Position xx.x degrees

This data is displayed only if the line voltage sensing option is installed. if not installed, no screen is displayed.

Compressor Power Factor and Watts

The following is displayed only if the Line Voltage Sensing Option is Installed AND the starter type is Not "Adaptive Frequency" or AFD AND Compressor Power Source is Utility AND External KW is Not Installed.

Compressor Power Factor: xx %
Compressor KiloWatts: xxxx KW

Compressor Winding Temperatures

Compressor Winding Temperatures
W1 xxx f/c W2 xxx f/c W3 xxx f/c

Compressor Starts and Running Time

The starts and hours counters are displayed as follows:

Compressor Starts: xxxxx
Compressor Running Time: HRS:MIN:SEC

Bearing Temperatures #1 and #2

The following will be displayed only if the Bearing Temp Sensors Option is Installed.

Bearing Temperature 1: xxx.x f/c
Bearing Temperature 2: xxx.x f/c

Solid State Starter Heat Sink Temp.

The following will be displayed only if the Solid State Starter is installed.

Solid State Starter Heat Sink: xxx.x f/c
Press (Next)(Previous) To Continue

HGBP Time

If HGBP is installed in the unit the following screen is displayed:

HGBP Time: HRS:MIN:SEC
Press (Next)(Previous) To Continue

Operator Settings

Settings Group Keys

The four settings Group Keys for CVHE/CVHF/ CVHG are as follows:

- **Operator Settings** - non-password protected menu items that can be changed by the operator
- **Service Settings** - menu items that should only be changed by a qualified service technician
- **Service Tests** - activate outputs of Chiller (e.g. oil pump)
- **Diagnostics** - abnormal operating conditions, informational warnings, automatic reset, and manual reset types and other information.

Operator Settings Group Heading

Important! *FACTORY DEFAULT SETTINGS: Menu items that are programmable using the keypad may have a selectable choice that is listed as Factory Default. This Factory Default setting is the software default that is initially factory-programmed for a new module assembly and may NOT be the correct setting for a specific operating chiller. Always review all settings when any module is replaced to verify that the settings agree with the desired settings that were selected at initial startup or programmed at the factory.*

The Operator Settings Group sequence follows.

Chilled Water & Current Limit Setpts
Press (Next)(Previous) To Continue

If the Menu Settings Password feature is Enabled in the Service Setup Group following each setting group heading the following is displayed:

Settings In This Menu Are [status]
[password message]

Likewise, if the Menu Settings Password is Disabled in the Service Setup Group, the above screen will not appear.

The possible values for status are "Locked" or "Unlocked". If the password status is locked, the password message will be "Enter Password to Unlock". The user will then depress **(-)(+)(-)(+)(-)(+)** followed by the <Enter> key. The password keystrokes will be echoed to the screen as a visual aide. The last six keystrokes represent the current password, and up to twenty keystrokes can be entered. An incorrect password, or the twenty-first keystroke will result in the password message "Invalid Password".

If the password status is unlocked, the password message will be "Press (Enter) to Lock". Pressing <Enter> locks the settings in ALL the menus. If the password is entered to unlock the settings, this unlocks the settings in ALL menus.

Whenever a password is in use the "Press (+)(-) to change setting" message will be suppressed on setpoint screens. Any attempt to change the setting will result in the message "Setting is Locked". The password once entered will remain valid until canceled.

Set Contrast - Applies to CCCLD Display Only.

Set Contrast: Press (√) to Save
Press (+)(-) to Change Setting

Purge Operating Mode

The following screen(s) does not appear if the selected Purge Control/Type is "Stand-Alone Purge."

Purge Operating Mode: [Mode]
Press (+)(-) to Change Setting

Possible values of [Mode] are: Stop, On, Auto (Factory Default) and Adaptive.

Time Of Day Setting

Current Time/Date HH:MM xm Mon,XX XXXX
(Enter) to Change : (Next) to Continue

The top level "CurrentTime/Date" will be displayed when this screen is first selected. Pressing the <Next> or <Previous> key will go to the next or previous screen as usual.

If the <Enter> key is selected, five separate screens can be displayed with which the time may be set. The "Current Time/Date" will be displayed on line one of each of these screens. Each of these screens will change one element of the current time/date. The second line of each screen will indicate which element of the current time/date is being changed.

If the first time changing screen is being displayed and the <Previous> key is pressed, the top level "Current Time/Date" screen will be displayed and the <Enter> key will have to be selected to re-enter the time changing screens. If the fifth time changing screen is being displayed and the <Next> key is pressed, the next screen will be displayed. If <Previous> is selected at this point, the top level "Current Time/Date" screen will be displayed and the <Enter> key will have to be selected to re-enter the time changing screens

To change an element of the current time/date, select <Enter> from the top level "Current Time/Date" screen to enter the time changing screens. Hit <Next> or <Previous> to get to the proper screen. Press the <+> <-> keys to change the element to it's proper value and press the <Enter> key to store the new time/date. A message "Updating Chiller Clock, Please Wait" is displayed for two seconds after the <Enter> key is pressed.

The five time changing screens are as follows:

Current Time/Date HH:MM xm Mon XX,XXXX
To Change Hour, Press (+)(-) & (Enter)

Current Time/Date HH:MM xm Mon XX,XXXX
To Change Minute,Press (+)(-) &(Enter)

Current Time/Date HH:MM xm Mon XX,XXXX
To Change Month, Press(+)(-) & (Enter)

Current Time/Date HH:MM xm Mon XX,XXXX
To Change Day, Press (+)(-) & (Enter)

Current Time/Date HH:MM xm Mon XX,XXXX
To Change Year, Press (+)(-) & (Enter)

Front Panel Chilled Water Setpoint

Front Panel Chilled Wtr Setpt:xxx.x f/c
Press (+)(-) to Change Setting

Range of values is 0 to 65°F (-17.8 to 18.3°C) in increments of 1 or 0.1°F or °C depending on the Service Setup Screen xxx or xxx.x. Factory Default is 44.0°F (6.7°C).

As shown above, the second line of a setting display normally says:

"Press (+)(-) to Change Setting"

However, the following is displayed as the second line of the display if an attempt is made to increment the setpoint above the end of the setpoint range:

"Top of Range, Press (-) to Change"

The following is displayed as the second line of the display if an attempt is made to decrement the display below the end of the setpoint range:

"Bottom of Range, Press (+) to Change"

The following is displayed as the second line of the display if a key other than <+>, <->, <Enter>, or <Cancel> is pressed after <+> or <-> is pressed:

"Press (+)(-)(Enter)(Cancel) to Advance"

The exception to the above message is when the <Stop> key is pressed. <Stop> is always active.

Other messages are displayed on the second line of the display for special cases as noted below in association with the affected setpoint display.

When the Front Panel Chilled Water Setpoint is within 1.7°F of the Leaving Water Temperature Cutout Setpoint, the second line of this display will read:

"Limited by Cutout Setpt, (+) to Change"

Front Panel Hot Water Setpoint

The Front Panel Hot Water Setpoint is only displayed when the Hot water option is Installed.

Front Panel Hot Wtr Setpt: xxx.x f/c
Press (+)(-) to Change Setting

Range of values is 85 to 140°F (37.8 to 60.0°C) in increments of 1 or 0.1°F or °C depending on the Service Setup Screen xxx or xxx.x. Factory Default is 130°F (54.4°C).

Front Panel Current Limit Setpoint

Front Panel Current Limit Stpt: xxx %
Press (+)(-) to Change Setting

Range of values is 40 to 100% in increments of 1 %. Factory Default is 100%.

Print Report

This screen is shown only when the Printer Option is Installed.

Press (Enter) to Print Report
Press (Next)(Previous) To Continue

When <Enter> is pushed, a 2 second message appears as shown below and then returns to the above screen.

The Print Command is Being Sent to the Printer

Control Type

The following will be displayed only if the Hot Water Control Option is Installed.

Control Type is: [control]
Press (+)(-) to Change Setting

Possible values of [control] are: Chilled Water (Factory Default), Hot Water, and Ext. Hot/Chilled Wtr Input.

Free Cooling

The free cooling enable screen is displayed only if the free cooling option is installed.

Free Cooling: [Status]
Press (+)(-) to Change Setting

Possible values are: Disable (Factory Default) and Enable.

Chilled Water Reset Type

Chilled Water Reset Type: [type]
Press (+)(-) to Change Setting

The possible values for [type] are: Disable (Factory Default), Return, Constant Return, and Outdoor Air.

If either Disable or Constant Return are selected, the remaining chilled water reset displays are skipped by the CLD. If either Return or Outdoor Air are selected, the first word of the remaining chilled water reset displays will be the type of reset.

Help Notes:

1. When CWR is enabled, the UCM will step to CWS at a rate of 1°F every five minutes.
2. Constant Return is a short version of Return CWR; it will reset the leaving chilled water setpoint to provide a constant entering water temperature. The reset ratio defaults to 100%, start rest point to design delta T and max reset setpoint to design.
3. Chilled water is reset based on either return water temperature or outdoor air temperature.
4. This screen does not appear when the chiller is under Duplex Control and it is Compressor B.

Reset Ratio

This is the aggressive value. A higher number is a quicker response.

[type] Reset Ratio: xxx %
Press (+)(-) to Change Setting

The values for Reset Ratio for each of the reset types are:

Reset Type	Reset Ratio Range	Increment (Eng. units)	Increment (SI)	Default Value
Return	*10 to 120%*	*1%*	*1%*	*50%*
Outdoor	*80 to -80%*	*1%*	*1%*	*10%*

Start Reset Setpoint

This is the Delta T the unit is trying to maintain.

[type] Start Reset Setpoint: xxx.x F
Press (+)(-) to Change Setting

The values for Start Reset for each of the reset types are:

Reset Type	Start Reset Range	Increment (Eng. units)	Increment (SI)	Default Value
Return	*4 to 30°F (2.2 to 16.7°C)*	*1°F*	*1°C*	*10°F (5.6°C)*
Outdoor	*50 to 130°F (10 to 54.4°C)*	*1°F*	*1°C*	*90°F (32.2°C)*

Maximum Reset Setpoint

Controllable Maximum Reset value. Allows a reset "Up" of this value. The chilled water is maintained between the leaving chilled water setpoint and the new reset value.

[type] Max Reset Setpoint: xxx.x F
Press (+)(-) to Change Setting

The values for Maximum Reset for each of the reset types are:

Reset Type	Maximum Reset Range	Increment (Eng. units)	Increment (SI)	Default Value
Return	*0 to 20°F (0.1 to 11.1°C)*	*1°F*	*1°C*	*5°F (2.8°C)*
Outdoor	*0 to 20°F (0.1 to 11.1°C)*	*1°F*	*1°C*	*5°F (2.8°C)*

Ice Building Enable

The following will be displayed only if the ice building option is installed.

Ice Building: [d/e]
Press (+)(-) to Change Setting

Possible values of [d/e] are: Disable (Factory Default) and Enable.

Front Panel Ice Termination Setpoint

The following will be displayed only if ice building option is installed.

Panel Ice Termination Setpoint:xxx.x f/c
Press (+)(-) to Change Setting

Range of values is 20.0 to 32.0°F (-6.7 to 0.0°C) in increments of 1 or 0.1°F or °C depending on the Service Setup Screen xxx or xxx.x. Factory Default is 27.0°F (-2.8°C).

Ice Making To Normal Cooling Transition Timer

The following will be displayed only if the ice building option is installed. This allows for a timed idle/stop period for (X) minutes when coming out of ice before going into the cooling mode (timed by Chiller).

Ice-To-Normal Cooling Timer: xx min
Press (+)(-) to Change Setting

Range of values is 0 to 10 min. Factory Default is 5 min.

Chilled Water Setpoint Source

If the Tracer Option is installed, the word "Default" will appear in front of the setpoint source.

[Default] Chilled Water Setpoint Source:
[source]

Possible values of [source] are: Front Panel (Factory Default) and External Source (This choice shows up only if the External Chilled Water Setpoint is Installed at the Machine Configuration menu.).

Note: There is a Tracer installed screen in the Machine configuration menu. If Tracer does not choose to write a setpoint then the "default" setpoint source is used, e.g. Front Panel.

Current Limit Setpoint Source

If the Tracer Option is installed, the word "Default" will appear in front of the setpoint source.

[Default] Current Limit Setpoint Source:
[source]

Possible values of [source] are: Front Panel (Factory Default), and External Source. (This choice shows up only if the External Current Limit Setpoint is Installed at the Machine Configuration menu.)

Note: There is a Tracer installed screen in the Machine configuration menu. If Tracer does not choose to write a setpoint then the "default" setpoint source is used, e.g. Front Panel.

Hot Water Setpoint Source

If the Tracer Option is installed, the word "Default" will appear in front of the setpoint source.

[Default] Hot Water Setpoint Source:
[source]

Possible values of [source] are: Front Panel (Factory Default) and External Source (This choice shows up only if the External Hot Water Setpoint is Installed at the Machine Configuration menu.)

Note: There is a Tracer installed screen in the Machine configuration menu. If Tracer does not choose to write a setpoint then the "default" setpoint source is used, e.g. Front Panel.

Ice Termination Setpoint Source

The following will be displayed only if the Ice Building Option is installed.

If the Tracer Option is installed, the word "Default" will appear in front of the setpoint source.

[Default] Ice Termination Setpoint Source:
[source]

Possible values of [source] are: Front Panel (Factory Default).

Note: There is a Tracer installed screen in the Machine configuration menu. If Tracer does not choose to write a setpoint then the "default" setpoint source is used, e.g. Front Panel.

Outdoor Air Temperature Source

If the Tracer is installed the Tracer Outdoor Air Temp. is both used and displayed. If no Tracer is installed the chiller module outdoor air temperature sensor is used. If no sensor is installed, dashes are displayed on the display of Outdoor Air Temperature.

Setpoint Source Override

Setpoint Source Override:
[source]

Possible values of [source] are: "None" (Factory Default), "Use Front Panel Setpoints", "Override Tracer, and Use Default Setpoints" (Available only if Tracer Option installed).

Service Settings (Non Password Protected Service Settings Group)

Important! *FACTORY DEFAULT SETTINGS: Menu items that are programmable using the keypad may have a selectable choice that is listed as Factory Default. This Factory Default setting is the software default that is initially factory-programmed for a new module assembly and may NOT be the correct setting for a specific operating chiller. Always review all settings when any module is replaced to verify that the settings agree with the desired settings that were selected at initial startup or programmed at the factory.*

The Service settings menu has three distinct grouping of items within it. The first group is the non-password protected group that consists of all of the settings, feature enables, setpoints etc., that are benign; while they are unlikely to be changed often by a user or operator, changes in them do not seriously effect the standard protection or reliability of the chiller.

The other two groupings are protected, each with a separate password. These two groups are for changing parameters and settings regarding field commissioning and fundamental protection and control of the chiller subsystems (Field Startup) or for programming of the UCM as to how the specific chiller was built in the Factory (Machine Configuration). Once properly set, the items in these protected menus should never be changed again without specific knowledge of the effects of the changes. In rare instances, certain field problems may be corrected by making changes in these protected menus but certain aspects of chiller reliability may be compromised. The main reason these are accessible at all, is for field commissioning and to allow for the field programming of service replacement UCMs.

Two additional password protected menus are available in the Service Settings group if the IPC Refrigerant Monitor is installed. The Refrigerant Monitor Settings Group and the Refrigerant Monitor Calibration Group are used to configure the IPC Refrigerant Monitor.

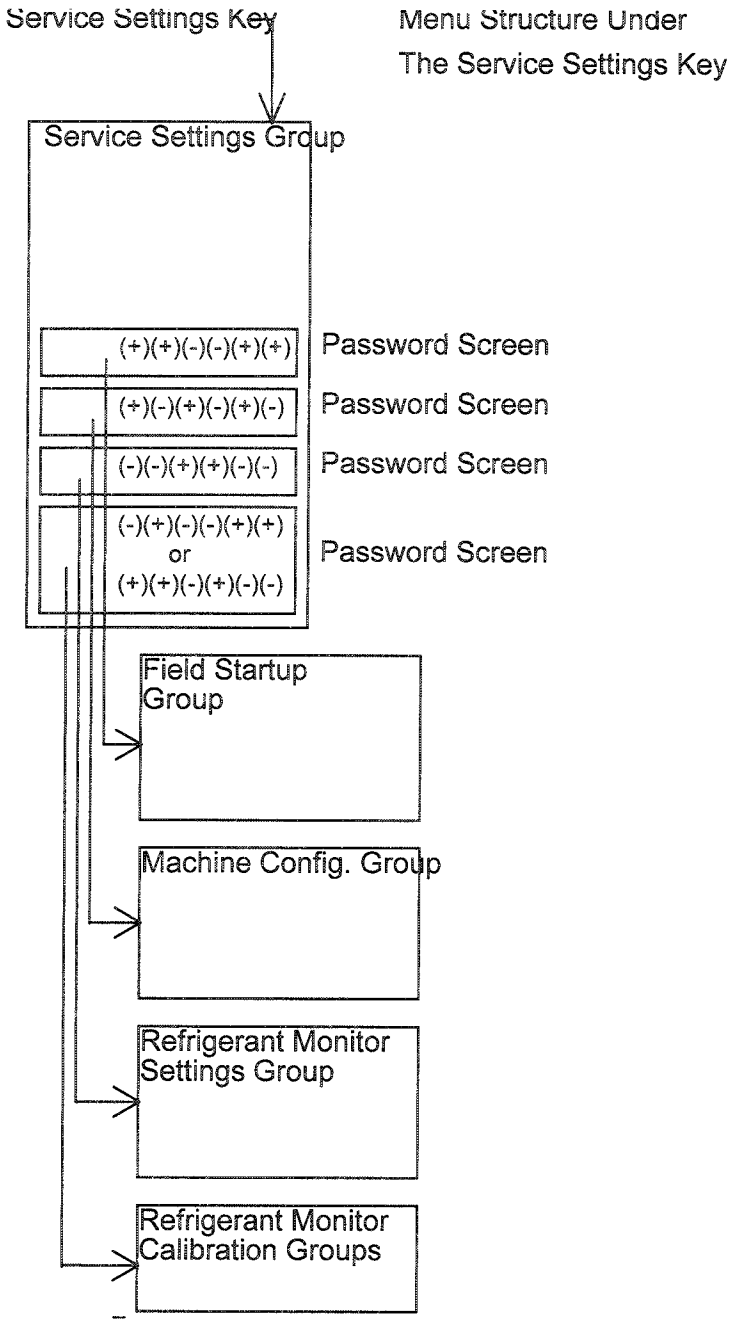
Service Setting Group Heading

Service Settings: Basic Setups
Press (Next)(Previous) To Continue

Menu Settings Password

If the Menu Settings Password is Enabled in the Service Setup Group, following each setting group heading the following will be displayed:

Settings In This Menu Are [status]
[password message]



Likewise, if the Menu Settings Password is Disabled in the Service Setup Group, the above screen will not appear.

The possible values for status are "Locked" or "Unlocked". If the password status is locked, the password message will be "Enter Password to Unlock". The user will then depress (-)(+)(-)(+)(-)(+) followed by the <Enter> key. The password keystrokes will be echoed to the screen as a visual aide. The last six keystrokes represent the current password, and up to twenty keystrokes can be entered. An incorrect password, or the twenty-first keystroke will result in the password message "Invalid Password".

If the password status is unlocked, the password message will be "Press (Enter) to Lock". Pressing <Enter> will lock all of the setpoint menus. Likewise, if the password status is locked and the correct password is entered, all of the setpoint menus will be unlocked.

Whenever a password is in use the "Press (+)(-) to change setting" message will be suppressed on all setpoint screens. Any attempt to change a setpoint will result in the message "Setting is Locked" being displayed for 1 second. The password once entered will remain valid until canceled.

Figure 3

Keypad/Display Lockout

This display only appears if the keypad lockout feature is enabled.

Press (Enter) to Lock Display & Keypad
Password will be required to Unlock

If the <Enter> key is pressed to lock the keypad, the following message is displayed, and all further input from the keypad is ignored, including the <Stop> key, until the password is entered. The password consists

of pressing the <Previous> and <Enter> keys at the same time.

******DISPLAY AND KEYPAD ARE LOCKED******
********ENTER PASSWORD TO UNLOCK********

If the keypad is locked and the password is entered, the display will go to the Chiller Operating Mode display of the Chiller Report.

Language Setting

Language: xxxxxxxx
Press (+) (-) to Change Setting

Possible Language Selections for the CLD are: English (Factory Default), Francais, Deutsche, Espanol, Nippon (also known as Katakana (uses Japanese Characters), Italian, Nederland, and CODED. Possible Language Selections for the CCCLD are: English (Factory Default), Traditional Chinese, Simplified Chinese, Korean, Thai, and Japanese.

Display Units

Display Units: [Type]
Press (+) (-) to Change Setting

Possible values of [Type] are: English (Factory Default) and SI.

Decimal Places Displayed Setpoint

Decimal Places Displayed: [Status]
Press (+) (-) to Change Setting

The choices for Status are: XXX.X (Factory Default) and XXX.

Display Menu Headings Enable

Display Menu Headings: [d/e]
Press (+) (-) to Change Setting

The Factory Default value is Enabled. If disabled the Menu Headings in each Menu or Group do not appear.

Clear Custom Menu

Press (Enter) To
Clear The Custom Menu

When <Enter> is pushed a 2 second message appears as shown below and then returns to above screen.

Custom Menu Has Been Cleared

Differential to Start Setpoint

Differential to Start Setpoint: xxx.x f/c
Press (+) (-) to Change Setting

Range of values is 1 to 10°F (0.5 to 5.5°C) in increments of 1 or 0.1°F or C depending on the Service Setup Screen xxx or xxx.x. Factory Default is 5°F (2.8°C).

Differential to Stop Setpoint

Differential to Stop Setpoint: xxx.x f/c
Press (+) (-) to Change Setting

Range of values is 1 to 10°F (0.5 to 5.5°C) in increments of 1 or 0.1°F or °C depending on the Service Setup Screen xxx or xxx.x. Factory Default is 5°F (2.8°C).

Evap/Cond Pump Off Delay Time

Evap Pump Off Delay: xxx Min
Press (+)(-) to Change Setting

Range of values is 0 to 30 minutes in increments of 1 Minute. Factory Default is 1 Minute.

If the current running mode is hot water control state the following display is substituted for the above display:

Cond Pump Off Delay: xxx Min
Press (+)(-) to Change Setting

Printer Setups

This screen is shown only when the Printer Option is Installed.

Printer Setups
(Enter) to Change : (Next) to Continue

If <Next> is pressed the following printer setup screens are skipped. If <Enter> is pressed the following screens are displayed to permit modification of the printer setups.

Print on Time Interval: [Status]
Press (+)(-) to Change Setting

The choices for Status are: Enable (Factory Default) and Disable.

Print Time Interval: xxx Hours
Press (+)(-) to Change Setting

Range of values is 1 to 24 Hours in increments of 1 Hour. Factory Default is 8 Hours.

Print on Diagnostic: [Status]
Press (+)(-) to Change Setting

The choices for Status are: Enable (Factory Default) and Disable.

Help Note:
This will print every time a diagnostic happens.

Number of Pre-Diag Reports: xx
Press (+)(-) to Change Setting

Range of values is 1 to 5 in increments of 1. Factory Default is 5.

Diagnostic Report Interval: xx sec
Press (+)(-) to Change Setting

Range of values is 2 to 120 seconds in increments of 1 second. Factory Default is 5 seconds.

Printer, Baud Rate: [Status]
Press (+)(-) to Change Setting

The choices for Status are: 300, 1200, 2400, 4800, 9600 (Factory Default), and 19,200.

Printer, Parity: [Status]
Press (+)(-) to Change Setting

The choices for Status are: None (Factory Default), Odd, and Even.

Printer, Data Bits: [Status]
Press (+)(-) to Change Setting

The choices for Status are: 8 (Factory Default) and 7.

Printer, Stop Bits: [Status]
Press (+)(-) to Change Setting

The choices for Status are: 1 (Factory Default) and 2.

Printer Handshaking: [Status]
Press (+)(-) to Change Setting

The choices for Status are: XON/XOFF (Factory Default), DTR, RTS, and None.

Clear Restart Inhibit Timer

Press (Enter) to
Clear the Restart Inhibit Timer

When <Enter> is pushed, a 2 second message appears as shown below and then returns to above screen.

Restart Inhibit Timer Has Been Cleared

Field Start-up

Important! *FACTORY DEFAULT SETTINGS: Menu items that are programmable using the keypad may have a selectable choice that is listed as Factory Default. This Factory Default setting is the software default that is initially factory-programmed for a new module assembly and may NOT be the correct setting for a specific operating chiller. Always review all settings when any module is replaced to verify that the settings agree with the desired settings that were selected at initial startup or programmed at the factory.*

Field Startup

The Field Startup Group password is + + - - + + <Enter>. The Field Startup Group contains items that are primarily associated with Field Commissioning of the chiller as well as the fundamental control and protection of the chiller subsystems. If the field startup password is entered, the display goes to the menu defined below. If a key is not pressed every 10 minutes in this password protected menu, the display returns to the Chiller Operating Mode display of the Chiller Report, and the password must be entered again to return to this menu.

Field Start-up Group Heading

Field Start-up Group Settings
Press (Next)(Previous) To Continue

This header appears when the headers do not appear in the Service Settings menu.

Keypad/Display Lock Feature Enable

This feature permits the entire Keypad and Display to be locked out. A message appears on the screen to describe this condition. No access is permitted to either the Report screens or the Setting Screens when this feature is both Enabled here and Locked at the Service Settings Menu. It is important to note that in this condition, both the <Stop> and <Auto> keys do not function.

Keypad/Display Lock Feature: [d/e]
Press (+)(-) to Change Setting

Possible values of [d/e] are: Disable (Factory Default) and Enable.

When the keypad lock feature is Disabled, the keypad lock display does not appear in the non-password protected area of the Service Settings menu and the Keypad/Display cannot be locked. When the keypad/display lock feature is Enabled, the keypad lock display does appear in the Service Settings menu so the keypad can be locked.

Menu Settings Password Enable

The Menu Settings Password permits the Settings in each of the menus to be password protected. All Report Menus and Setting Menus can still be viewed at any time if this feature is either Enabled or Disabled; the <Stop> and <Auto> keys also remain active. If this feature is Enabled, then all Menu Settings are password protected.

Menu Settings Password Feature: [d/e]
Press (+)(-) to Change Setting

Possible values of [d/e] are: Disable (Factory Default) and Enable.

When the feature is Disabled, the Menu Setting Password display does not appear at the top of each of the Settings Menus and the Menu Settings cannot be password protected. When the Menu Setting Password feature is Enabled, the Menu Settings Password display appears just below each of the Settings Menu Headers so the settings can be changed if the proper password is entered.

ICS Address

ICS Address: xx
Press (+)(-) to Change Setting

Range of values is 1 to 127 in increments of 1. Factory Default is 65.

Power Up Start Delay Time

Help Note:
Used primarily for scheduling multiple units or to minimize current inrush.

Power Up Start Delay Time: xxx sec
Press (+)(-) to Change Setting

Range of values is 0 to 600 seconds in increments of 1. Factory Default is 0 sec.

Design Delta Temperature Setpoint

Design Delta Temp Setpoint: xxx.x f/c
Press (+)(-) to Change Setting

Range of values is 4 to 30°F (2.2 to 16.7°C) in increments of 1 or 0.1°F or °C depending on the Service Setup Screen xxx or xxx.x. Factory Default is 10°F (5.5°C).

Leaving Water Temperature Cutout Setpoint

Lvg Wtr Temp Cutout Setpoint:xxx.x f/c
Press (+)(-) to Change Setting

Range of values is -10 to 36°F (-23.3 to 2.2°C) in increments of 1 or 0.1 °F or °C depending on the Service Setup Screen xxx or xxx.x. The Factory Default is 36.0°F (2.2°C).

When this setpoint is within 1.7°F of the Front Panel Chilled Water Setpoint, the Front Panel Chilled Water Setpoint is increased along with this setpoint to maintain the differential. A message will be displayed for 2 seconds to indicate that the FPCW setpoint has been increased.

When this setpoint is adjusted below 35.3°F the following is displayed on the second line:

"Warning: Adequate Antifreeze Required".

Low Refrigerant Temperature Cutout Setpoint

Low Rfgt Temp Cutout Setpt: xxx.x f/c
Press (+)(-) to Change Setting

Range of values is -35 to 36°F (-37.2 to 2.2°C) in increments of 1 or 0.1°F or °C depending on the Service Setup Screen xxx or xxx.x. The Factory Default is 32.0°F (0.0°C).

Low Evaporator Water Flow Warning Setpoint

The following will be displayed only if the Differential Water Sensing Option is installed.

Low Evap Flow Warning: xx.x gpm/ton
Press (+)(-) to Change Setting

Range of values is 0.0 to 4.0 gpm/ton (0.0 to 15.1 lpm/ton) in increments of 0.1. Factory Default is 1.2 gpm/ton (4.5 lpm/ton).

Condenser Limit Setpoint

Help Note:
This limits load by vane closure.

Condenser Limit Setpoint: xx % HPC
Press (+)(-) to Change Setting

Range of values is 80 to 120% in increments of 1%. Factory Default is 93%.

Maximum Restart Inhibit (RI) Timer Setting

Maximum RI Timer: xxx Minutes
Press (+)(-) to Change Setting

The Range of values is 30 to 60 Minutes in increments of 1 Minute. Factory Default is 60 Minutes.

Purge Control/Type

Purge Control/Type: [Type]
Press (+) (-) to Change Setting

Possible values of [Type] are: Micro Purge (Factory Default) and Stand-Alone Purge.

Purge Service Log Reset

The following screen(s) shall be suppressed if the selected Purge Control/Type is "Stand-Alone Purge".

Service Log: Press (Enter) to Reset
Purge Pumpout Time: xxxxxxxx.x Pumpout Min

Service Log: Press (Enter) to Reset
Time Since Last Reset: xxxxx Cal Days

Note: Resetting in either screen above will reset both fields of data to Zero.

Purge Maximum Pumpout Rate

The following screen(s) does not appear if the selected Purge Control/Type is "Stand-Alone Purge."

Purge Max Pumpout Rate: xx Min/24 Hrs
Press (+) (-) to Change Setting

Range of values is 1 to 100 Minutes/24 Hrs in increments of 1 Minute/24 Hrs. Factory Default is 20 Minutes/24 Hrs.

Purge Service Excessive Pumpout Override Timer

The following screen(s) does not appear if the selected Purge Control/Type is "Stand-Alone Purge."

Purge Disable Pumpout Alarm for: xx Hrs
Press (+) (-) to Change Setting

Range of values is 1 to 72 Hours in increments of 1 Hour. Factory Default is 0 Hours.

Purge Low Chiller Sat. Cond. Liquid Temp. Protection Enable

The following screen(s) does not appear if the selected Purge Control/Type is "Stand-Alone Purge."

Purge Low Liquid Temp Inhibit: [d/e]
Press (+) (-) to Change Setting

Possible values of [d/e] are: Disable (Factory Default) and Enable.

Purge Low Chiller Sat. Cond. Temp Setpoint

The following screen(s) does not appear if the selected Purge Control/Type is "Stand-Alone Purge."

Prg Low Liquid Temp Inhibit Setpt xx.x f/c
Press (+) (-) to Change Setting

Range of values is 32 to 50°F(0.0 to 10.0°C) in increments of 1 or 0.1°F or°C depending on the Service Setup Screen xxx or xxx.x. Factory Default is 40°F (4.4°C).

Surge Protection Enable

Help Note:
This detects gas surge as een through current.

Surge Protection: [d/e]
Press (+) (-) to Change Setting

Possible values of [d/e] are: Disable and Enable (Factory Default). Surge protection is based on motor current fluctuation.

Under/Over Voltage Protection Enable

This screen does not appear if the Line Voltage Sensing Option is not installed or Compressor Power Source is Engine/Generator.

Line voltage above + 10% of nominal. (Must hold = + 10 % of nominal. Must trip = + 15 % of nominal. Reset differential = min. of 2% and max. of 4%. Time to trip = minimum of 1 min. 10 sec. and maximum of 5 min. 20 seconds).

Under/Over Voltage Protection: [d/e]
Press (+) (-) to Change Setting

Possible values of [d/e] are: Disable (Factory Default) and Enable.

Help Note:
Holds at ±10% of nominal voltage. Trips at ±15% nominal voltage. Trips in 60 seconds at ±12% nominal. The trip timer resets at ±9% nominal (ie. if you are in the 12%-60 second trip window and the voltage drops to +9% from +12%, the trip timer resets.)

Note: Under/Over Voltage Protection is activated only if Under/Over Voltage Protection is enabled and Line Voltage Sensing Option is Installed.

Phase Reversal Protection Enable

This screen does not appear if the starter type is "Adaptive Frequency" or "AFDB."

Phase Reversal Protection: [d/e]
Press (+) (-) to Change Setting

Possible values of [d/e] are: Disable and Enable (Factory Default).

A phase reversal is detected on the incoming current. On a compressor startup, the phase reversal logic must detect and trip in 0.7 seconds.

Help Note:
Rotation must be clockwise (ABC) from the thrustbearing end.

Phase Unbalance Limit Enable

Phase Unbalance Limit: [d/e]
Press (+) (-) to Change Setting

Possible values of [d/e] are: Disable and Enable (Factory Default).

The RLA of the motor is derated by resetting the active current limit. The trip point is a 30% phase unbalance for 90 seconds.

Momentary Power Loss (MPL) Protection Enable

This screen does not appear if the starter type is "Adaptive Frequency" or "AFDB." or Compressor Power Source is Engine/Generator.

Momentary Power Loss Protection: [d/e]
Press (+) (-) to Change Setting

Possible values of [d/e] are: Disable and Enable (Factory Default).

For MPL, on every power down, the reset inhibit timer is reset to 30 seconds if the motor temperature is <165°F and 15 minutes if the motor temperature is > or = to 165°F.

Enhanced Oil Temp. Protection

This screen does not appear if the starter type is "Adaptive Frequency" or "AFDB.

When enhanced oil protection is enabled, the oil heater relay is energized at 140.5°F (60.3°C) and de-energized at 145.5°F (63.1°C). The low oil temperature cutout "setpoint" is equal to the saturated evaporator refrigerant temperature plus 30°F (16.6°C) or 100 °F (37.8°C) which ever is larger."

Enhanced Oil Temp Protection: [option]
Press (+) (-) to Change Setting

Possible options are: Disable and Enable (Factory Default).

Help Note:

*Enhanced oil protection **must** be enabled for all refrigerant pump units to sense the "Low Oil Temperature Running" diagnostics.*

Oil Temp Setpoint

This screen does not appear when Enhanced Oil Temperature Protection is enabled.

Oil Temp SetPoint: xxx.x f/c
Press (+)(-) to Change Setting

The range of values is 100°F to 160°F (37.8 to 71.1°C) in increments of 1 or 0.1°F or °C, depending on the Service Setup Screen xxx or xxx.x. Factory Default is 143°F (61.9°C).

Low Oil Temp Cutout

This screen does not appear when Enhanced Oil Temperature Protection is enabled.

Low Oil Temp Cutout: xxx.x f/c
Press (+)(-) to Change Setting

Range of values is 80 to 140°F (26.7 to 60.0°C) in increments of 1 or 0.1°F or °C depending on the Service Setup Screen xxx or xxx.x. Factory Default is 95°F (35.0°C).

Low Oil Temp Start Inhibit Differential

This screen only appears when Enhanced Oil Temperature Protection is enabled.

Low Oil Temp Start Inhibit Diff: xxx.x f/c
Press (+)(-) to Change Setting

Range of values is 20 to 30°F (11.1 to 16.7°C) in increments of 1 or 0.1°F or °C depending on the Service Setup Screen xxx or xxx.x. Factory Default is 27.5°F (15.3°C).

High Discharge Temp Cutout

This screen is displayed only if the Discharge Sensor Option is installed.

High Discharge Temp Cutout: xxx.x f/c
Press (+)(-) to Change Setting

Range of values is 170 to 220°F (76.6 to 104.4°C) in increments of 1 or 0.1°F or °C depending on the Service Setup Screen xxx or xxx.x. Factory Default is 200°F (93.3°C).

External Base Loading Enable

External Base Loading: [d/e]
Press (+)(-) to Change Setting

Possible values of [d/e] are: Disable (Factory Default) and Enable.

Soft Load Control Enable

Soft Load Control: [d/e]
Press (+)(-) to Change Setting

Possible values of [d/e] are: Disable (Factory Default) and Enable.

Soft Load Starting Current Limit

Soft Load Starting Current Limit: xx %
Press (+)(-) to Change Setting

Range of values is 40 to 100% in increments of 1%. Factory Default is 100%.

Help Note:
The unit will start using the set number, i.e. 60% and SLOWLY ramp up to 100%.

Soft Load Current Limit Rate Of Change

Soft Load Current Limit Rate:x.x %/min
Press (+)(-) to Change Setting

Range of values is 0.5 to 5%/Min in increments of 1 or 0.1%/Min depending on the Service Setup Screen xxx or xxx.x. Factory Default is 5%/Min.

Help Note:
This controls the soft load rate of change.

Soft Load Lvng Wtr Temp Rate of Change

Soft Load Lvg Water Rate: x.x f/c/min
Press (+)(-) to Change Setting

Range of values is 0.5 to 5°F/Min (0.3 to 2.8°C/Min) in increments of 1 or 0.1°F/Min depending on the Service Setup Screen xxx or xxx.x. Factory Default is 5°F/Min (2.8°C/Min).

Hot Gas Bypass Enable

This screen does not appear when the hot gas bypass option is not installed.

Hot Gas Bypass Control: [d/e]
Press (+)(-) to Change Setting

Possible values of [d/e] are: Disable (Factory Default) and Enable.

HGBP Timer Enable

The following will be displayed only if HGBP is installed.

HGBP Timer: [Status]
Press (+)(-) to Change Setting

The choices for Status are: Enable (Factory Default) and Disable (Unimtd Time).

Maximum HGBP Time

The following will be displayed only if HGBP is Installed and the HGBP Timer is Enabled.

Maximum HGBP Time: xxx Min
Press (+)(-) to Change Setting

Range of values is 1 to 480 minutes in increments of 1 Minute. Factory Default is 30 Minutes.

Help Note:
Turns off the unit at the maximum time, i.e. 30 minutes

HGBP Mode, Vane Target

This screen does not appear when the hot gas bypass option is not installed.

Hot Gas Bypass Mode IGV Target:xx %
Press (+)(-) to Change Setting

Range of values is 0 to 30% in increments of 1%. Factory Default is 10%. This setting drives the IGVs to the target when HGBP is entered.

LWT Control Proportional Gain (Kp) Setpt

LWT Proportional Gain: xxx.x %/F
Factory Dflt is 10.0 %/F & 18.0 %/C

The range of valves is 0 to 100%/°F (0 to 180%/°C) in increments of 0.1.

Help Note:
Looks at how far from setpoint and how fast we move the vanes. Higher number is faster.

LWT Control Integral Gain (Ki) Setpt

LWT Integral Gain:x.xxx %/F
Factory Dflt is 0.110 %/F & 0.198 %/C

The range of valves is 0 to 1%/°F (0 to 1.8%/°C) in increments of 0.001. The Factory Default is 0.110%/°F (0.198%/°C).

Help Note:
Looks at error from setpoint, how long we have been away (Time) from setpoint. A higher number means the faster we converge on the setpoint, but may make the control oscillatory.

LWT Control Derivative Gain (Kd) Setpt

LWT Derivative Gain: xx.x %/F
Factory Dflt is 00.0 %/F & 00.0 %/C

The range of valves is 0 to 10.0%/F (0 to 18.0%/C) in increments of 0.1. The Factory Default is 00.0%/F (00.0%/C).

Help Note:
Rate of change. Higher number settles out an oscillating system.

IGV Maximum Travel Setpt

This screen is displayed only if "Inlet Guide Vane Output" is "Stepper Motor."

IGV Maximum Travel: xx,xxx Steps
Press (+) (-) to Change Setting

Range of values is 0 to 60,000 Steps in increments of 100 Steps. Factory Default is 50,000 Steps.

Note: this is also known as the 90 degree vane setting. You must use the value determined at the factory. Each unit is unique and must be individually set. If the factory setting cannot be determined, it must be field-supplied by following the procedure in Trane CVHF-CSB-2B.

Guide Vane Closed Travel Stop

This screen is displayed only if "Inlet Guide Vane Output" is "Stepper Motor."

Guide Vane Closed Travel Stop: xx.x %
Press (+) (-) to Change Setting

Range of values is 0 to 100% in increments of 1%. Factory Default is 0%.

AF Adjustable Speed Control Algorithm Enable

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

AF Adaptive Speed Control Alg: d/e
Press (+) (-) to Change Setting

Possible values of [d/e] are: Disable and Enable (Factory Default).

AF Leaving Water Standard Deviation

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

AF Leaving Water Standard Deviation: x.x
Press (+) (-) to Change Setting

Range of values is 0.5 to 4.0 in increments of 0.1. Factory Default is 1.0.

AF Pressure Coefficient Constant

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

AF Pressure Coefficient Constant: xxxx
Press (+) (-) to Change Setting

Range of values is 0 to 2000 in increments of 1. Factory Default is 800.

Note: The above value entered is 1.316 X 10^9 / (# Stages X (Impeller Dia ^2)) all divided by 1000 for the purpose of display and IPC data transmission (e.g. the actual range is 0-2,000,000 in increments of 1000). In the chiller module it is multiplied by 1000 again so it is properly scaled.

AF Re-Optimization Factor

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

AF Re-Optimization Factor: x.xx
Press (+)(-) to Change Setting

Range of values is 0.03 to 1.00 in increments of 0.01. Factory Default is 0.30.

AF Re-Optimization Timer

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

AF Re-Optimization Timer: xxx Hrs
Press (+)(-) to Change Setting

Range of values is 1 to 255 in increments of 1. Factory Default is 24.

AF Boundary Pressure Coefficient Y Intercept

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

AF Boundary PC Y-Intercept: x.xx
Press (+)(-) to Change Setting

Range of values is 0.01 to 2.00 in increments of 0.01. Factory Default is 0.40. This setpoint is settable from this screen but also changes as the Adjustable Frequency Control Algorithm runs. It is similar to a clock setting where you set it and then it runs from there.

AF Boundary Pressure Coefficient Y Intercept Max

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

AF Boundary PC Y-Intercept Maximum: x.xx
Press (+)(-) to Change Setting

Range of values is 0.01 to 2.00 in increments of 0.01. Factory Default is 2.00.

AF Pressure Error Deadband

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

AF Pressure Error Deadband: x.xxx
Press (+)(-) to Change Setting

Range of values is 0.001 to 1.000 in increments of 0.001. Factory Default is 0.030.

AF Proportional Speed Gain

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

AF Proportional Speed Gain: xxx
Press (+) (-) to Change Setting

Range of values is 1 to 100 in increments of 1. Factory Default is 50.

Minimum Capacity Timer Enable

Min Capacity Timer: [Status]
Press (+) (-) to Change Setting

The choices for Status are: Enable (Factory Default) and Disable (Unlmtd Time).

Note: On Non-Adaptive Frequency chillers this Timer times out when the chiller is at minimum IGV position and the Leaving Water Temp is below the CWS. On Adaptive Frequency chillers this Timer times out when the chiller is at minimum IGV position or minimum AF speed and LWT < CWS.

Time Permitted at Minimum Capacity

The following will be displayed only if the Minimum Capacity Timer setpoint is Enabled.

Time Permitted at Min Cap: xxx Min
Press (+) (-) to Change Setting

Range of values is 1 to 480 minutes in increments of 1 Minute. Factory Default is 30 Minutes.

Evaporator Flow Coefficient

The following is displayed only if the Differential Water Press Sensor Option is Installed.

Evap Flow Coefficient: xxxx
Press (+) (-) to Change Setting

Range of values is 0 to 3000 in increments of 5. Factory Default is 1000.

Help Note:
Flow coefficients and flow exponents screens are factory-set and used only for differential water pressure sensing option.

Evaporator Flow Equation Exponent

The following is displayed only if the Differential Water Press Sensor Option is Installed.

Evap Flow Equation Exponent: xxxx
Press (+) (-) to Change Setting

Range of values is 0 to 1000 in increments of 1. Factory Default is 600.

Note: The desired range for the above is 0.5000 to 0.6000. To put in this kind of range into the CLD, the fact that it does not start at zero represents a special case. To minimize special cases it is preferred that a multiplier of 10,000 and a offset of 5000 be used in the computer that generates the number.

Evaporator Fluid Coefficient

The following is displayed only if the Differential Water Press Sensor Option is Installed.

Evap Fluid Coefficient: xxxx
Press (+) (-) to Change Setting

Range of values is 0 to 1000 in increments of 1. Factory Default is 400.

Note: The desired range for the above is 0.0000 to 0.1000. To put in this kind of range into the CLD, the fact that it does not start at zero represents a special case. To minimize special cases it is preferred that a multiplier of 10,000 be used in the computer that generates the number.

Condenser Flow Coefficient

The following is displayed only if the Differential Water Press Sensor Option is Installed.

Cond Flow Coefficient: xxxx
Press (+) (-) to Change Setting

Range of values is 0 to 2000 in increments of 5. Factory Default is 500.

Condenser Flow Equation Exponent

The following is displayed only if the Differential Water Press Sensor Option is Installed.

Cond Flow Equation Exponent: xxxx
Press (+)(-) to Change Setting

Range of values is 0 to 1000 in increments of 1. Factory Default is 600.

Help Notes:
Flow coefficients and flow exponents screens are factory-set and used only for differential water pressure sensing option.The desired range for the above is 0.5000 to 0.6000. To put in this kind of range into the CLD, the fact that it does not start at zero represents a special case. To minimize special cases it is preferred that a multiplier of 10,000 and a offset of 5000 be used in the computer that generates the number.

Local Atmospheric Pressure

Local Atmospheric Pressure: xx.x psia/kpa
Press (+)(-) to Change Setting

The range of settings is 10 to 16 psig in increments of 1 or 0.1 psig or kPa depending on the Service Setup Screen xxx or xxx.x. The Factory Default is 14.7 psig.

Help Note:
This is important for correct temperature to pressure conversion

Refrigerant Pressure Analog Output Option

Rfgt Pressure Output Option: [status]
Press (+)(-) to Change Setting

Possible values for status are: % Cond (Factory Default) and Delta.

Min Delta Pressure Calibration

The following is displayed only if the "Refrigerant Pressure Analog Output Option" is set to "Delta".

Min Delta Press Calib (2 VDC):XXXXPSID/kPa
Press (+)(-) to Change Setting

The range of values is 0-400 psid (0-2758 kPa) in increments of 1 psid/kPa. Factory Default is 0 psid (0 kPa).

Note: 6.8948 kPa = 1 psi.

Max Delta Pressure Calibration

The following is displayed only if the "Refrigerant Pressure Analog Output Option" is set to "Delta".

Max Delta PressCalib (10 VDC):XXXXPSID/kPa
Press (+)(-) to Change Setting

The range of values is 1-400 psid (7-2758 kPa) in increments of 1 psid/kPa. Factory Default is 30 psid (207 kPa).

Note: 6.8948 kPa = 1 psi.

IGV Stroke Time

The following is displayed only if the "Inlet Guide Vane Output" is set to "Pulsed".

Inlet Guide Vane Stroke Time: XXX Sec
Press (+)(-) to Change Setting

The range of values is 15 to 100 seconds in increments of 1 second. Default is 45 seconds.

Low Differential Oil Pressure Cutout

This screen is displayed only if the "Oil Pressure Protection" is "Transducer".

Low Diff Oil Press Cutout: XX psid/kpa
Press (+)(-) to Change Setting

The range of values is 9 to 35 psid in increments of 1 psid. Default is 12 psid.

Check Oil Filter Diagnostic

This screen is available only if differential oil pressure transducer(s) are installed.

Check Oil Filter Diagnostic: [setting]
Press (+) (-) to Change Setting

Possible values of [setting] are: Disable (Factory Default) and Enable.

Check Oil Filter Setpoint

This screen is displayed only if differential oil pressure transducer(s) are installed and check oil filter diagnostic is enabled.

Check Oil Filter Setpt: [setting]
Press (+) (-) to Change Setting

Possible values of [setting] are: 9 to 60 psid in 1 psid increments. Factory Default is 15 psid.

Evap Leaving Water Temp Offset

Evap Leaving Water Temp Offset: [setting]
Press (+) (-) to Change Setting

Possible values of [setting] are: -2.0°F to 2.0°F in 0.1°F increments (-/+ 1.1°C in 0.1°C increments). Factory Default is 0.0°F.

Saturated Evap Rfgt Temp Offset

Saturated Evap Rfgt Temp Offset: [setting]
Press (+) (-) to Change Setting

Possible values of [setting] are: -2.0°F to 2.0°F in 0.1°F increments (-/+ 1.1°C in 0.1°C increments). Factory Default is 0.0°F.

Water Pressure Calibration

The following menus is displayed only if the "Diff Wtr Press Sensor" setpoint is set to "Installed, <= 150 psig."

Water Pressure Calibration: [setting]
Press (+) (-) to Change Setting

Possible values of [setting] are: Auto (Factory Default) and Manual

If the above menu is set to "Manual," the following two menus are displayed.

Measured Evap Diff Wtr Press: X.X PSID/kPa
Press (+) (-) to Change Setting

Possible values is 0 to 25 psid (0 to 172.4 kPa) in 0.1 psid (kPa) increments. Factory Default is 0.0 psid (kPa).

Measured Cond Diff Wtr Press: X.X PSID/kPa
Press (+) (-) to Change Setting

Possible values is 0 to 25 psid (0 to 172.4 kPa) in 0.1 psid (kPa) increments. Factory Default is 0.0 psid (kPa).

The value displayed in the preceding two menus shall normally be 0.0 psid (kPa). When a manual calibration of the evaporator or condenser water pressure is desired, the measured differential pressure shall be entered in the appropriate menu. This non-zero value shall return to 0.0 psid (kPa) when the water pressure calibration is completed.

Machine Configuration

Important! *FACTORY DEFAULT SETTINGS: Menu items that are programmable using the keypad may have a selectable choice that is listed as Factory Default. This Factory Default setting is the software default that is initially factory-programmed for a new module assembly and may NOT be the correct setting for a specific operating chiller. Always review all settings when any module is replaced to verify that the settings agree with the desired settings that were selected at initial startup or programmed at the factory.*

Service Settings - Machine Configuration

The Machine Configuration password is + - + - + - <Enter>. If the machine configuration password is entered, the display goes to the menu defined below. If a key is not pressed every 10 minutes in this password protected menu, the display returns to the Chiller Operating Mode display of the Chiller Report, and the password must be entered again to return to this menu.

Machine Configuration Group Heading

Machine Configuration Group Settings
Press (Next)(Previous) To Continue

This header appears when the headers do not appear in the Service Settings menu.

Unit Frequency

Unit Frequency: [Freq]
Press (+)(-) to Change Setting

Possible values of Frequency are: 60 Hz (Factory Default) and 50 Hz.

Unit Type

Unit Type: [type]
Press (+)(-) to Change Setting

Unit type will default to one of three chiller types. The default unit type will limit the selections to chillers of that type.

When the Factory Default is CVHE, possible values of unit type are: CVHE, CVGF, FastPak water-cooled, FastPak air cooled, CVHG, CVHF, CVHB, CVGE, and CVGG.

Nominal Unit Tons

Help Note:
Used for ton display resolution

Nominal Unit Tons: [tons]
Press (+)(-) to Change Setting

Possible values of [tons] are "100" through "1800" in 10 ton increments. Factory Default is 500 tons.

Refrigerant Type

Refrigerant Type: [type]
Press (+)(-) to Change Setting

Possible values for type are: R11, R123 (Factory Default), R12, R134a, Water, R22, and R113.

Help Note:
This is important for correct temperature to pressure conversion

Refrigerant Monitor Type

Refrigerant Monitor Type: [type]
Press (+)(-) to Change Setting

Possible values for type are: None (Factory Default), Analog interface, and IPC Interface.

Starter Type

Starter Type: [type]
Press (+)(-) to Change Setting

Possible values for type are: Undefined, Adaptive Frequency (AFDA), Y Delta (Factory Default), X Line, Solid State (C515 Series), Auto Transformer, and Primary Reactor, AFDB, Solid State (SMCPP) (Standalone for FastPak only).

Startup Contactor Test - Y-D Starters Only

This screen shall be displayed only when the starter type is Y-Delta.

Level 2 ContactorIntegrityTest: [d/e]
Press (+)(-) to Change Setting

Possible values of [d/e] are: Disable (Factory Default) and Enable. This test checks for welded contactors before every start.

Rated Load Amps

Rated Load Amps: xxxx Amps
Press (+)(-) to Change Setting

The range of values is 0-2500 in 1 amp increments. Factory Default is 500 Amps.

Motor Heating Constant

Motor Heating Constant Setpt: xxx Min
Press (+)(-) to Change Setting

The range of values XXX is 0 to 100 Minutes in 1 Minute increments. Factory Default is 25 Minutes.

Select the Motor Heating Constant using the following table:

NTON		Motor Heating Constant
60 Hz	50 Hz	
230-320	190-270	30 Min
360-500	300-420	35 Min
560-800	470-660	40 Min
890-1280	740-1040	45 Min

Current Overload Setting #1

Current Overload Setting #1: xxxxxxxx
Press (+) (-) to Change Setting

The range of values is Decimal 00 through 31. Factory Default is 00. Factory set per nameplate.

Current Overload Setting #2

Current Overload Setting #2: xxxxxxxx
Press (+) (-) to Change Setting

The range of values is Decimal 224 through 255. Factory Default is 255. For security purposes the second setting is the 8-bit one's complement of the first setting above. The current overload settings establish the running current protection.

Procedure For Selecting Current Overload Settings for UCP2

1 Determine the Rated Load Amps (RLA) from the Unit Nameplate.

2 Refer to *Table 2* or *Table 3* as follows:

Select *Table 2* if any of the following conditions are met:

- ❑ the unit has a unit mounted starter with an RLA less than 936 Amps.
- ❑ The unit has a 24" wide control panel; no unit mounted starter, and RLA less the 936 Amps.
- ❑ The starter has a single CT/phase wired directly to the starter module.

Select *Table 3* if any of the following conditions are met:

- ❑ The unit has an RLA over 935 Amps.
- ❑ The unit has a 38" wide "Starter By Others" control panel.
- ❑ The starter has two CTs/phase wired to the starter module (greater than 600 volts).

3 Using *Table 2* or *Table 3* (determined from Step 2), determine the CT Meter Scale Rating based on the RLA from Step 1.

4 Calculate the CT factor using one of the following two equations:

If *Table 2* was used: CT Factor = (Motor RLA/CT Meter Scale Rating) x 100

If *Table 3* was used: CT Factor = (Motor RLA/CT Meter Scale Rating) x 139

5 Refer to *Table 4* . Determine Current Overload Settings #1 and #2 based on the CT Factor calculated in Step 4.

Verify Current Overload Setting #1.

Verify Current Overload Setting #2.

Table 2
CT Factor = (Motor RLA/CT Meter Scale Rating) X 100

Motor RLA	*CT Part No.*	*Ext*	*CT Meter Scale Rating*
34-50A	*x13580253*	*09*	*50A*
51-67A		*10*	*75A*
68-100A		*01*	*100A*
101-134A		*02*	*150A*
135-184A		*03*	*200A*
185-267A		*04*	*275A*
268-334A		*05*	*400A*
335-467A		*06*	*500A*
468-667A		*07*	*700A*
668-935A		*08*	*1000A*

Table 3
CT Factor = (Motor RLA/CT Meter Scale Rating) X 139

Line CT Part No.	Ext	Line CT Ratio	CT Ter. Conn	No. of Prim. Turns	RLA Ranges	Meter Scale
X13580272	-01	50:5	X1 to X2	3	8.0 – 11.9	16.7
				2	12.0 – 17.9	25.0

						99	30	225

Maximum Acceleration Timer #1

Maximum Accel Timer Setpt #1: xx Sec
Press (+)(-) to Change Setting

The range of values is 6 to 64 seconds. Factory default is 27 seconds.

Starter Type	*Recommended Max. Accel. Timer #1 Setting*
Undefined	*Contact Factory*
Variable Speed	*20*
Y-Delta	*27 (Factory Default)*
X-Line	*6*
Sold State	*20*
Auto-transformer	*16*
Primary Reactor	*11*

Maximum Acceleration Timer #2

The maximum acceleration timers establish the starting overcurrent protection.

Maximum Accel Timer Setpt #2: xx Sec
Press (+)(-) to Change Setting

The range of values is 191 to 249 Sec. Factory Default is 228 Seconds. For security purposes the second setting is the 8-bit one's complement of the Timer #1 setting above. Both the Maximum Accel. Timers and the Overload Settings are not adjustable from either the Remote CLD or Tracer or any other Remote/External Device.

Hot Water Control Option

This screen does not appear if compressor power source is "Engine/Generator."

Hot Water Control Option: [status]
Press (+)(-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Heatsink Start Inhibit Temperature Setpoint (FastPak)

Heatsink Start Inhibit Temp: xxx.x f/c
Press <+> <-> To Change Setting

The range of values shall be 100.0 to 200.0 °F (37.8 to 93.3 °C) in increments of .1°F/°C. Default shall be 100 °F (93.3 °C).

External Chilled Water Setpoint Option

External Chilled Wtr Setpoint:[Status]
Press (+)(-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

External Current Limit Setpoint Option

External Current Limit Setpt:[Status]
Press (+)(-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

External Hot Water Setpoint Option

External Hot Water Setpoint: [Status]
Press (+)(-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Acceleration Time Out Action

Acceleration Time Out Action: [action]
Press (+)(-) to Change Setting

Possible values for "action" include: Shutdown (Factory Default) and Transition. Transition results in an IFW diagnostic.

Motor Over Temperature Protection

Motor Temp Protection: [input]
Press <+> < - > to Change Setting

Possible value of [input] are: 3 Winding Sensors, MTC Switch. Factory default is 3 Winding Sensors

Motor Winding RTD Type

Motor Winding RTD Type: [type]
Press (+)(-) to Change Setting

Possible values for type are: 75 Ohm at 75°F (Factory Default) and 100 Ohm at 0°C

High Pressure Cutout Setting

High Pressure Cutout Setting:xxxx Psig/kPa
Press (+)(-) to Change Setting

The range of values is -5-500 psig (350-3447 kPa) in increments of 5 psig/kPa. Factory Default is 15 psig (103 kPa) from -5 to 5 psig in increments of 1.

Help Note:
This is the pressure limit algorithm that will, in sequence, Limit-Hold-Close vane opening.

Line Voltage Sensing Option

Line Voltage Sensing Option: [status]
Press (+)(-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Unit Line Voltage

This screen will not appear if the Line Voltage Sensing Option is not installed.

Unit Line Voltage: [volt]
Press (+)(-) to Change Setting

Possible values of [volt] are "180" through "6600" in 5 volt increments. Factory Default is 460 volts.

Auxiliary Condenser Option

Auxiliary Condenser Option: [status]
Press (+)(-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Heat Recovery Option

Heat Recovery Option: [status]
Press (+)(-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Hot Gas Bypass Option

Hot Gas Bypass Option : [status]
Press (+)(-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Free Cooling Option

Inlet Guide Vane Output
Has been Set to Stepper Motor

Free Cooling Option: [status]
Press (+)(-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Condenser Pressure Sensor Option

Condenser Press Sensor Option: [status]
Press (+) (-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Bearing Temperature Sensors Option

Bearing Temp Sensors Option: [status]
Press (+) (-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Discharge Temperature Sensor Option

Discharge Temp Sensor Option: [status]
Press (+) (-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Ice Building Option

Ice Building Option: [status]
Press (+) (-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Differential Water Press Sensing Option

Diff Wtr Press Sensor Opt: [status]
Press (+) (-) to Change Setting

Possible values for status are: Installed, <= 150 psig (1035 kPa), Installed, > 150 psig (1035 kPa), and Not Installed (Factory Default).

This option screen applies to both the Evap and Cond differential water pressure sensors for both systems less than or equal to 150 psig (Sensors at the Chiller Module) and systems greater than 150 psig (Sensors at the Options Module).

External Analog Input Type Selection, 4-20 ma/2-10 VDC

External Setpoint Inputs: [type]
Press (+) (-) to Change Setting

Possible values for status are: 4-20ma (Factory Default) and 2-10 VDC.

Tracer Option

Tracer Option: [status]
Press (+) (-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

TCI Option

TCI Option: [status]
Press (+) (-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Printer Option

Printer Option: [status]
Press (+) (-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

Duplex Control Module (DCM) Option

DCM Option: [status]
Press (+)(-) to Change Setting

Possible values for status are: Installed and Not Installed (Factory Default).

IGV Output Type

Inlet Guide Vane Output: [Y]
Press (+)(-) to Change Setting

Possible values for Y are: Stepper Motor (Factory Default) and Pulsed.

If Inlet Guide Vane Output is set to Pulsed and the Hot Gas Bypass Option is currently set to Installed, the Hot Gas Bypass Option will be set to Not Installed and the following will be displayed for 3 sec to indicate the change.

Hot Gas Bypass Option
Has Been Set to Not Installed

Oil Pressure Protection

Oil Pressure Protection: [status]
Press (+)(-) to Change Setting

Possible values for [status] are: Transducer (Factory Default), and Diff Switch, Xducer & Switch.

Programmable Analog Output

Program Analog Output: [Output]
Press <+> <-> To Change Setting

Possible values of [Output] are:

Not Used	% Cond Pres
% RLA	Refrig Diff Pres

Factory Default is % RLA.

Programmable Relay Outputs

The following represents three menu items and is repeated for [N] = 1, 2, or 3.

Program Relay [N]: [Relay]
Press <+> <-> To Change Setting

Possible values of [Relay] are:

Not Used	Limit Warning
Comp Running	Ice Making
MMR Alarm	Head Relief Request
MAR Alarm	Tracer Controlled
MMR + MAR Alarm	Max Capacity

Factory Default for

[N] = 1 is MMR + MAR Alarm.
[N] = 2 is Comp Running.
[N] = 3 is Not Used.

Current Transducer Setpoint

The following will only be displayed if starter type is set to "Stand Alone - No Starter Module".

Current Xducer: [Setting]
Press <+> <-> To Change Setting

Possible values for [Setting] are: Cutler Hammer; Other Factory Default is "Cutler Hammer"

Note: Select "Cutler Hammer" if starter has an A-1 module, otherwise select "Other".

Current Transducer at 100% RLA

The following will only be displayed if Current Transducer is set to "Other".

Current Xducer at 100% RLA: XX.X VDC
Press <+> <-> To Change Setting

Range of values is -10.0 to -5.0 VDC in increments of 0.1 VDC

Note: Calculate setpoint as follows:

Current Transducer at 100% RLA =

$$\frac{\textit{Machine LRA}}{\textit{CT Span}} X(-10)$$

Compressor Power Source

Cprsr Power Source: [status]
Press (+)(-) to Change Setting

Possible settings for [status] are: Utility (Factory Default) and Engine/Generator.

Refrigerant Monitor Settings Group

The Refrigerant Monitor Settings password is - - + + - - <Enter>. If the refrigerant monitor settings password is entered, the display goes to the menu defined below. If a key is not pressed every 10 minutes in this password protected menu, the display returns to the Chiller Operating Mode display of the Chiller Report, and the password must be entered again to return to this menu.

Refrigerant Monitor Settings Group Heading

Refrigerant Monitor Group Settings
Press (Next)(Previous) To Continue

Alarm Level 1

Alarm Level 1: XXXX PPM [Rfgt Type]
Press (+)(-) to Change Setting

Range of values are 3 to Alarm Level 2 minus 1 in increments of 1. The maximum value for R-123 is 30.

Alarm Level 2

Alarm Level 2: XXXX PPM [Rfgt Type]
Press (+)(-) to Change Setting

Range of values are Alarm Level 1 plus 1 to Alarm Level 3 minus 1 in increments of 1.

Alarm Level 3

Alarm Level 3: XXXX PPM [Rfgt Type]
Press (+)(-) to Change Setting

Range of values are Alarm Level 2 plus 1 to 1000 in increments of 1.

Refrigerant Audible Alarm

Refrigerant Audible Alarm: [Setting]
Press (+)(-) to Change Setting

Possible values are: Disable, Alarm 1, Alarm 2, Alarm 3.

Trouble Audible Alarm

Trouble Audible Alarm: [Status]
Press (+)(-) to Change Setting

Possible values of status are: Disable, Enable.

Alarm 1 Latching Status

Alarm 1 Latching Status: [Status]
Press (+)(-) to Change Setting

Possible values of status are: Latching, Non-Latching.

Alarm 2 Latching Status

Alarm 2 Latching Status: [Status]
Press (+)(-) to Change Setting

Possible values of status are: Latching, Non-Latching.

Alarm 3 Latching Status

Alarm 3 Latching Status: [Status]
Press (+)(-) to Change Setting

Possible values of status are: Latching, Non-Latching.

Channel Scanner

This item shall be displayed only when the refrigerant monitor mode is Warmup.

Channel Scanner: [Status]
Press (+)(-) to Change Setting

Possible values of status are: Installed, Not Installed.

Scanner Channel 1

Scanner Channel 1: [Status]
Press (+)(-) to Change Setting

Possible values of status are: Active, Inactive.

Scanner Channel 2

Scanner Channel 2: [Status]
Press (+)(-) to Change Setting

Possible values of status are: Active, Inactive.

Scanner Channel 3

Scanner Channel 3: [Status]
Press (+)(-) to Change Setting

Possible values of status are: Active, Inactive.

Scanner Channel 4

Scanner Channel 4: [Status]
Press (+)(-) to Change Setting

Possible values of status are: Active, Inactive.

Scanner Dwell Threshold

Scanner Dwell Threshold: XX %
Press (+)(-) to Change Setting

The range of values for Scanner Dwell Threshold is 30 to 70 in increments of 1.

Auxiliary Input

Auxiliary Input: [Status]
Press (+)(-) to Change Setting

Possible values of status are: Installed, Not Installed.

Auxiliary Input Alarm

Auxiliary Input Alarm: [Status]
Press (+)(-) to Change Setting

Possible values of status are: Enable, Disable.

Auxiliary Input Alarm Level: XX.X mA
Press (+)(-) to Change Setting

Range of values is 4.0 to 20.0 in increments of 0.1.

Auxiliary InputAlarm Direction:[Direction]
Press (+)(-) to Change Setting

Possible values of Direction are: Above, Below.

Auxiliary Input Audible Alarm:[Status]
Press (+)(-) to Change Setting

Possible values of Status are: Disable, Enable.

Analog Output Range

Analog Output Range: [Range] PPM
Press (+)(-) to Change Setting

Refrigerant Monitor Calibration

The Refrigerant Monitor Calibration password is - + - - + + <Enter> for the field calibration menu. If a refrigerant monitor calibration password is entered, the display goes to the menu items defined below. If a key is not pressed every 20 minutes in this password protected menu, the display returns to the Chiller Operating Mode display of the Chiller Report, and a refrigerant monitor calibration password must be entered again to return to this menu.

Refrigerant Monitor Settings Group Heading

This header is displayed if the field calibration password was entered.

Rfgt Monitor Field Calibration Group
Press (Next)(Previous) To Continue

This header is displayed if the factory calibration password was entered.

Rfgt Monitor Factory Calibration Group
Press (Next)(Previous) To Continue

Refrigerant Monitor Mode

Refrigerant Monitor Mode: [Mode]
Scanner Channel X XXXX PPM [Rfgt Type]

This item is displayed if the Channel Scanner is not installed.

Refrigerant Monitor Mode: [Mode]
XXXX PPM [Rfgt Type]

Refrigerant Zero Calibration

Refrigerant Zero Calibration
(Enter) to Start, (Next) to Continue

If <Next> is pressed the following refrigerant zero calibration screens are skipped. If <Enter> is pressed the following screens are displayed to permit refrigerant zero calibration.

Starting The Calibration Procedure
Please Wait

If the refrigerant monitor is unable to calibrate, the following item is displayed.

Unable to Calibrate

Otherwise, continue with the following screens.

Connect Refrigerant Zero Gas
(Next) To Continue, (Cancel) To Exit

Open Gas Sample Valve
(Next) To Continue, (Cancel) To Exit

XXXX PPM [Rfgt Type]
(Enter) To Adjust Conc, (Cancel) to Exit

Locking The Reading
Please Wait

If the refrigerant monitor is unable to calibrate, the following item is displayed.

Unable to Calibrate

Otherwise, the following screens continue.

Refrigerant Zero Calibration XXXX
Press (Enter)(Cancel)(+)(-) To Continue

Starting The Calibration Procedure
Please Wait

This item is followed by one of the following two items.

Successful Calibration

Calibration Failed
(Enter) To Retry, (Cancel) To Exit

If the <Enter> key is pressed, the display will return to the second menu item above. If the <Cancel> key is pressed, the display continues to the next display.

Refrigerant Span Calibration

Refrigerant Span Calibration
(Enter) to Start, (Next) to Continue

If <Next> is pressed the following refrigerant span calibration screens are skipped. If <Enter> is pressed the following screens are displayed to permit refrigerant span calibration.

Starting The Calibration Procedure
Please Wait

If the refrigerant monitor is unable to calibrate, the following item is displayed.

Unable to Calibrate

Otherwise, the following screens continue.

Connect Refrigerant Span Gas
(Next) To Continue, (Cancel) To Exit

Open Gas Sample Valve
(Next) To Continue, (Cancel) To Exit

XXXX PPM [Rfgt Type]
(Enter) To Adjust Conc, (Cancel) to Exit

Locking The Reading
Please Wait

If the refrigerant monitor is unable to calibrate, the following item is displayed.

Unable to Calibrate

Otherwise, the following screens continue.

Refrigerant Span Calibration XXXX
Press (Enter)(Cancel)(+)(-) To Continue

Starting The Calibration Procedure
Please Wait

This item is followed by one of the following two items.

Successful Calibration

Calibration Failed
(Enter) To Retry, (Cancel) To Exit

If the <Enter> key is pressed, the display returns to the second menu item above. If the <Cancel> key is pressed, the display continues to the next display.

Service Tests Group

***Important!** FACTORY DEFAULT SETTINGS: Menu items that are programmable using the keypad may have a selectable choice that is listed as Factory Default. This Factory Default setting is the software default that is initially factory-programmed for a new module assembly and may NOT be the correct setting for a specific operating chiller. Always review all settings when any module is replaced to verify that the settings agree with the desired settings that were selected at initial startup or programmed at the factory.*

Service Tools Group Password Request

Pswd Reqd to Access Service ToolsGroup
Please Enter Password

The Service Tools Password is + + - - + + <Enter>. Successfully entering the password sends you to the Service Tools Group Heading Screen as defined below.

Pressing the <Next> and Increment keys simultaneously while the Service Tools Group Password Request screen is displayed will send you to the CLD-Chiller IPC communications screen shown below. This screen can be used as a debugging tool when CLD-Chiller IPC communications are suspect. The first line on the comm screen indicates which Chiller packets the CLD is checking. The second line on the comm screen indicates how many times in a 15 second interval the particular packet was received by the CLD. If a packet is received more than 9 times in the interval, a "+" is displayed. The counters are reset to 0 every 15 seconds. Hitting any key while on this screen will cause an exit.

Packet#:2 3 4 5 6 7 8 9 10 11 12 14 15
Received:x x x x x x x x x x x x x

If any item in the Service Tools Group is in manual override, the alarm LED will be on and non-flashing. The following table contains the Service Tools setpoints which affect the alarm light.To turn the alarm light off (from an on and non-flashing state), all the conditions applicable to the unit type must be satisfied.

Unit Type:	Function / Setpoint:	Condition to Turn Off manual Alarm LED:
ALL	"Chilled Water Pump:"	Auto
ALL except CVAE	"Condenser Water Pump:"	Auto
CTV	"Oil Pump:"	Auto
CTV with IGV Output set to Stepper Motor.	"Vane Control:"	Auto
CTV with HGBP installed:	"HGBP Valve Control Is:"	Auto
CTV with IGV Output set to Pulsed.	"IGV Control Is:"	Auto
CTV with AF starter:	"AF Manual Speed Control:"	Disable

Service Tools Group Heading

Service Tests & Overrides
Press (Next)(Previous) To Continue

This header appears when the headers do not appear in the Service Settings menu.

Chilled Water Pump

Chilled Water Pump: [Status]
Press (+)(-) to Change Setting

Possible values for Status are: Auto (Factory Default) and On.

Chilled Water Flow Switch Status

This screen displays the status of the chilled water flow switch status at the input to the UCM.

Chilled Water Flow Switch Status:
[y]

Possible values for [y] are: Flow Switch is Open/No Flow and Flow Switch is Closed/Flow.

Evaporator Differential Water Pressure

The following will be displayed only if the Differential Water Pressure Sensor Option is Installed.

Evap Differential Wtr Press: xx.x psid/kPa
Press (Next)(Previous) To Continue

Evaporator Entering/Leaving Water Pressure

The following will be displayed only if the low pressure (< or = to 150 psig) Differential Water Pressure Sensor Option is Installed.

Evap Entering Water Pressure:xx.x psid/kPa
Evap Leaving Water Pressure: xx.x psid/kPa

Condenser Water Pump

Condenser Water Pump: [Status]
[y]

Possible values for Status are: Auto (Factory Default) and On.

Possible values for [y] are: Press (+)(-) to Change Setting.

Condenser Water Flow Switch Status

This screen displays the status of the condenser water flow switch status at the input to the UCM.

Condenser Water Flow Switch Status:
[y]

Possible values for [y] are: Flow Switch is Open/No Flow and Flow Switch is Closed/Flow.

Condenser Differential Water Pressure

The following will be displayed only if the Differential Water Pressure Sensor Option is Installed.

Cond Differential Wtr Press: xx.x psid/kPa
Press (Next)(Previous) To Continue

Condenser Entering/Leaving Water Pressure

The following will be displayed only if the low pressure (< or = to 150 psig) Differential Water Pressure Sensor Option is Installed.

Cond Entering Water Pressure:xx.x psid/kPa
Cond Leaving Water Pressure: xx.x psid/kPa

Starter Dry Run

Use the following screen when [xx] = "Disabled".

Starter Dry Run: [xx]
Press +/- to Change

Use the following screen when [xx] Not equal to "Disabled".

Starter Dry Run: [xx]
(+) (-) (Enter): Trans Compl Inp: [y]

Possible values of [xx] are: Disabled (Factory Default), Shorting Relay On, Run Relay On, Start Relay On, Transition Relay On, and Start and Run Relays On.

Possible values of [y] are:

Closed This denotes that the Transition Complete input is seeing a contact closure.

Open This denotes that the Transition Complete input is seeing a contact open.

If the unit is not in the local Stop mode the following is displayed.

Starter Dry Run: Disabled
Unit Must Be In Local Stop To Execute

Oil Pump Status

This screen is displayed only if "Oil Pressure Protection" is set to "Transducer" or "Xducer & Switch."

Oil Pump: [Status]
Differential Oil Pressure: xx.x psid

Possible values for Status are: Auto (Factory Default) and On.

Differential Oil Pressure is not a setpoint but a status display.

Vane Control Status/Vane Position Commands

The following screens will be displayed only when the "Inlet Guide Vane Output" is set to "Stepper Motor".

Vane Control Is: [Status]
Press (+) (-) to Change Setting

The possible values of [status] are "Auto" or "Manual". Factory Default is "Auto".

If the vane control status is "Auto" the following is displayed:

Inlet Guide Vane Position: xxx.x %Open
[Limit mode]

If the vane control status is "Manual" the following is displayed. When the Vane Control Status is transitioned from "Auto" to "Manual", the manual target is initialized to the current vane position.

Vane Pos xxx.x % Target xxx.x % Open
LWT = xx.x [limit mode]

The possible values of limit mode are: "Current Limit", "Condenser Limit", "Evap Limit", and "(+) (-) and <Enter>".

Vane Position

The following screen will be displayed only when the "Inlet Guide Vane Output" is set to "Stepper Motor".

Inlet Guide Vane Position: xxxxx steps
Inlet Guide Vane Position:xx.x degrees

HGBP Valve Control Status/Manual Open and Close Commands

If HGBP is installed in the unit, the following screen is displayed:

HGBP Valve Control Is: [Status]
LWT = xx.x f/c [Y]

The possible values of [status] are "Auto", "Hold", "Open", or "Close". Factory Default is "Auto".

The possible values of Y are: "Current Limit", "Condenser Limit", "Evap Limit", and (+)-) and <Enter>". The latter is displayed when there are no limits operating.

HGBP Valve Manual Opening/Closing Duty Cycle

If HGBP is installed in the unit, the following screen is displayed:

Manual Opening/Closing Duty Cycle: xx%
Press (+)(-) to Change Setting

Range of values is 0 to 50% in increments of 1%. Factory Default is 30%.

Vane Control Status/Manual Load and Unload Commands

The following screen will be displayed only when the "Inlet Guide Vane Output" is set to "Pulsed".

IGV Control Is: [Status]
LWT = xx.x f/c [Y]

The possible values of [status] are "Auto", "Hold", "Load", or "Unload". Factory Default is "Auto".

The possible values of Y are: "Current Limit", "Condenser Limit", "Evap Limit", and "(+)(-) and <Enter>". The latter is displayed when there are no limits operating.

Manual Loading/Unloading Duty Cycle

The following screen will be displayed only when the "Inlet Guide Vane Output" is set to "Pulsed".

Manual Loading/Unloading Duty Cycle: xx%
Press (+)(-) to Change Setting

Range of values is 0 to 50% in increments of 1%. Factory Default is 30%.

Condenser Fan 3 [Status]
Fan 1 [x] Fan 2 [y] Fan 3 [z].....

Possible values for Status are: Auto (Factory Default) and On

Fan 1, Fan 2, and Fan 3 are not setpoints but a status display.

Possible values for x,y,z are Auto/On and On/Off.

Note: status display (2nd line) does not appear while in free cooling mode.

AF Manual Speed Control - CVHE/F/G Only

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

AF Manual Speed Control: [d/e]
Press (+)(-) to Change Setting

The possible values of [d/e] are: Disable (Factory Default) and Enable.

AF Compressor Speed Command - CVHE/F/G Only

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB", or the Compressor Power Source is Engine/Generator, and AF Manual Speed Control is Enabled.

AF Compressor Speed Command: xxxx RPM
Press (+)(-) to Change Setting

Range of values is 2520 to 3600 RPM for "Adaptive Frequency" Starter Type (2280 to 3600 RPM for "AFDB" Starter Type) in increments of 1 RPM. Factory Default is 3600 RPM.

AF Compressor Speed Command - CVHE/F/G Only

The following is displayed only if the Starter Type is "Adaptive Frequency" or AFDB" or the Compressor Power Source is Engine/Generator.

AF Compressor Speed Command: xx.x Hz
AF Compressor Speed Command:xxxx.x RPM

Note This is a Report only for Troubleshooting purposes.

AF Boundary Pressure Coefficient/AF Pressure Coefficient - CVHE/F/G Only

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

AF Boundary Press Coefficient: x.xxx
AF Pressure Coefficient: x.xxx

Note This is a Report only for Troubleshooting purposes.

AF Re-Optimization Timer Time Remaining- CVHE/F/G Only

The following is displayed only if the Starter Type is "Adaptive Frequency" or "AFDB" or the Compressor Power Source is Engine/Generator.

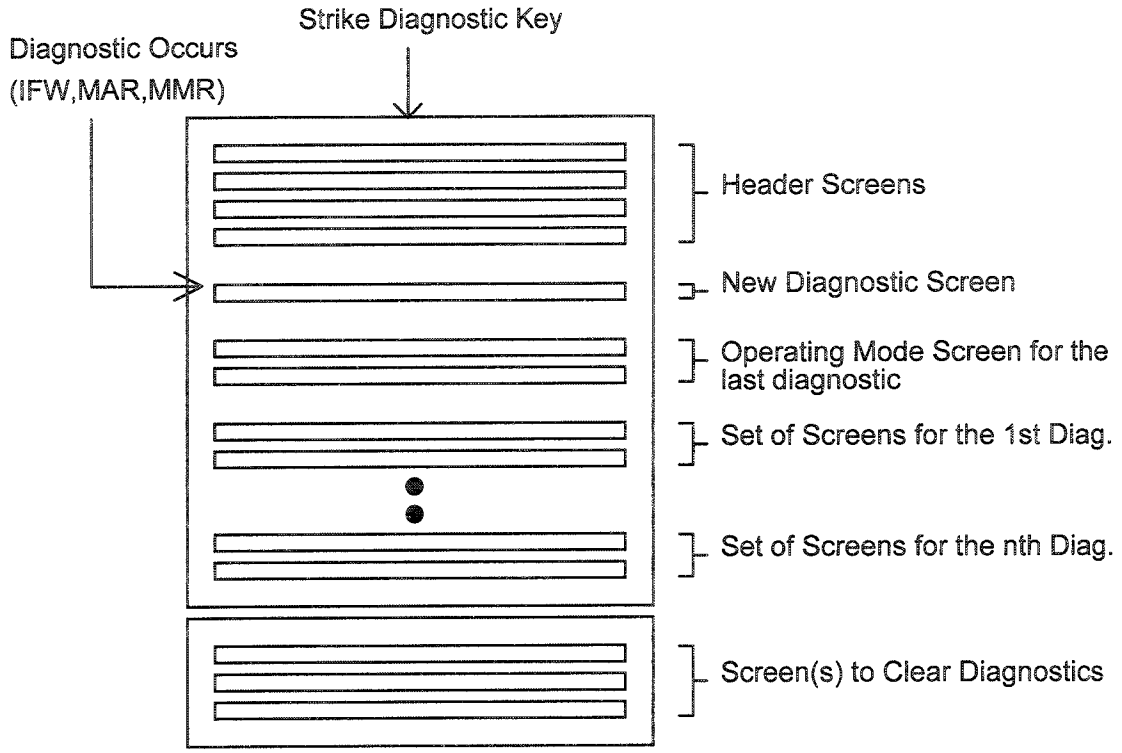
AF Re-Optimization Time Remaining:x.xx Hrs
Press (+)(-) to Change Setting

Note This is a Report only for Troubleshooting purposes.

Module Software Revision Levels

Press (Enter) To Display Software Revision Levels Or (Next) To Continue

If <Enter> is selected the following screen can be displayed 5 times with 5 different pairs of modules.



[Module 1:] [Revision Level]
[Module 2:] [Revision Level]

Module 1/2 will be one of the following: Chiller, Circuit, Starter, Options, Stepper 1, Stepper 2, TCI, Purge, LCLD, RCLD, I/O, Refrigerant Monitor, Scorpio, DCM.

Revision Level will either be an integer representing the software version number of the particular module or occurrence of a diagnostic, the display will automatically go to this menu and display certain messages as explained in the next section "Diagnostics Menu."

Diagnostics Menu

The Diagnostics Group is where all diagnostics, both historical and active are presented. The group also contains the facility to clear active diagnostics, historic diagnostics, and purge diagnostics as individual groups. To clearly annunciate the occurrence of a diagnostic, the display will automatically go to this menu and display certain messages as explained below. The following illustration gives an overview of how the diagnostic key and screens below it work.

Diagnostics Group Heading

Active & Historic Diagnostics
Press (Next)(Previous) To Continue

Menu Settings Password

If the Menu Settings Password is Enabled in the Service Setup Group, following each setting group heading the following will be displayed:

Settings In This Menu Are [status]
[password message]

Likewise, if the Menu Settings Password is Disabled in the Service Setup Group, the above screen will not appear.

The possible values for status are "Locked" or "Unlocked". If the password status is locked, the password message will be "Enter Password to Unlock". The user will then depress "-+-+-+" followed by the <Enter> key. The password keystrokes will be echoed to the screen as a visual aide. The last six keystrokes represent the current password, and up to twenty keystrokes can be entered. An incorrect password, or the twenty-first keystroke will result in the password message "Invalid Password".

If the password status is unlocked, the password message will be "Press (Enter) to Lock". Any attempt to change the setting will result in the message "Setting is Locked". The password, once entered, will remain valid until canceled.

Diagnostics and Annunciation

If there are no diagnostics present, only the following screen will be displayed under the Diagnostics Group heading screen.

No Diagnostics Present
Press (Next) (Previous) To Continue

If there are any diagnostics present, the following 3 screens are displayed sequentially when the <Next> key is pressed. The first screen is:

Diagnostic Report Follows
Press (Next) For More

The second screen is:

Press (Enter) To Display Operating Mode
At Time Of LastDiagnostic or(Next)For More

The third screen is the chiller operating mode display that was present at the time that the most recent diagnostic occurred.

If there are one or more diagnostics present, the following displays will be inserted into the display sequence. Diagnostics will be listed in order of occurrence from newest to oldest. Diagnostics will be displayed on 2 screens. The two screens will vary slightly depending on whether the diagnostic is active or historic.

The first active diagnostic screen will be:

[sequence number] [diagnostic]
(Next) [diagnostic type]

The sequence number will run from 1 through n (n <= 20) and number the diagnostics sequentially where the most recent diagnostic is sequence number [01].

The possible replacements for "diagnostic type" are:

Warning Only - Reset Not Reqd (Applies to all IFW diagnostics.)

Unit Shutdown - Reset Reqd (Applies to all MMR diagnostics)

Unit Shutdown - Automatic Reset (Applies to all MAR diagnostics)

The second active diagnostic display screen will contain the diagnostic sequence number, a time and date stamp, and a help message suggesting possible service procedures. The second active diagnostic display screen will be:

[sn] occurred at HH:MM xm Mon xx, 199x
[help message]

The time will be displayed as xx:xx am/pm.

The date will be displayed as month - date- year.

The month will use a standard 3-letter abbreviation. The year will not be abbreviated.

Depressing the next key will advance the display to the next diagnostic in the sequence.

The first historic diagnostic screen will be:

[sequence number] [Diagnostic]
Historic Only, Press (Next) For More

The definitions of diagnostic and sequence number are the same as for the active diagnostic messages. If <Next> is pressed the second historic diagnostic screen is displayed. The second historic diagnostic screen will be:

[sn] occurred at HH:MM xm Mon xx, 199x
Historic Only, Reset At End Of Diag Menu

Up to 20 diagnostics will be displayed.

Clearing Diagnostics

At the end of the diagnostic menu, there will be 4 screens that allow the user to Clear/Reset the different diagnostic groups.

If any active diagnostics are present, the following screen will be displayed:

Press (Enter) To Clr Active Diagnostics
And Shutdown / Reset System

If the <Enter> key is pressed, the following message is displayed for 2 seconds:

Active Diagnostics Have Been Cleared
System Is Resetting

The display will be reset to the operating mode screen of the chiller report after this message clears.

If any historic diagnostics are present, the following screen will be displayed:

Press (Enter) To
Clear Historic Diagnostics

If the <Enter> key is pressed, the following message is displayed for 4 seconds:

Historic Diagnostics Have Been Cleared
Diagnostic Report Is Being Reset

The display will be reset to the top of the Diagnostic Menu after this message clears.

If any purge diagnostics are present, the following screen will be displayed:

Press (Enter) To
Clear Purge Diagnostics

If the <Enter> key is pressed, the following message is displayed for 4 seconds:

Purge Diagnostics Have Been Cleared
Diagnostic Report Is Being Reset

The display will be reset to the top of the Diagnostic Menu after this message clears.

If any IPC refrigerant monitor diagnostics are present, the following screen will be displayed:

Press (+) To
Silence Rfgt Mon Audible Alarm

Note: Pressing <+> will silence the audible alarm. The IPC refrigerant monitor will cause all the refrigerant monitor alarms (diagnostics) to become non-latching for approximately 7.5 seconds. This allows any latching alarms to clear if the trip condition has been removed. This clearing function differs from the balance of UCP2 in that the balance of UCP2 diagnostics are cleared on reset and reestablished if the trip condition is still present.

If the <+> key is pressed, the following message is displayed for 4 seconds:

Silencing Rfgt Mon Audible Alarm
Clearing Nonactive Rfgt Alarms

New Diagnostic Display

When a new diagnostic is sensed by the system, the display will reset to the diagnostic menu. A "one-time" screen will be displayed to inform the user that a new diagnostic has been detected. This screen will vary depending on the type of diagnostic detected. The two major categories of diagnostics are those which are informational only, and those which have resulted in machine shutdown.

If the diagnostic is an MMR/MAR, the screen will be:

*** A MACHINE SHUTDOWN HAS OCCURRED ***
Press (Next) For More

Otherwise, the screen will be:

A New Warning Has Been Detected
Press (Next) For More

This screen will be inserted into the diagnostic menu directly after the "Diagnostic Report Follows" screen. Pressing <Next> will therefore take the user to the "Press (Next) to display operating mode at time of last diagnostic" screen. If <Next>or <Previous> is pressed, this screen will no longer be in the display sequence.

Diagnostics

In the table following, a "Latching" diagnostic is a condition which will cause the machine or a portion of the machine as noted to shut down and will require a manual reset to restore operation. A diagnostic that is non-latching is reset automatically when the condition causing the diagnostic goes away. A non-latching diagnostic will shut down the machine or a part of the machine if so indicated. If a diagnostic is information only, no machine action is taken.

Unless otherwise stated, all active diagnostics will be lost on loss of power.

Diagnostic Types And Action

MMR = Machine Shutdown - Manual Reset

MAR = Machine Shutdown - Auto Reset

IFW = Information Warning - May affect machine operation; lowest level of diagnostic

Remotely Resettable Diagnostics:

Except for the following, all diagnostics can be reset remotely from either the Remote Clear Language Display, the Tracer, or the External Diagnostic Reset input at the Options Module. The following diagnostics shall only be resettable ONLY at the Local Clear Language Display, e.g. with the operator standing at the unit.

Table 5

DIAGNOSTIC DESCRIPTION	Diag Type	Can Be Remotely Reset
Starter Contactor Interrupt Failure	MMR	No
Low Evap Rfgt Pressure	MMR	No
Phase Loss	MMR	No
Phase Reversal	MMR	No
High Bearing #1 Temp	MMR	No
High Bearing #2 Temp	MMR	No
Current Overload	MMR	No
Cprsr did not Accelerate: Shutdown	MMR	No
Starter did not Transition	MMR	No
High Pressure Cutout Tripped	MMR	No
Low Evap Rfgt Temp.	MMR	No
Emergency Stop Input	MMR	No
Starter Dry Run Test	MMR	No
Solid State Starter Fault Rly Open	MMR	No
Adapt Freq Drive Fault Relay Open	MMR	No
High Motor Temp Position #1	MMR	No
High Motor Temp Position #2	MMR	No

DIAGNOSTIC DESCRIPTION	Diag Type	Can Be Remotely Reset
High Motor Temp Position #3	MMR	No
Severe Phase Unbalance	MMR	No
Starter Fault Type I	MMR	No
Starter Fault Type II	MMR	No
Starter Fault Type III	MMR	No
Cprsr did not Accelerate Fully	MMR	No
High Cprsr Discharge Temp.	MMR	No
Phase Seq Monitor: Phase Reversal	MMR	No
Transition Complete Input Shorted	MMR	No
At Speed Input Shorted	MMR	No
Transition Complete Input Opened	MMR	No
At Speed Input Opened	MMR	No

Table 6
Diagnostic Table

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
Adapt Freq Drive Fault Relay Open	MMR	Starter	All Start and Run Mode	The Adaptive Frequency Drive fault relay is open.	See Adaptive Frequency Drive Service Bulletin, check for an open wire.
At Speed Input Shorted	MMR	Starter	Pre-Start	a. Using either a Solid State Starter or an Adaptive Frequency Drive, the Up to Speed/At Speed input was found to be shorted before the compressor was started. b. Applies only to Solid State Starters and Adaptive Frequency Drives.	Check End of Limt/At Speed Input
At Speed Input Opened	MMR	Starter	All Running Modes	a. The At Speed input was found to be opened with the compressor motor running after successfully obtaining at speed condition. b. Applies only to Solid State Starters.	Check End of Limt/At Speed Input
Aux/Ht Rcvry Ent Water Temp Sensor	IFW	Options	All	Open or shorted and Heat Recovery is installed (at the CLD).	Check Sensor, Wiring, and Connections
Aux/Ht Rcvry Lvg Water Temp Sensor	IFW	Options	All	Open or shorted and Heat Recovery is installed (at the CLD).	Check Sensor, Wiring, and Connections
Bearing Temp Sensor #1	MMR	Stepper	All	Open or Short, only if this option is enabled at the Human Interface.	Check Sensor, Wiring And Connections
Bearing Temp Sensor #2	MMR	Stepper	All	Open or Short, only if this option is enabled at the Human Interface.	Check Sensor, Wiring And Connections
Check Clock	IFW	Chiller	All	On loss of power the clock does not keep time, if there is an extended power loss (greater than 15 seconds) this diag. is also generated to alert the operator to check the clock.	Check Main Power Supply, Reset Clock
Check Oil Filter	IFW	Chiller	All Running Modes	a. The differential oil pressure fell below the Check Oil Filter Setpoint for 1000 psid-seconds and the Check Oil Filter Diagnostic setpoint is enabled. b. This diagnostic shall not be active for 15 minutes after the compressor is started. c. This IFW diagnostic will automatically reset when the differential oil pressure rise above the Check Oil Filter Setpoint for 1000 psid-seconds or the compressor is not running.	

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
Chilled Water Flow Lost	MAR	Chiller	Chilled Water Control: (All Stop modes) All modes except STOP (00) and EXTERN AL STOP (100) Hot Water Control: Start and All Run Modes.	a. The chilled water flow switch input was open for more than 6-10 contiguous seconds. b. 6-10 seconds of contiguous flow shall clear this diagnostic. c. Even though the pump times out in the STOP modes, this diagnostic shall not be called out in the STOP modes.	Check Pump, Valves, Flow Switch
Chiller: Loss of Comm with Purge	IFW	Chiller	All	The chiller module lost communications with the Purge module for 15 contiguous seconds.	Check IPC Wiring/ Connections
Chiller: Loss of Comm with Starter	MMR	Chiller	All	The chiller module lost communications with the Starter module for 15 contiguous seconds.	Check IPC Wiring/ Connections
Chiller: Loss of Comm with Options	IFW	Chiller	All	The chiller module lost communications with the Options module for 15 contiguous seconds. This IFW diagnostic is generated if Free Cooling is Not Installed, otherwise this is an MMR diag. under code 2F6	Check IPC Wiring/ Connections
Chiller: Loss of Comm with Circuit	MMR	Chiller	All	The chiller module lost communications with the Circuit module for 15 contiguous seconds.	Check IPC Wiring/ Connections
Chiller: Loss of Comm with I/O Mod	IFW	Chiller	All	The chiller module lost communications with the I/O module for 15 contiguous seconds; And HGBP is installed (at the CLD).	Check IPC Wiring/ Connections
Chiller: Loss of Comm with I/O Mod	MMR	Chiller	All	The chiller module lost communications with the I/O module for 15 contiguous seconds; And Pulsed IGV is installed (at the CLD).	Check IPC Wiring/ Connections
Chiller: Loss of Comm with DCM	IFW	Chiller	All	The DCM was setup as "installed" at the CLD and the chiller module lost communications with the DCM module for 15 contiguous seconds	Check IPC Wiring/ Connections
Chiller: Loss of Comm with Stepper #1	MMR	Chiller	All	The chiller module lost communications with the Stepper #1 module for 15 contiguous seconds.	Check IPC Wiring/ Connections
Chiller: Loss of Comm with Local CLD Note: As implemented this is a latching IFW diagnostic. That is, once generated it cannot be re-generated until a manual reset is done.	IFW-AR	Chiller	All	The chiller module lost communications with the LCLD module for 15 contiguous seconds.	Check IPC Wiring/ Connections
Chiller: Loss of Comm with Options	MMR	Chiller	All	The chiller module lost communications with the Options module for 15 contiguous seconds. This MMR diagnostic is generated if Free Cooling is Installed, otherwise this is an IFW diag. under code 2AE	Check IPC Wiring/ Connections

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
Chiller: Loss of Comm with Rfgt Monitor	IFW-AR	Chiller	All	The Chiller module lost communications with the Refrigerant Monitor for 15 contiguous seconds.	Check IPC Wiring/ Connections
Chiller: Loss of Comm with TCI	IFW	Chiller	All	The Tracer was setup as "installed" at the CLD and the chiller module lost communications with the TCI (comm 3 or comm 4) module for 15 contiguous seconds	Check IPC Wiring/ Connections
Chiller Mod Off-Brd 5V Range	IFW	Chiller	All	An improper Off Board 5v voltage was detected at the Chiller Module. A 5vdc is used for off-board devices such as the pressure transducers. The micro checks to see that the A/D value falls within an acceptable range.	Check Chiller Module Voltages
Chiller Mod Ref Voltage Calibration	IFW	Chiller	All	An improper reference voltage was detected at the Chiller Module. A 2.5 vdc reference is used to calibrate the non-ratiometric analog I/O such as 2-10vdc and 4-20ma inputs as well as PWM Analog outputs. The micro checks to see that the A/D value falls within an acceptable range. This diagnostic has not been implemented	Check Chiller Module Voltages
Chlr Sat Cond Temp Sensor (Purge) (As Sensed by the Purge module in Retrofit applications)	IFW	Purge	All	Open or Shorted Sensor a. Applies to Retrofit applications of the Purge Only. Does not apply to UCP2 applications. b. IFW to the chiller, MMR to the Purge.	Purge Inop: See Purge O & M Manual
Circuit: Loss of Comm with Starter	MMR	Circuit	All	The circuit module lost communications with the Starter module for 15 contiguous seconds.	Check IPC Wiring/ Connections
Circuit: Loss of Comm with Chiller	MMR	Circuit	All	The circuit module lost communications with the Chiller module for 15 contiguous seconds. On loss of communications, the circuit module shall run the oil pump for the post lube time and then turn the oil pump off. On loss of communications, the circuit module shall continue to control the oil heater.	Check IPC Wiring/ Connections
Circuit Module 24 Vdc Ref Missing	IFW	Circuit	All	24vdc reference missing and the Rfgt monitor is installed.	Check Rfgt Monitor Wiring/ 24 Vdc Supply.
Circuit Mod Off-Brd 5V Range	MMR	Circuit	All	An improper Off Board 5v voltage was detected at the Circuit Module. A 5vdc is used for off-board devices such as the pressure transducers. The micro checks to see that the A/D value falls within an acceptable range.	Check Circuit Module Voltages
Circuit Mod Ref Voltage Calibration	IFW	Circuit	All	An improper reference voltage was detected at the Circuit Module. A 2.5 vdc reference is used to calibrate the non-ratiometric analog I/O such as 2-10vdc and 4-20ma inputs as well as PWM Analog outputs. The micro checks to see that the A/D value falls within an acceptable range.	See Troubleshooting Service Bulletin
Cond Diff Water Press Transducer	IFW	Options	All	Input Shorted or Open and the Diff. water pressure sensing option, > 150 psig, is "installed" at the CLD.	Check Sensor, Wiring, and Connections
Cond Entering Wtr Temp Sensor	IFW	Chiller	All	Open or Short	Check Sensor, Wiring And Connections
Cond Leaving Wtr Temp Sensor	See Description	Chiller	All	Open or Short. a. IFW on Chilled Water Control b. MMR on Heat Pump (Hot Water) Control.	Check Sensor, Wiring And Connections

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
Condenser Rfgt Pressure Sensor	MMR	Circuit	All	Open or Short. Must Hold on open AND short input is 2.0 Psia. Design: Both opens and shorts result in the pressure going to the low end of the scale. Therefore a Must Hold on the high pressure end is not required.	Check Sensor, Wiring And Connections
Condenser Rfgt Temp Sensor	MMR	Stepper	All	Open or Short	Check Sensor, Wiring And Connections
Condenser Water Flow Lost	MAR	Chiller	Chilled Water Control: Start and All Run Modes. Hot Water Control: (All Stop modes)	a. The chilled water flow switch input was open for more than 6-10 contiguous seconds. b. 6-10 seconds of contiguous flow shall clear this diagnostic. c. Even though the pump times out in the STOP modes, this diagnostic shall not be called out in the STOP modes.	Check Pumps, Valves, Flow Switch
Condenser Water Flow Overdue	MAR	Chiller	Estab. Cond Water Flow	Condenser water flow was not proven within 4.25 minutes of the condenser pump relay being energized.	Check Pump, Valves, Flow Switch
Condenser Water Pressure Sensor	IFW	Chiller	All	Open or Short and the Cond Water Pressure Sensor is setup as installed at the Clear Language Display.	Check Sensor, Wiring, and Connections
Cprsr did not Accelerate: Shutdown	MMR	Starter	Start Mode	a. The compressor did not come up to speed in the allotted time defined by the Maximum Acceleration Timer. b. The Human Interface setups defined "Shutdown" as the action when the Maximum Acceleration Timer was exceeded.	Check Main Power Supply & Wiring
Cprsr did not Accelerate Fully	MMR	Starter	Starting	a. Using either a Solid State Starter or an Adaptive Frequency. Drive the UCM did not receive an Up to Speed or At Speed Signal within the Maximum Acceleration Timer Setting. b. Applies only to Solid State Starters and Adaptive Frequency. Drives.	Check End of Limt/At Speed Input
Cprsr Did Not Accelerate: Transition (The Motor is put across the line.)	IFW	Starter	Start Mode	a. The compressor did not come up to speed in the allotted time defined by the Maximum Acceleration Timer. b. The Human Interface setups defined "Transition" as the action when the Maximum Acceleration Timer was exceeded.	See Troubleshooting Service Bulletin
Current Overload	MMR	Starter	All Running Modes	Motor current exceeded overload time vs. trip characteristic.	Check Main Power Supply & Wiring
Current Overload Setpts Error	IFW	Starter	All	a. The redundant overload settings did not agree for 30 contiguous seconds. (Continue to use the previous value for the 30 second timeout.) When this diagnostic occurs the affected Starter Module shall use the minimum (00000 binary, 00 decimal) overload setting as a default until either the UCM is reset or, if the redundant settings agree again, the starter module can go back to using the actual setting.	Review Overload Set Up

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
CWS/Leaving Wtr Temp. Cutout Setpt Overlap also overlap of CWS and Low Refrigerant Temp Cutout.	None	None	All	No diagnostic, limit value to last legal value and tell the operator about it on the second line of the display. NOTE: The above is not a diagnostic because you don't want the display vectoring you to a different display state when you are trying to set either the chilled water setpoint or the leaving water temp. cutout setpoint as it will in the case of a diagnostic.	N/A
DCM: Loss of Comm with Chiller A	IFW	Chiller	All	The DCM module lost communications with the chiller A Chiller module for 15 contiguous seconds	Check IPC Wiring/ Connections
DCM: Loss of Comm with Chiller B	IFW	Chiller	All	The DCM module lost communications with the chiller B Chiller module for 15 contiguous seconds	Check IPC Wiring/ Connections
DCM: Loss of Comm with Starter A	IFW	Chiller	All	The DCM module lost communications with the chiller A Starter module for 15 contiguous seconds	Check IPC Wiring/ Connections
DCM: Loss of Comm with Starter B	IFW	Chiller	All	The DCM module lost communications with the chiller B Starter module for 15 contiguous seconds	Check IPC Wiring/ Connections
DCM: Loss of Comm with TCI A	IFW	Chiller	All	The DCM module lost communications with the chiller A TCI module for 15 contiguous seconds	Check IPC Wiring/ Connections
DCM: Loss of Comm with Stepper A	IFW	Chiller	All	The DCM module lost communications with the chiller A Stepper module for 15 contiguous seconds	Check IPC Wiring/ Connections
Differential Oil Pressure Overdue	MMR	Circuit	Pre-Lube	A differential oil pressure 0f 9 psid was not established within 3 minutes of starting the Oil Pump in the Pre-Lube Mode. Design: Some hysteresis was introduced into this diagnostic. 9 psid is the criteria to establish pre-lube oil flow and 8 psid is used to define a loss of oil flow on pre-lube.	See Troubleshooting Service Bulletin
Differential Oil Pressure Switch (CVGD and CVAD units only)	MMR	Circuit	Pre-Lube	Just prior to starting the oil pump the Differential Oil Pressure Switch is checked to be sure it's contacts are open (not stuck or jumpered), if not set this diagnostic.	Check Oil Pressure Switch/Wiring.
Discharge Temp Sensor	MMR	Stepper	All	Open or Short, only if HGBP and the Discharge Temp. Sensor is called out as "Installed" at the Human Interface.	Check Sensor Wiring And Connections
Emergency Stop Input	MMR	Chiller	All	a. EMERGENCY STOP input is open. An external interlock has tripped. Time to trip from input opening to unit stop shall be 0.1 to 1.0 seconds.	Check Emergency Stop Input Device
Evap Diff Water Press Transducer	IFW	Options	All	Input Shorted or Open and the Diff. water pressure sensing option, > 150 psig, is "installed" at the CLD.	Check Sensor, Wiring, and Connections
Evap Entering Wtr Temp Sensor	IFW	Chiller	All	Open or Short a. Normal operation, no effects on control. b. Chilled Water Reset, Will just run at either normal CWS or will run at maximum reset permitted.	Check Sensor, Wiring And Connections
Evap Leaving Water Temp Sensor	MMR	Chiller	All	Open or Short	Check Sensor, Wiring And Connections

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
Evap Rfgt Temp Sensor	MMR	Stepper	All	Open or Short	Check Sensor, Wiring And Connections
Evap Water Pressure Sensor	IFW	Chiller	All	Open or Short and the Evap Water Pressure Sensor is setup as installed at the Clear Language Display.	Check Sensor, Wiring, and Connections
Evaporator Water Flow Overdue	MAR	Chiller	Estab. Evap. Water Flow on going from STOP to AUTO.	Evaporator water flow was not proven within 4.25 minutes of the Evaporator pump relay being energized.	Check Pump, Valves, Flow Switch
Extended Compressor Surge	MMR	Starter	All Running Modes	An extended Surge condition was detected and the Surge protection feature was Enabled at the Clear Lang. Display. An extended Surge condition is defined being in a "continuous" surge condition for 15 ± 10% minutes.	Check Condenser Water Temp.
Extended Power Loss Note: This diagnostic and the functions tied to it are handled by the Check Clock diagnostic.	IFW	Starter	All	The unit lost power for an extended period of time. On CTV units if power is lost for an extended period of time the oil pump is not run on Power Up. If a power loss is determined to be a Momentary Power Loss the Oil Pump is run on the Power Up to Post Lube the bearings. The deciding factor determining if a power loss is Extended or Momentary is TBD.	Check Main Power Supply & Wiring
External Base Load Setpoint	IFW-AR	Chiller	All	a. Not "Enabled": no diagnostics. b. "Enabled": Out-Of-Range Low or Hi, set diagnostic, Terminate external base loading function. This IFW diagnostic will automatically reset if the input returns to the normal range.	Check Signal At Input
External Chilled Water Setpoint	IFW-AR	Options	All	a. Not "Enabled": no diagnostics. b. "Enabled": Out-Of-Range Low or Hi, set diagnostic, default CWS to next level of priority (e.g. Front Panel SetPoint). This IFW diagnostic will automatically reset if the input returns to the normal range.	Check Signal At Input
External Current Limit Setpoint	IFW-AR	Options	All	a. Not "Enabled": no diagnostics. b. "Enabled": Out-Of-Range Low or Hi, set diagnostic, default CLS to next level of priority (e.g. Front Panel SetPoint. This IFW diagnostic will automatically reset if the input returns to the normal range.	Check Signal At Input
External Hot Water Setpoint	IFW-AR	Options	All	a. Not "Enabled": no diagnostics. b. "Enabled": Out-Of-Range Low or Hi, set diagnostic, default HWS to next level of priority (e.g. Front Panel SetPoint). This IFW diagnostic will automatically reset if the input returns to the normal range.	Check Signal At Input
External Vane Position Setpoint	MMR	Chiller	All	a. Not "Enabled": no diagnostics. b. "Enabled": Out-Of-Range Low or Hi, set diagnostic.	Check Signal at Input

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
Free Cooling Valves	MMR	Options	When exiting Free cooling	a. The Free Cooling Valves were commanded to close and did not close in the three minutes allowed for closure. And FC is installed (at the CLD) and commanded off. b. The Free Cooling Valves were commanded to open and did not open in the three minutes allowed for closure. And FC is installed (at the CLD) and commanded On.	Check Clsd End-Switches, Valves, Wiring
Heat Sink Temp Sensor	IFW	Starter	All	Open or Short and Solid State Starter installed. Note: The Solid State Starter is expected to be protected from overheating via a thermal cutout. Since this sensor is not used to protect the starter, the failure of the sensor is treated as an IFW.	Check Sensor Wiring And Connections
HGBP Valve Closure Overdue	IFW			a. The HGBP Valve was commanded to close and did not close in the three minutes allowed for closure	Check Clsd End-Switches, Valves, Wiring
High Bearing #1 Temp	MMR	Stepper	All starting and running modes	a. The bearing temperature at sensor #1 exceeded 180 + or - 5 °F (82.2 °C) for 0.5 - 2 seconds (Note: BT, WT, and DT may be "instantaneous trip" but consistent with the analog input filtering function.), and b. This function is enabled at the CLD.	Check Oil System
High Bearing #2 Temp	MMR	Stepper	All starting and running modes	a. The bearing temperature at sensor #2 exceeded 180 + or - 5 °F (82.2 °C) for 0.5 - 2 seconds (Note: BT, WT, and DT may be "instantaneous trip" but consistent with the analog input filtering function.), and b. This function is enabled at the Human Interface.	Check Oil System
High Cprsr Discharge Temp.	MAR	Stepper	All	a. The discharge temp. exceeded the trip value; 200°F + or - 5°F for CVHE/F, CVG and CVA. The Discharge Temp Cutout is adjustable at the Human Interface. See also section P4_CPRSR.Doc of this Functional Specification. b. Time to trip from trip value exceeded shall be 0.5 to 2.0 seconds. (Note: BT, WT, and DT may be "instantaneous trip" but consistent with the analog input filtering function.) d. The diag. shall reset automatically 50 °F below the trip point.	See Troubleshooting Service Bulletin
High Motor Temp Position #1	MMR	Circuit	Any Start and Run Mode	The Motor winding temp. at sensor #1 exceeded 265 °F + or - 15°F for 0.5 - 2 seconds. (Note: BT, WT, and DT may be "instantaneous trip" but consistent with the analog input filtering function.)	See Troubleshooting Service Bulletin
High Motor Temp Position #2	MMR	Circuit	Any Start and Run Mode	The Motor Winding Temp. at sensor #2 exceeded 265 °F + or - 15 °F for 0.5 - 2 seconds. (Note: BT, WT, and DT may be "instantaneous trip" but consistent with the analog input filtering function.)	See Troubleshooting Service Bulletin
High Motor Temp Position #3	MMR	Circuit	Any Start and Run Mode	The Motor Winding Temp. at sensor #3 exceeded 265° F + or - 15° F for 0.5 - 2 seconds. (Note: BT, WT, and DT may be "instantaneous trip" but consistent with the analog input filtering function.)	See Troubleshooting Service Bulletin

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
High Oil Temp	MMR	Circuit	All starting and running Modes	UCP2 shall provide a fixed High Oil Temperature Cutout of 180 °F (82.2°C). If the oil temperature violates the cutout by 120 degree F seconds (66.6 degree C seconds) an MMR diagnostic shall be generated.	Check Oil System
High Pressure Cutout Tripped	MMR	Circuit	All	A high pressure cutout was detected. See the trip points for the various products under the HPC switch description of this specification.	Check Condenser Water Temp.
High Restart Inhibit Timer Warning	IFW	Starter	All	The Restart Inhibit timer has reached a maximum threshold for the host chiller. For CTV chillers this is 45 minutes. This indicates excessive chiller cycling, steps should be taken to correct this.	Check for Excessive Chiller Cycling
High Vacuum Lockout	MMR	Circuit	Pre-Start	The Oil Tank Pressure transducer shall be used to sense for very low pressures in all Non-running cprsr modes.	See Troubleshooting Service Bulletin
IGV BPI Not Found During Search	IFW	Stepper	All	The Inlet Guide Vane Actuator Binary Position Indicator was not found over the entire stroke of the IGV during the BPI search.	See Troubleshooting Service Bulletin
IGV BPI Found Low During Search	IFW	Stepper	All	The Inlet Guide Vane Actuator Binary Position Indicator was found too low in the stroke of the IGV during the BPI search.	Check Stepper Module, Wiring, & Motor
IGV BPI Shorted	IFW	Stepper	Pre-Start	At what is believed to be a closed position, the IGV BPI was found to be shorted.	Check Sensor, Wiring, and Connections
IGV Electrical Drive Circuit Open	MMR	Stepper	On Demand and Pre-Start	Run the IGV Actuator electrical drive circuit test both on demand from the human interface and just before the chiller starts.	See Troubleshooting Service Bulletin
Incorrect Chiller Software Installed	MMR	Chiller	All	The incorrect Eprom was loaded into this module. This diagnostic is detected when a factory test computer sets the unit type to something other than what the Eprom software was intended for.	(No message is required.)
Incorrect Stepper Software Installed	MMR	Stepper	All	The incorrect Eprom was loaded into this module. This diagnostic is detected when a factory test computer sets the unit type to something other than what the Eprom software was intended for.	(No message is required.)
Inlet Guide Vane Closure Ovordue	IFW	I/O	All Non-running modes, Starting, Pre-Stop (IGV manual modes)	a. The inlet guide vanes were commanded to close and did not close in the three minutes allowed for closure.	Check Clsd End-Switches, Vanes, Wiring
I/O Mod: Loss of Comm with Chiller	IFW	I/O	All	The I/O module lost communications with the Chiller module for 15 contiguous seconds.	Check IPC Wiring/ Connections
Invalid Starter Selection	MMR	Starter	All Modes	The Cld has been setup for an AFD starter type, however the starter module is not AFD compatible. **(Note: This feature is not supported by hardware.) (Special Note not for Publishing; See Starter Module Design Specification for requirements to enable AFD operation.)**	Call Local Trane Service Agency

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
Low Chilled Water Temp: Unit Off (Unit in Auto but not Starting or Running)	IFW-AR	Chiller	Unit in Auto and No Ckt's Energized (Any Ckt(s) Energized)	a. The chilled water temp. fell below the cutout setpoint while the compressor (or Solution Pump) was not running for 30 degree F Seconds. Automatic Reset of the IFW dig shall occur 2 degrees F (1.1 °C) above the cutout setpoint.	Check Flow, Sensor, & Wiring
Low Chilled Water Temp: Unit On (Unit Starting or Running)	MAR	Chiller	Any Ckt(s) Energized (No Ckt's Energized)	a. The chilled water temp. fell below the cutout setpoint while the compressor (or Solution Pump) was running for 30 degree F Seconds. Automatic Reset of the MAR diag shall occur 2 degrees F (1.1 °C) above the cutout setpoint.	Check Flow, Sensor, & Wiring
Low Differential Oil Pressure	MMR	Circuit	All starting and running Modes	**Pre-Lube Mode on CVHE/F Chillers:** a. See Diagnostic 1FF. **Start & Run Mode on CVHE/F Chillers:** a. If during these modes the Differential oil pressure drops below 9 PSID for more than 90 Psid Seconds, an MMR diagnostic shall be generated. The 90 Psid Seconds integral shall be reset to zero when the differential pressure rises above 9 psid. **Pre-Lube Mode on CVGD/CVAD Chillers:** a. See Diagnostic 1FF. **Start & Run Mode on CVGD/CVAD Chillers:** a. While Starting and Running, if the differential oil pressure switch opens for more than 3-5 seconds, generate an MMR diagnostic.	Check Oil System
Low Evap Rfgt Temp.	MMR	Stepper	Starter Contactor Energized or in Free Cooling	a. The Saturated Evap Rfgt Temp dropped below the Low Rfgt Temp. Cutout Setpoint when the circuit was running for 30 °F seconds.	Check Operation, Call Service
Low Evap.Water Flow (To be implemented in CTV Phase C release and ABS Phase B release.)	IFW-AR	Chiller	Chiller Auto and All Running Modes	a. The evap. water flow measurement option was installed and the flow dropped to a setpoint set at the CLD. This IFW shall be Auto Reset and reset 0.1 gpm/ton above the adjustable trip point or when the Evaporator pump is turned off. b. There shall be a 2 minute delay in permitting this diagnostic to be called out from the time the evap pump has been turned on AND flow has been established/confirmed via the flow switch input. c. This is not necessarily active in a Manual On of the Evaporator pump. That is, if the chiller is in the Stop mode and the Evap. Relay is manually turned on, this diagnostic shall not be active. (Manual On is not taken into account.)	See Troubleshooting Service Bulletin
Low Oil Temp	MAR	Circuit	All Non-running Modes.	The oil temperature dropped below it's adjustable Low Oil Temp. Cutout. ("Instantaneous trip" but consistent with the analog input filtering function.) See Section P4_CPRSR for further description of this diagnostic. Automatic Reset of the MAR diag shall occur 5 degrees F (2.8 °C) above the cutout setpoint.	See Troubleshooting Service Bulletin

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
Max Acceleration Setpts Error	IFW	Starter	All	a. The redundant Maximum Acceleration settings did not agree for 30 contiguous seconds. (Continue to use the previous value for the 30 second timeout.) When this diagnostic occurs the affected Starter Module shall use 6 seconds as a default until either the UCM is reset or, if the redundant settings agree again, the starter module can go back to using the actual setting.	Review Max Acceleration Set Up
Max Pumpout Rate Exceeded-Svc (Prg)	IFW	Purge	All	a. IFW to the chiller, MAR to the Purge.	Purge Inop: See Purge O & M Manual
Max Pumpout Rate Exceeded (Prg)	IFW	Purge	All	a. IFW to the chiller, MAR to the Purge.	Purge Inop: See Purge O & M Manual
Memory Error Type I: NOVRAM	MMR	Chiller	On UCM Power Up or following a Type II Memory error diag.	a. On UCM either power up or following a Type II Memory Error a NOVRAM memory error was detected. The UCM is operating on all Engineering Factory defaults for all setup parameters. Check all setup parameters and continue to run chiller. Replace the Chiller Module as soon as a replacement is available. Note: It is expected that this diagnostic will be detected on the very first power up of the Chiller Module at the Manufacturer since the NOVRAM will not contain valid data on first power up.	Call Service to Check all Settings
Memory Error Type IV	IFW	Chiller	All	A page timeout error was detected while trying to write data into EEPROM. There will likely be a recall of Engineering Factory defaults on the next reset or power transition. Replace the Chiller Module as soon as a replacement is available.	Call Service to Check all Settings
Memory Error Type II: Shadow RAM	IFW	Chiller	All	a. A Shadow RAM memory error was detected. The UCM is operating on all last valid values (pulled from NOVRAM) for all setup parameters. No setup parameter changes were pending to be loaded into NOVRAM, a complete recovery of all setup parameters was made and there is no need to check unit setup parameters. Compressor starts and hour were lost for not more than the last 24 hours. This is expected to be an isolated event and repair or replacement is not required. If this diagnostic does occur repeatedly, then replace the Chiller module.	No Settings Were Lost
Memory Error Type III	IFW	Chiller	All	a. A Shadow Ram memory error was detected. The UCM is operating on all last valid values (pulled from NOVRAM) for all setup parameters. Setup parameter changes less than 24 hours old pending to be loaded into NOVRAM were lost. Check all setup parameters made in the last 24 hours. Compressor starts and hours were lost for not more than the last 24 hours. This is expected to be an isolated event and repair or replacement is not required. If this diagnostic does occur repeatedly, then replace the Chiller module.	Settings Changed in The Last 24 Hours Lost

Severe Phase Unbalance	MMR	Starter	All Running Modes	a. A 30% Phase Unbalance diagnostic has been detected. Items to check are the Current Transformer Part Numbers (they should all match), The Current Transformer resistances, line voltage phase balance, all power wiring connections, the contactor pole faces, and the motor. If all these are OK, replace the Starter module.	Check Main Power Supply & Wiring
Solid State Starter Fault Rly Open	MMR	Starter	All Start and Run Mode	The SSS fault relay is open.	See Solid State Starter Service Bulletin, check for an open wire.
Soln Pump Winding Thermostat Open	MMR	Circuit	All	a. The motor winding temperature thermostat opened; nominally 230°F (110 °C). b. The motor temp. thermostat or wiring is open. c. Time to trip from input open to Solution Pump shutdown shall be 0.5 to 2.0 seconds.	Check Machine Operation

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
Starter Contactor Interrupt Failure	MMR	Starter	Starter Contact not Energized (Starter Contact Energized)	a. Welded Starter contactor. b. Detected a welded compressor contactor when the compressor was commanded off but the current did not go to zero. Detection time shall be 5 second minimum and 10 seconds maximum for all Electromechanical and Solid State Starters. Detection time for Adaptive Frequency. Drives shall be 12 seconds minimum and 20 seconds maximum. On detection, generate the diagnostic, energize the appropriate alarm relay, continue to command the affected compressor off.	Complete Starter Checkout Required
Starter did not Transition	MMR	Starter	On the first check after transition.	a. The UCM did not receive a transition complete signal in the designated time from the UCM command to transition. The must hold time from the UCM transition command is 1 second. The Must trip time from the transition command is 6 seconds. Actual design is 2.5 seconds. b. Item a. above is active only for Y-Delta, Auto-Transformer, and Primary Reactor, and X-Line Starters.	Complete Starter Checkout Required
Starter Dry Run Test	MMR	Starter	Starter Dry Run Mode	While in the Starter Dry Run Mode either 50% Line Voltage was sensed at the Potential Transformers or 10% RLA Current was sensed at the Current Transformers.	Current or Voltage Detected
Starter Fault Type I	MMR	Starter	Starting	a. This is a specific starter test where 1M(2k1) is closed first and a check is made to ensure that there are no currents detected by the CT's. If currents are detected when only 1M is closed first at start, then one of the other contactors is shorted. b. This test applies only to factory installed Y-Delta Closed Transition Starters.	See Troubleshooting Service Bulletin
Starter Fault Type II	MMR	Starter	Starting	a. This is a specific starter test where the Shorting Contactor (S)(2K3) is individually energized and a check is made to ensure that there are no currents detected by the CTs. If current is detected when only S is energized at Start, then 1M is shorted. b. This test in a. above applies to all forms of starters (Note: It is understood that many starters do not connect to the Shorting Contactor.).	See Troubleshooting Service Bulletin
Starter Fault Type III	MMR	Starter	Starting	a. As part of the normal start sequence to apply power to the compressor the Shorting Contactor (S) and then the Main Contactor (1M) were energized. 1.6 seconds later there were no currents detected by the CT's for the last 1.2 Seconds on all three phases. b. This test in a. above applies to all forms of starters except Adaptive Frequency. Drives (Note: It is understood that many starters do not connect to the Shorting Contactor.). c. For Adaptive Frequency Drives, TBD	See Troubleshooting Service Bulletin
Starter: Loss of Comm with Circuit	MMR	Starter	All	The starter module lost communications with the Circuit module for 15 contiguous seconds.	Check IPC Wiring/ Connections

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
Starter: Loss of Comm with Chiller	MMR	Starter	All	The starter module lost communications with the Chiller module for 15 contiguous seconds.	Check IPC Wiring/ Connections
Starter Mod Ref Voltage Calibration	IFW	Starter	All	An improper reference voltage was detected at the Starter Module. A 2.5 vdc reference is used to calibrate the non-ratiometric analog I/O such as 2-10vdc and 4-20ma inputs as well as PWM Analog outputs. The micro checks to see that the A/D value falls within an acceptable range.	See Troubleshooting Service Bulletin
Stepper #1:Loss of Comm with Starter	MMR	Stepper	All	The Stepper #1 module lost communications with the Starter module for 15 contiguous seconds.	Check IPC Wiring/ Connections
Stepper #1:Loss of Comm with Chiller	MMR	Stepper	All	The Stepper #1 module lost communications with the Chiller module for 15 contiguous seconds.	Check IPC Wiring/ Connections
Surge Shutdown: Ice Building	MAR	Starter	All Ice Building Modes	An extended Surge condition was detected while in Ice Building Mode. This diagnostic shall clear when the Ice Building command is withdrawn.	See Troubleshooting Service Bulletin
TCI: Loss of Comm with Purge	IFW	TCI	All	The TCI module lost communications with the Purge module for 15 contiguous seconds.	Check IPC Wiring/ Connections
TCI: Loss of Comm with Starter	IFW	TCI	All	The TCI module lost communications with the Starter module for 15 contiguous seconds.	Check IPC Wiring/ Connections
TCI: Loss of Comm with Options	IFW	TCI	All	The TCI module lost communications with the Options module for 15 contiguous seconds.	Check IPC Wiring/ Connections
TCI: Loss of Comm with Circuit	IFW	TCI	All	The TCI module lost communications with the Circuit module for 15 contiguous seconds.	Check IPC Wiring/ Connections
TCI: Loss of Comm with Chiller	IFW	TCI	All	The TCI module lost communications with the Chiller module for 15 contiguous seconds.	Check IPC Wiring/ Connections
TCI: Loss of Comm with Stepper #1	IFW	TCI	All	The TCI module lost communications with the Stepper #1 module for 15 contiguous seconds.	Check IPC Wiring/ Connections
Tracer Communications Lost	IFW	TCI	All	The Tracer was setup as "installed" at the CLD and the TCI lost communications with the Tracer for 15 contiguous minutes after it had been established. Continue to run the chiller with the last valid Tracer Setpoints/Mode.	Check Tracer to UCP Wiring/ Connections
Tracer failed to Establish Comm	IFW	TCI	At power-up	The Tracer was setup as "installed" at the CLD and the Tracer did not communicate with the TCI within 2 minutes after power-up.	Check Tracer Wiring/ Connections/ Power
Tracer Outdoor Air Temp Sensor Fail	IFW	Chiller	All		Check Sensor, Wiring, and Connections
Tracer Temperature Sensor	IFW	Options	All	Input Shorted.	Check Sensor, Wiring, and Connections
Transition Complete Input Shorted	MMR	Starter	Pre-Start	a. The Transition Complete input was found to be shorted before the compressor was started. b. This is active for all electromechanical starters.	Check transition complete contact

DIAGNOSTIC DESCRIPTION	Diag Type	Module that Called Diag.	Diag. Active Modes	CAUSE	Help Message
Transition Complete Input Opened	MMR	Starter	All Running Modes	a. The Transition Complete input was found to be opened with the compressor motor running after a successful completion of transition. b. This is active only for Y-Delta, Auto-Transformer, and Primary Reactor Starters.	Complete Starter Checkout Required
Under Voltage	MAR	Starter	Pre-Start and Any Ckt(s) Energzd	a. Line voltage below - 10% of nominal or the Under/Overvoltage transformer is not connected. (Must hold = - 10% of nominal. Must trip = - 15% of nominal. Reset differential = min. of 2% and max. of 4%. Time to trip = min. of 1 min. and max. of 5 min.)	Check Main Power Supply & Wiring

NOTE: For FastPak, the "module that called the diagnostic" is Scorpio if Circuit or Stepper is listed

*** **FastPak-only Diagnostic**

Notice

The Trane Company urges that all HVAC servicers working on Trane equipment, or any manufacturer's products, make every effort to eliminate, if possible, or vigorously reduce the emission of CFC, HCFC and HFC refrigerants to the atmosphere resulting from installation, operation, routine maintenance, or major service on this equipment. Always act in a responsible manner to conserve refrigerants for continued use even when acceptable alternatives are available.

Conservation and emission-reduction can be accomplished by following recommended Trane service and safety procedures published in Trane General Service Bulletin CTV-SB-81. The information and procedures provided in CTV-SB-81 supersedes those published in this manual. Copies of this bulletin may be obtained by contacting your local Trane commercial product representative.

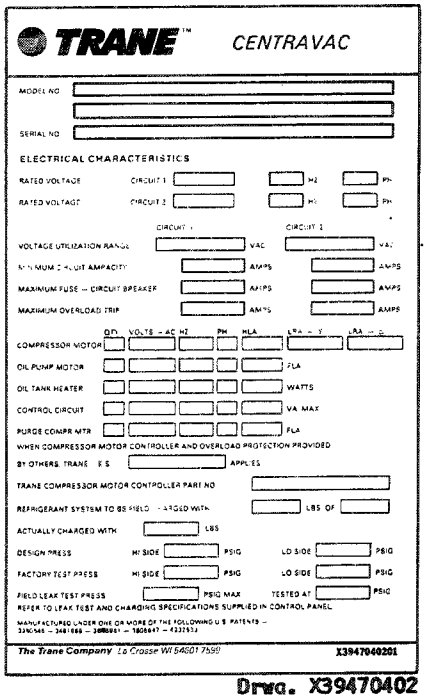
Model Number Description



All standard Trane products are identified by a multiple-character model number that precisely identifies a particular type of unit. An explanation of the alphanumeric identification code used with CenTraVac units is provided on the next three pages. Its use will enable the owner/operator, installing contractor(s), and service engineer(s) to define the operation, components and options for a particular unit.

Be sure to refer to the model number stamped on the unit nameplate (shown below, and mounted on the left-hand side of the unit control panel enclosure) when ordering replacement parts or requesting service.

Note: Trane-built unit-mounted starters are identified by a separate number found on the starter.

General Information

Literature Change History

CVHE-M-4 (February 1986)
Original issue of manual; provides operation, maintenance, and diagnostic information for CVHE units of "F" through "H" design. Also includes information on automatic condenser cleaning system.

CVHE-M-4A (September 1986)
Corrections made to front cover; manual also covers "J" design; changes made to purge maintenance instructions.

Introduction

This manual describes the operation and maintenance of Model CVHE Cooling-Only and Heat-Recovery CenTraVac liquid chillers. Its use will enable the owner/operator to understand the chiller systems, and to successfully operate and maintain the machine. Trouble analysis information is provided at the end of this manual to allow the operator to analyze and resolve a number of system malfunctions, if any should occur. (If mechanical problems do occur, however, Trane recommends that trained service personnel be contacted to ensure proper diagnosis and repair of the unit.)

Warnings and Cautions

Notice that warnings and cautions appear at appropriate intervals throughout this manual. Warnings are provided to alert operating and service personnel to potential hazards that could result in personal injury or death; they do not replace the manufacturer's recommendations. Cautions are designed to alert personnel to conditions that could result in equipment damage.

Your personal safety and the proper operation of this machine depend upon the strict observance of these precautions.

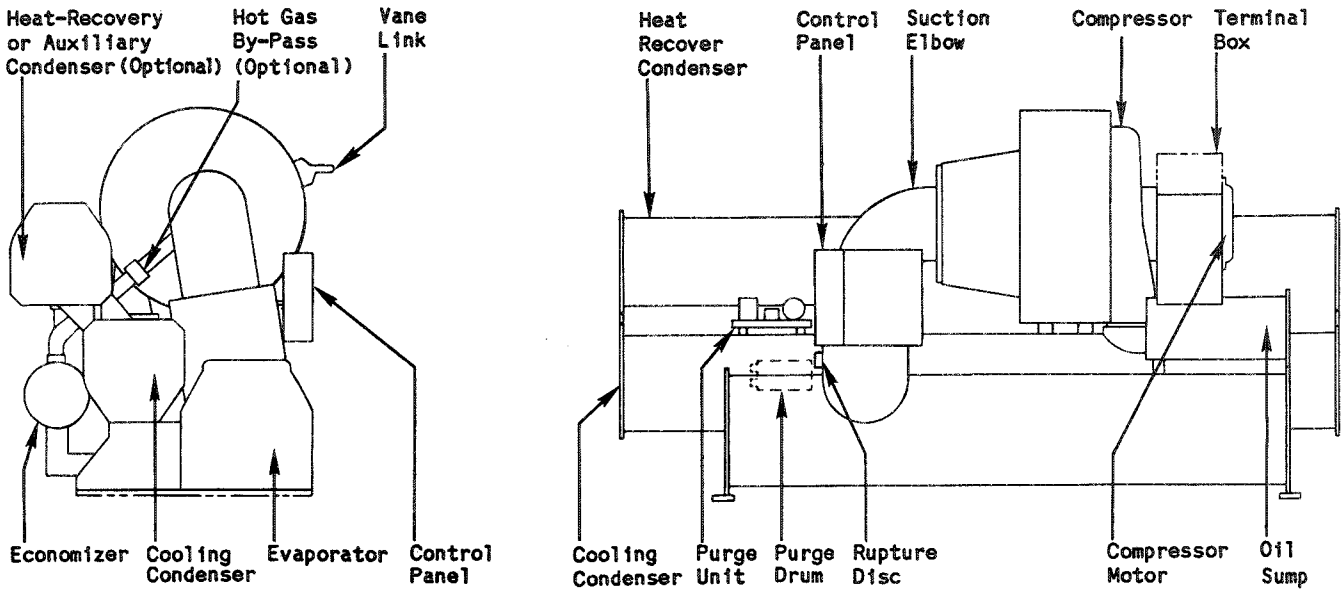
Mechanical Operation

General

Each CVHE unit is comprised of five basic components: the evaporator, three-stage compressor, water-cooled condenser, two-stage economizer, and related interconnecting piping. A heat-recovery or auxiliary condenser can be factory-added to the basic unit assembly to provide a heat-recovery cycle. Refer to Figure 1 for an illustration of a typical unit.

Following are discussions of the unit's cooling-only and heat-recovery modes of operation. A pressure/enthalpy diagram (shown in Figure 2) is provided to further illustrate unit operation.

Figure 1
Typical CVHE Chiller
(General Unit Assembly Shown)



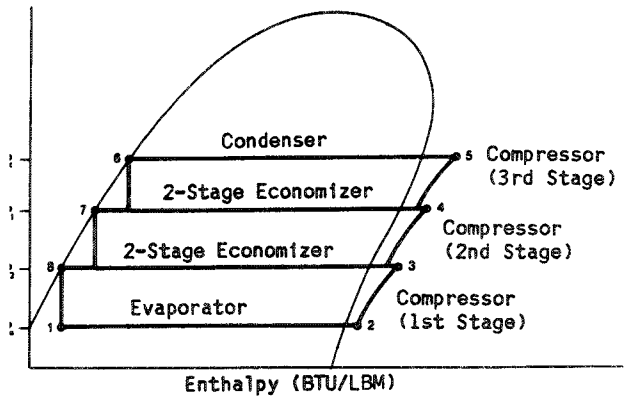


Figure 2
CVHE Pressure/ Enthalpy Curve

Cooling-Only Cycle

When the CVHE is functioning in the cooling mode, liquid refrigerant is distributed along the length of the evaporator and sprayed through small holes in a distributor (which runs the entire length of the shell) to uniformly coat each evaporator tube. Here, the liquid refrigerant absorbs enough heat from the system water circulating through the evaporator tubes to vaporize. The gaseous refrigerant is then drawn through the eliminators (which remove droplets of liquid refrigerant from the gas) and first-stage variable inlet guide vanes, and into the first-stage impeller. (The inlet guide vanes are designed to modulate the flow of gaseous refrigerant to meet system capacity requirements; they also prerotate the gas, allowing it to enter the impeller at an optimal angle that maximizes efficiency at all load conditions.)

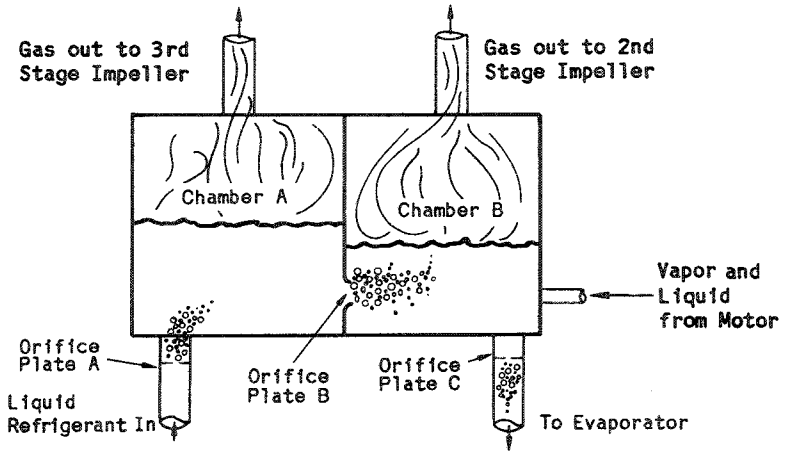
Compressed gas from the first-stage impeller flows through the fixed, second-stage inlet vanes and into the second-stage impeller. Here, the refrigerant gas is again compressed, and then discharged through the third-stage variable guide vanes and into the third-stage impeller. Once the gas is compressed a third time, it is discharged into the condenser.

Baffles within the condenser shell distribute the compressed refrigerant gas evenly across the condenser tube bundle. Cooling tower water--circulated through the condenser tubes--absorbs heat from the refrigerant, causing it to condense. The liquid refrigerant then passes through an orifice plate and into the two-stage economizer.

The economizer reduces the energy requirements of the refrigeration cycle by eliminating the need to pass all of the gaseous refrigerant through the three stages of compression. See Figure 3. Notice that some of the liquid refrigerant will "flash" to a gas because of the pressure drop created by the orifice plates, thus further cooling the liquid refrigerant. This flash gas is then drawn directly from the first (Chamber A) and second (Chamber B) stages of the economizer into the third- and second-stage impellers of the compressor, respectively. The remaining liquid refrigerant flows through another orifice plate (labelled "C" in Figure 3) to the evaporator.

Note: Some CVHE units are equipped with single-stage economizers. This type of economizer serves the same function as the two-stage economizer, but the flash gas is discharged only to the third stage of the compressor.

Heat-Recovery Cycle



The purpose of the heat-recovery cycle is to salvage the heat that is normally rejected to the atmosphere through the cooling tower, and put it to beneficial use. For example, a high-rise office building may experience simultaneous heating and cooling requirements during the winter months. With the addition of a heat-recovery cycle, the heat removed from the building cooling load can be transferred to that area of the building which requires heat. (Remember that a cooling load must exist to act as a heat source if the heat-recovery cycle is to be used.)

To provide a heat-recovery cycle, a heat-recovery condenser is added to the unit; see Figure 1. Though physically identical to the standard condenser, the heat-recovery condenser is piped into a heating circuit rather than to the cooling tower.

During the heat-recovery cycle, the unit operates just as it does in the cooling-only mode except that the cooling load heat is rejected to the heating water circuit rather than to the cooling tower water circuit. When hot water is required, the heating water circuit pumps energize. The water circulated through the heat-recovery (or auxiliary) condenser tube bundle by the pumps absorbs the cooling load heat from the compressed refrigerant gas discharged by the compressor. The heated water is then used to satisfy building comfort heating requirements.

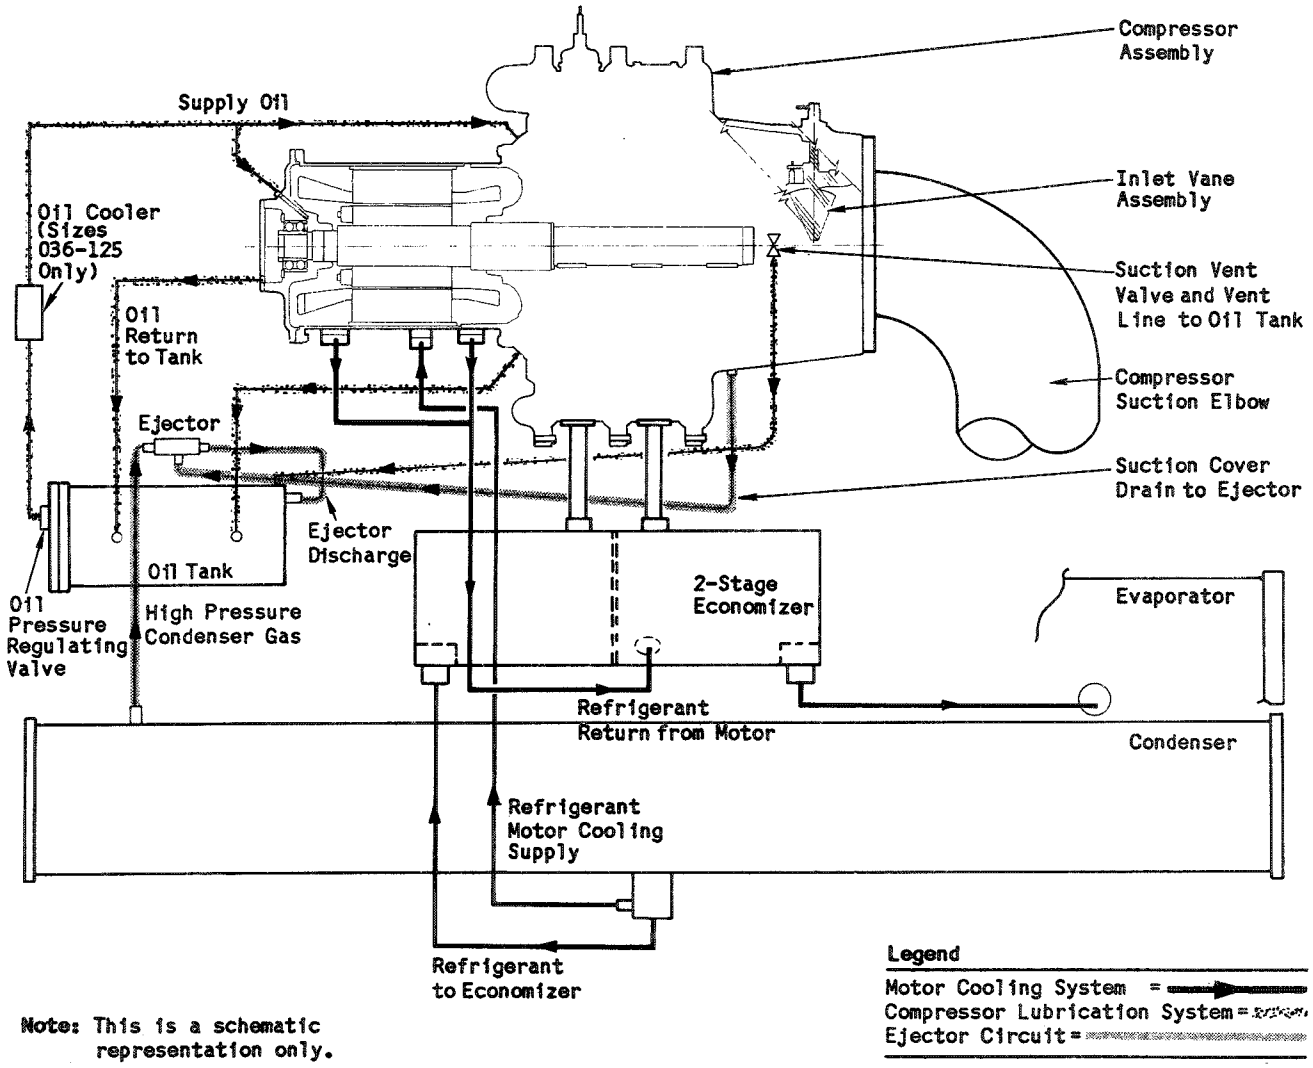
Note: Unlike the heat-recovery condenser (which is designed to satisfy comfort heating requirements), the auxiliary condenser serves a preheat function only, and is used in those applications where hot water is needed for use in kitchens, lavatories, etc. While the operation of the auxiliary condenser is physically identical to that of the heat-recovery condenser, it is comparatively smaller in size, and its heating capacity is not controlled. (Because of its small size, The Trane Company does not recommend operating the auxiliary condenser alone.)

Figure 3
Two-Stage Economizer

Compressor Lubrication System

A schematic diagram of the compressor lubrication system is illustrated in Figure 4; this system supplies oil to the compressor motor bearings.

Oil is pumped from the oil tank (by a pump and motor located within the tank) through an oil pressure-regulating valve designed to maintain a net oil pressure of 18 to 20 psig. It is then filtered and sent to the compressor motor bearings. From here, the oil drains back to the oil tank through return lines. Notice that each oil return line is equipped with a sight glass. This enables the operator to check for oil flow when the oil pump is energized.



To ensure proper lubrication and prevent refrigerant from condensing in the oil tank, a 1000-watt heater is secured to the oil tank exterior. Operating in response to the oil temperature control (S10), this heater energizes as necessary to maintain an oil tank temperature of 140 to 145 F when the chiller is not operating. When the chiller is operating, the temperature of the oil tank is typically 115 to 150 F.

Notice that the oil tank is vented between the compressor inlet vanes and the first-stage impeller suction cover; refer to Figure 4. During normal system operation, motor barrel pressure is greater than that of the oil tank. Therefore, any gaseous refrigerant that enters the motor bearing cavities is drawn toward the oil tank where it is removed by the vent line.

Any oil that collects in the suction cover area is pulled back to the oil tank by an ejector pump. This pump uses high-pressure condenser gas to draw the oil from the suction cover area back to the ejector; from the ejector, the oil is discharged into the oil tank.

Caution: The oil tank vent must remain completely open on those units equipped with ejectors; closure of the vent line may hamper the return of oil to the oil tank and result in damage to the chiller.

Figure 4
Compressor Lubrication and Motor-Cooling Systems

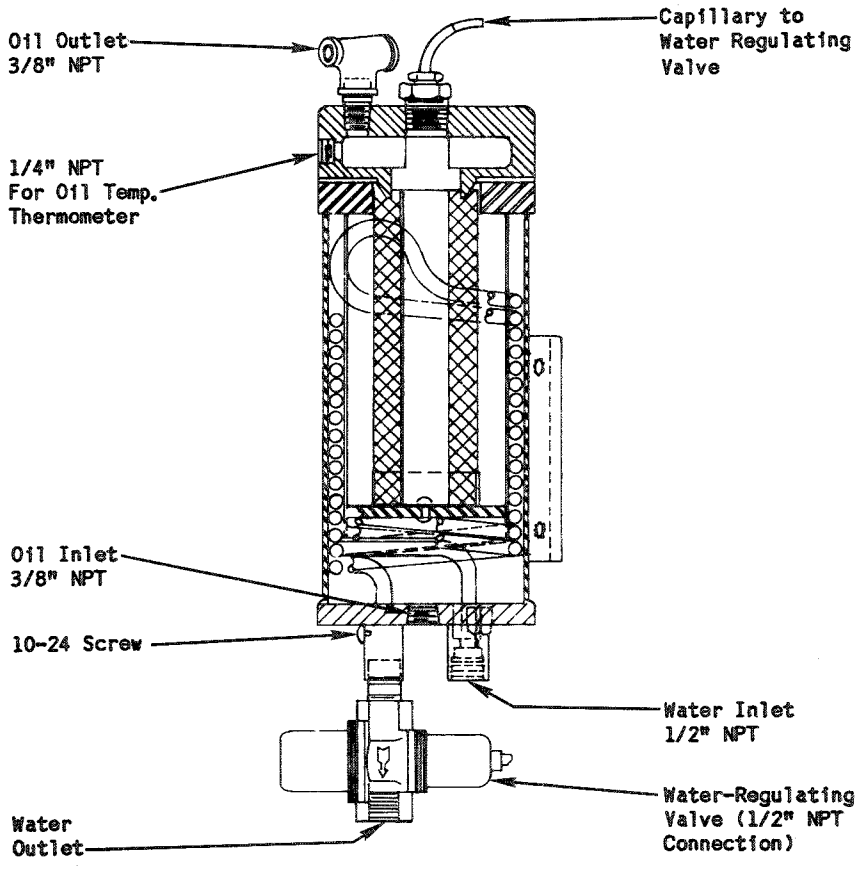
Note: This is a schematic representation only.

Oil Cooler (CVHE 036 thru 125 Only)

Oil coolers are installed as a standard feature on CVHE 036 through 125 chillers. See Figure 5 for an illustration of the oil cooler assembly.

Oil–at approximately 140 to 145 F and 18 to 20 psig–is pumped from the oil tank, through the oil pressure-regulating valve, and into the oil cooler. The oil cooler is designed to maintain a leaving oil temperature of 115 to 130 F; temperature control is accomplished with a water-regulating valve that responds to a sensor in the bearing oil supply line. When the sensor detects an increase in oil temperature, the valve opens to allow more cooling water through the oil cooler. Conversely, the valve will limit water flow through the cooler when the sensor detects a drop in oil temperature.

The water-regulating valve is field-adjustable; simply tighten the adjusting screw to decrease water flow, and loosen it to increase water flow.



Notice that a drain hole is provided in the leaving water nipple of the oil cooler; see Figure 5. When open, this drain relieves all of the water in the circuit between the cooling coil and the normally-closed water-regulating valve. Drain the water from the oil cooler as necessary (i.e., by removing the small screw tapped into the outlet pipe) to perform maintenance procedures, and to prevent cooler freeze-up during winter shutdown.

Motor Cooling System

The CVHE compressor motor is cooled with liquid refrigerant; a schematic illustration of this pressurized system is provided in Figure 4.

Liquid refrigerant flows from the condenser sump to the bottom of the compressor motor where it enters the motor chamber through a control orifice. As the liquid refrigerant touches the warmer motor components, a portion of it flashes to a gas and cools the motor. The flash gas and excess liquid refrigerant then drain to the second-stage of the economizer. Because of the positive pressure differential between the condenser and the economizer, proper refrigerant flow through the motor is maintained at all load conditions.

Figure 5
Oil Cooler Assembly
(Chiller Sizes 036 thru 125 Only)

Purge System

The purge system removes noncondensible gases and water from the refrigeration system. Refer to purge system schematic shown in Figure 6. Notice that this system uses an oilless purge compressor specifically designed for CenTraVac application, thus eliminating the need for an oil separator tank. In addition, a check valve and solenoid valve (as well as an isolation valve at the condenser) are used to isolate the purge compressor from the rest of the system when it is off; this prevents refrigerant leakage.

Caution: Before performing a standing vacuum test, be sure to close the manually-operated isolation valve at the condenser; this prevents air from entering the system.

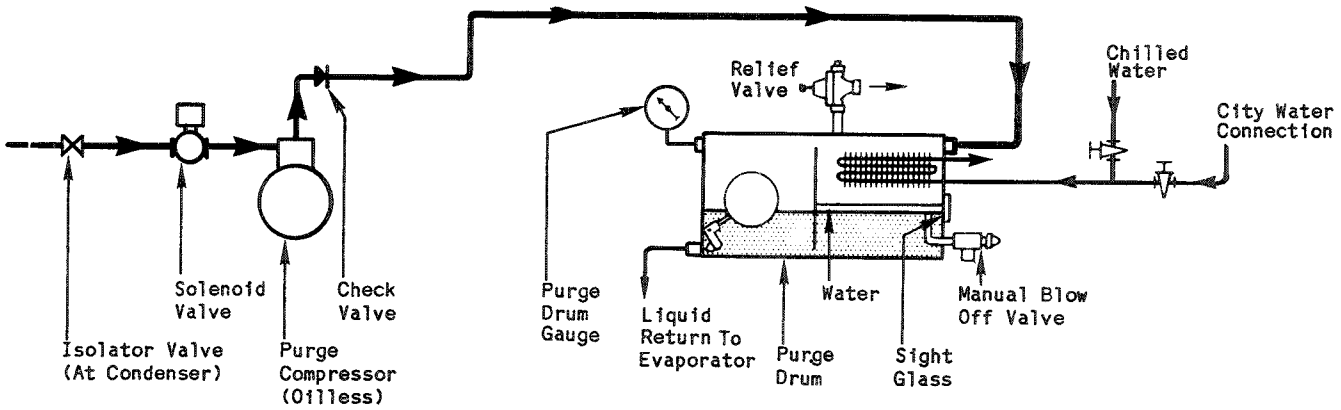
A mixture of refrigerant vapor, noncondensible gases and water is drawn from the condenser and compressed by the purge compressor. The compressed gas is then discharged directly into the purge drum; here, the condensible portion of the mixture condenses on the surfaces of the chilled water coil, while the noncondensibles rise to the top of the drum. (Refer to Figure 7 for an illustration of the CVHE's auxiliary chilled water piping.) When the pressure within the purge drum exceeds the setting of the purge drum relief valve (see Figure 6), the valve opens and exhausts the noncondensibles to the atmosphere. Any accumulated water floating on the surface of the refrigerant can be removed by opening the manual blow-off valve found on the water connection end of the purge drum.

Note: Check the purge drum for water accumulation on a weekly basis, and notice the amount of water removed. Any visible accumulation of water indicates that there is an air or water leak in the unit; if this condition occurs, be sure to contact a qualified service organization to correct this problem as soon as possible.

The remaining liquid refrigerant passes through a float valve within the purge drum and re-enters the refrigerant system through a valve at the evaporator.

The oilless ITT purge unit is controlled by the purge switch on the control panel as follows:

OFF - Purge will not operate.



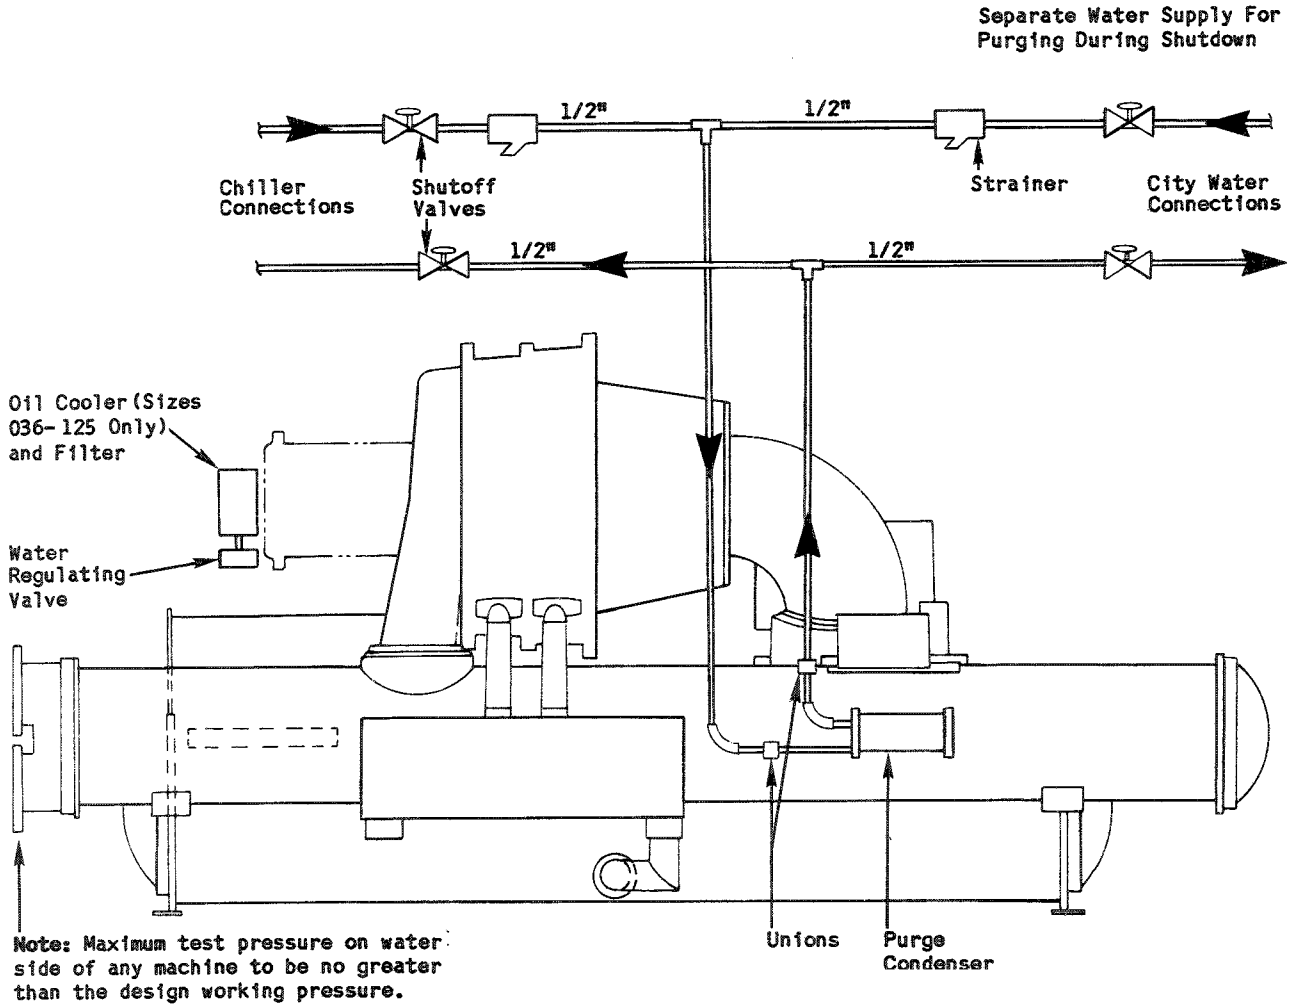
MANUAL - Purge will run continuously. This position is for service use only. The purge should not be left in this position during normal operation.

Note: When the unit is operating in the heating mode, close the manual shutoff valves on the cooling condenser. Reverse this procedure when the unit is operating in the heat-recovery mode. Purge only from the active condenser.

AUTO - In this position, the purge timer will run the compressor for five minutes out of every hour of machine operation. This is the normal switch position for machine purging.

Recommended operation of the new purge unit is in the "auto" mode or manually once per week for one hour.

Figure 6
Purge System Schematic



When the purge unit is operated in the "auto" mode, the purge compressor starts and stops under control of the timer. The timer should be set to operate for five minutes every hour. The timer can be adjusted to run the purge for less than five minutes per hour, if desired, to slow wear on the purge compressor rings.

Note: If five minutes per hour is not sufficient to keep the unit purged of air, the "on" time can be increased by adjusting the timer. However, operation in excess of five minutes per hour indicates an unacceptable leak rate that must be repaired to avoid machine damage and excessive wear on the purge compressor rings.

Note: Rotation of the time adjustment knob on the purge timer will not cycle the purge on and off. If the compressor is on, turning the knob will cycle the purge off. Further revolutions of the knob will not turn the compressor back on.

Figure 7
CVHE Auxiliary Chilled Water Piping Connections

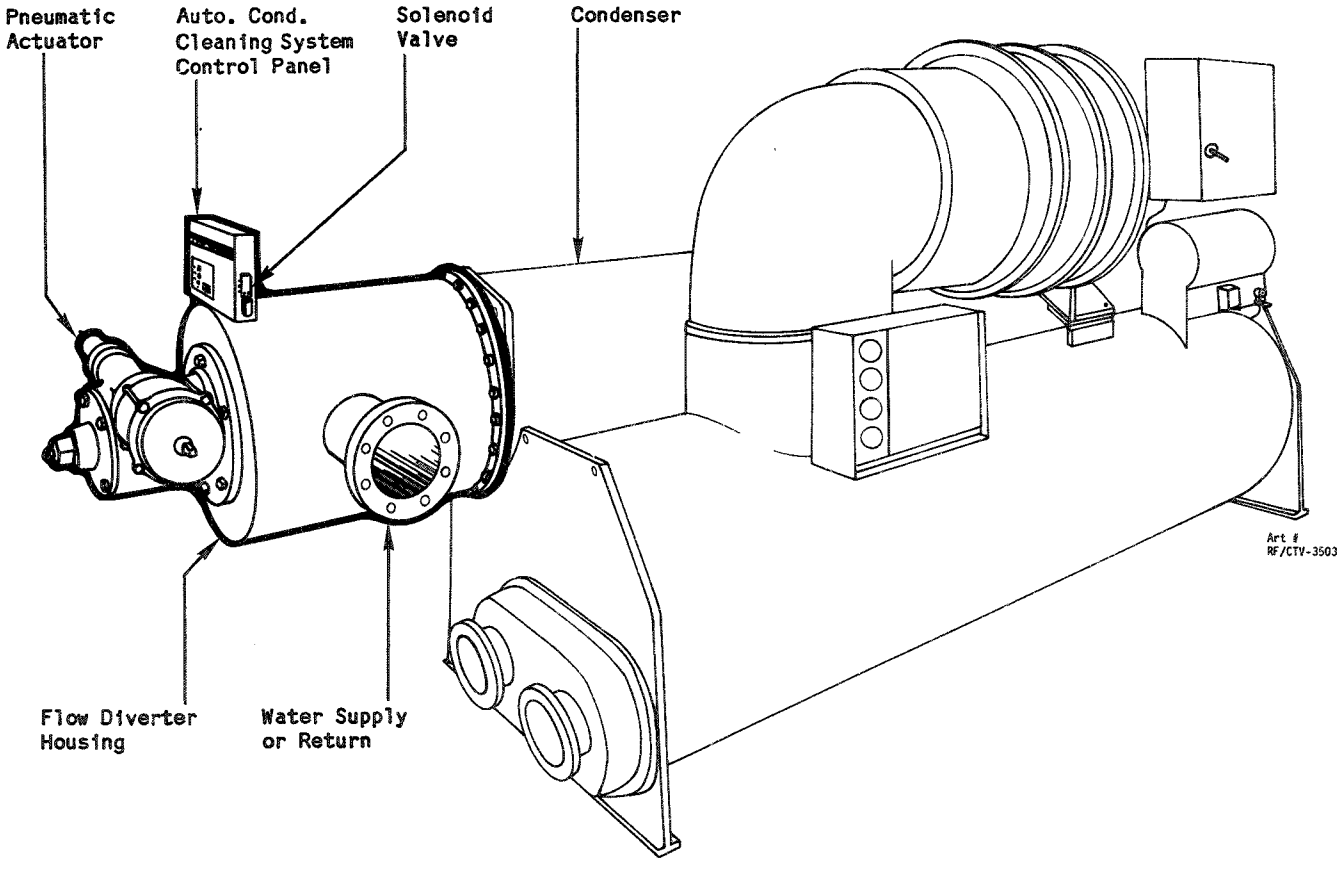
Automatic Condenser Cleaning System

The factory-installed automatic condenser cleaning system option is designed to maintain a "clean tube" fouling factor in the condenser. See Figure 8 for system components and assembly.

While the chiller is on-line, the 4-way flow diverter will activate upon a preset signal (normally every 4 to 6 hours) from the integral controller and reverse the water flow forcing the brushes through the tubes. Several seconds later, the diverter deactivates and water flow returns to normal flow causing the brushes to return to their original position.

At each tube end is a factory-installed basket and removeable end clip which retains the nylon-bristle brush.

A factory-installed and wired control panel (mounted on top of the flow diverter housing) controls all functions of the automatic condenser cleaning system. The control functions are described below.



Cycle Frequency

Cycle frequency is set at the 24-hour time clock at pre-determined time intervals. Appropriate pins should be pushed in to the desired actual time of the cleaning cycle operation. Recommened cycle intervals are every 6 hours of unit operation. With "IE" (internally enhanced) tubes, this time should be shortened to 4 hours. Cycle frequency should be increased if the water treatment program is inadequate or excessive fouling conditions exist.

Caution: To ensure proper brush release and movement, treat cooling tower water as required and install strainers or screening (3/16" openings maximum) in the condenser water supply.

In the event that a scheduled cycle would fall within a peak operating period, this cycle may be pushed ahead or back by 2 hours, provided all other scheduled times remain unchanged.

Figure 8
Automatic Condenser Cleaning System Option

Timer Clock Programming

After determining desired frequency times, program the clock by depressing the tripper pins (found around the outer edge of the timer clock) corresponding with desired times (see Figure 9).

Note: Schedule cleaning cycle times only during the time of day the unit is in operation. During unit shutdown there is no water flow to move the brushes.

Caution: If any extended shutdown occurs, make sure the flow diverter cycles at least once each day. This will prevent binding of the diverter and possible diverter damage.

Diverter Cycle Time

The cycle time period consists of the time the diverter transfers from the "normal" to "reverse" position, plus the time the diverter remains in the "reverse" position, plus the transfer time back to "normal" position. For normal cycle times, the diverter should remain in the "reverse" position for approximately 25 seconds.

Note: The 1TR timer in the control panel (see Figure 9) should be factory-set at 30 seconds. This is the time the solenoid valve remains energized. Insure that 1TR is set at 30 seconds.

Diverter transfer times are factory-set at the exhaust restrictor set-screws located on the 4-way solenoid valve (see Figure 10). By turning each set-screw counter-clockwise, the transfer time will decrease (speeding movement) or vice-versa. Use the test cycle push-button located on the control panel to cycle the diverter until the proper transfer time is established. The pointer on the end of the pneumatic actuator (see Figure 11) will allow you to monitor diverter movement. The "N" is the normal diverter position, while "R" is the reverse flow position.

As a guideline, the transfer time in each direction should be approximately 5-6 seconds, or fast enough to minimize condenser water stagnation, but slow enough to prevent water hammer or slamming action of the diverter under full flow conditions.

Incomplete Sequence Alarm

If at any time the diverter should take longer to transfer than the alarm time time is set, the "Incomplete Sequence" alarm light will illuminate on the control panel indicating a diverter movement problem. The alarm time is set at the 2TR timer located inside the control panel (see Figure 9). The timer should be set at 3 seconds greater than the "set" transfer time. For example, if transfer time is 6 seconds, set the 2TR timer at 9 seconds. If the diverter takes longer than 9 seconds to transfer, the 2TR timer will time out, illuminating the "Incomplete Sequence Alarm" light.

Pneumatic Actuator (End View)

System Control

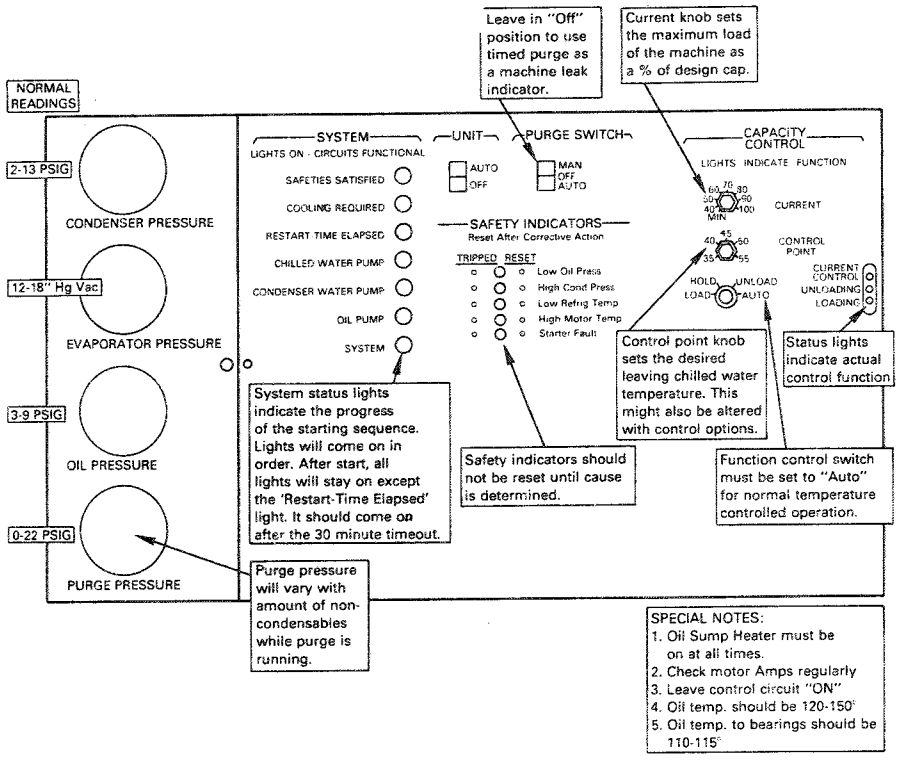
Control Panel

Safety and operating controls are housed in the CenTraVac unit control panel. Panel functions are divided into four categories, as indicated by the physical layout of the panel; see Figure 12.

1. Pressure gauges--located on the left-hand side of the panel--indicate condenser, evaporator, lubricating oil, and purge drum pressures.

2. Seven system sequence status lights (located to the immediate right of the pressure gauges) perform an important diagnostic function by monitoring the progress of the chiller start-up sequence. As each of the seven control circuit interlocks is verified, its control panel pilot light illuminates. If, for some reason, the start-up sequence is aborted, the operator can determine the point of the breach by checking these pilot lights.

3. Five safety indicators are provided in the center of the control panel, directly below the unit AUTO/OFF and purge MAN/OFF/AUTO switches; see Figure 12. These circuit interrupters are used to open the control circuit since they will hold their position in the event of a power interruption. This means that a power failure does NOT require manual resetting of all safeties.



Note: Additional alarm contacts on each of the safety indicators are brought to a terminal strip for external field-installed connection.

4. The electronic capacity control system, located on the right-hand side of the control panel, operates an electric vane motor to load and unload the chiller. This system consists of three elements: a current limiter, a chilled water temperature control, and the function control switch (and indicator lights).

The current limit control (labelled % CURRENT) can be set to control at any value below 100 percent of the motor rated load current. Motor current is sensed by three current transformers, and processed into a proportional DC voltage signal by the CenTraVac motor overload (A1). This same DC voltage signal is monitored by the current limiter. When the set percentage of rated load current is reached, the current limiter prohibits the inlet vanes from opening further; if the setting is exceeded, the inlet vanes are modulated toward the closed position.

The chilled water temperature control module uses a solid-state temperature sensor to monitor leaving chilled water temperature. If this temperature varies

Figure 12
CVHE Unit Control Panel

from setpoint (which is set using the knob labelled CONTROL POINT, and is based on design conditions), an electronic controller sends a pulsing signal to the inlet vane actuator; this tells the actuator to adjust the guide vanes to compensate for the variance from setpoint. (The standard control point is adjustable between 35 and 55 F.)

The function control switch, labelled with LOAD/HOLD/UNLOAD/AUTO positions, governs the function of the capacity control module. It must be set at AUTO to provide normal unit operation, and is only readjusted to one of the other switch positions for service work. To the right of the function control switch are three pilot lights which indicate whether the chiller is loading, unloading, or limiting the chiller capacity based on current draw. If all three of these pilot lights are out, the three conditions they represent are presently satisfied and the unit is functioning normally (i.e., holding with no inlet vane movement).

Note: The unit safety controls can override the setting of the function control switch regardless of its position; this override capability ensures that the chiller is protected from most dangerous operating conditions; however, no safety device protects against surge!

In addition to the gauges, status lights, safety indicators, and electronic capacity control system, the unit AUTO/OFF and purge MAN/OFF/AUTO switches are also located on the unit control panel. The unit AUTO/OFF switch allows the chiller to be shut down manually; when positioned at AUTO, the chiller will operate in response to the unit controls and safeties. (Remember that the unit will not start automatically unless all of the start-up safety conditions have been satisfied and cooling is required.) This switch is usually left in the AUTO position when cooling is needed.

Caution: Do NOT operate the purge compressor in the manual mode unless there is water flow through the purge drum! If the purge switch is positioned at MAN without water flow through the drum, refrigerant will be purged from the machine, resulting in excessive refrigerant loss.

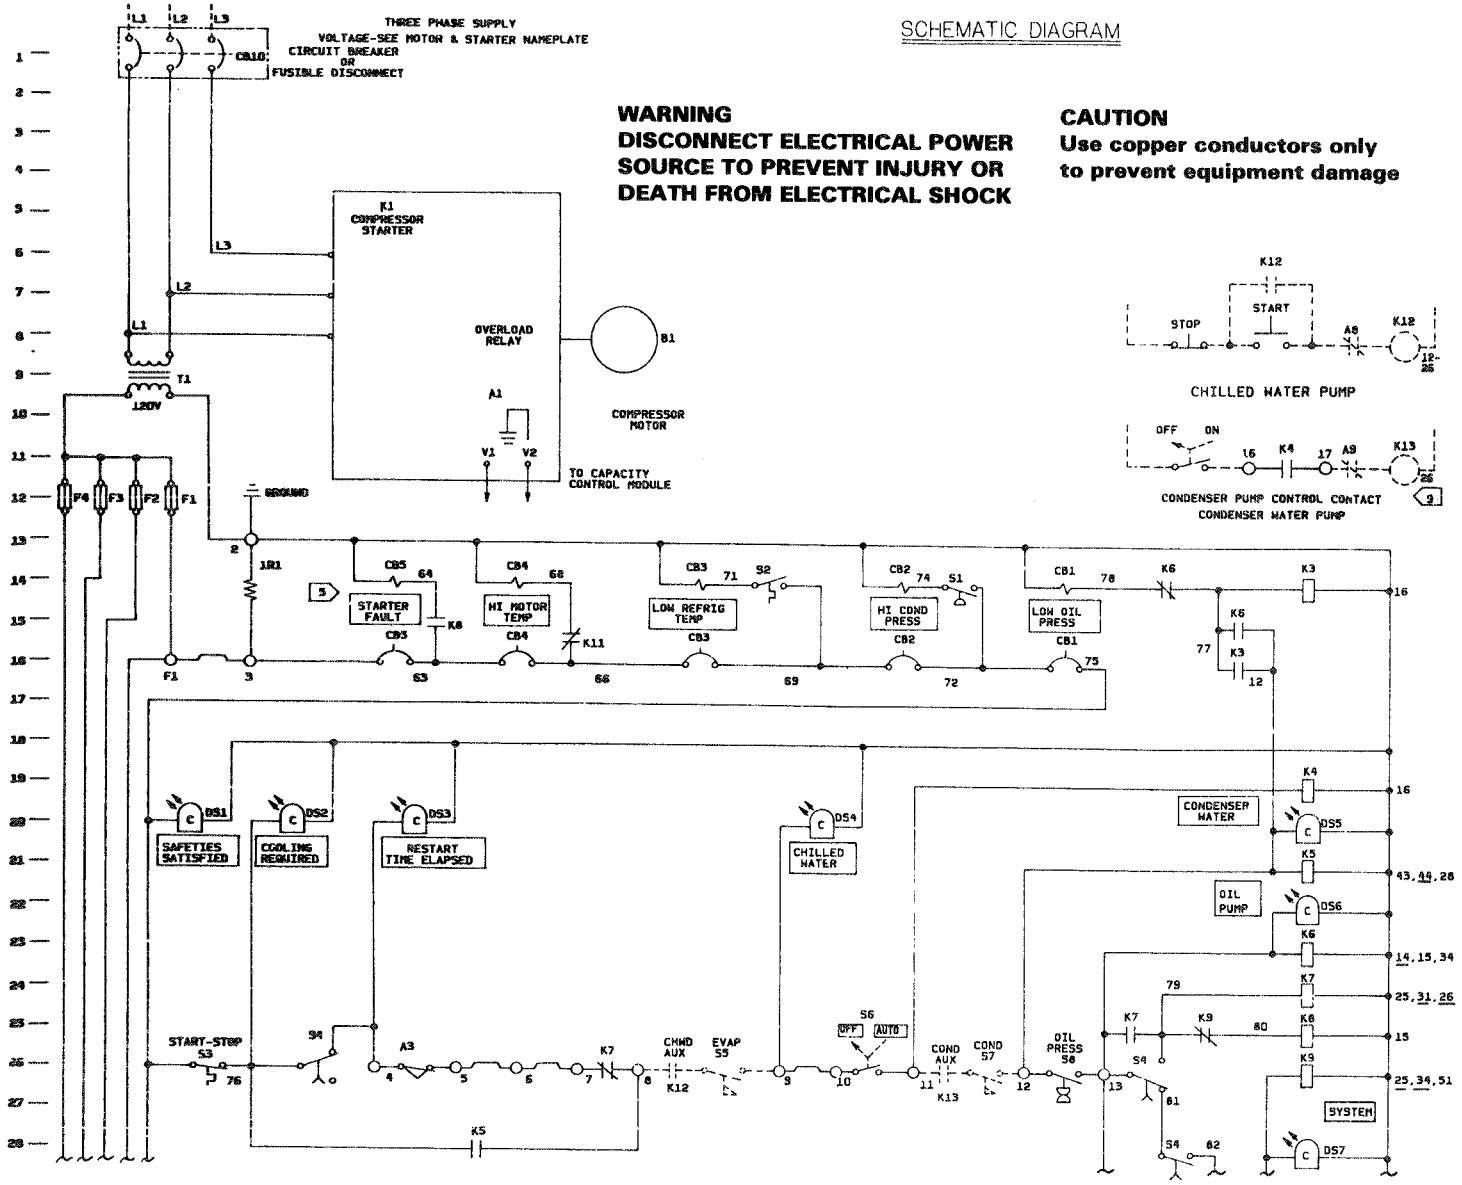
Electrical Sequence of Operation

Be sure to refer to the typical wiring schematic provided in Figure 13 when reviewing the step-by-step electrical sequences of operation provided below

Caution: The wiring diagram provided in Figure 13 is only typical and is provided ONLY for general reference; it may not reflect the actual wiring of your unit. For specific electrical connection and schematic information, refer to the wiring diagrams which shipped with the chiller.

Electronic Capacity Control System

The electronic capacity control system used to govern chiller operation consists of six control devices; their functions are reviewed below:



Electronic Starter Overload Relay (A1) - This device monitors the compressor motor starting current, and initiates transition to full voltage when the current draw falls to 85 percent of motor RLA. Once transition is complete, it compares the motor current against a calibrated value of 107 percent of RLA; if the current reaches this value, the overload will trip to disconnect the motor.

Compressor Inlet Vane Actuator (A3) - The actuator end switch (see Line 26, Figure 13) is closed when the compressor inlet vanes are at the full closed position. A3's limit switch (see Line 38) is open whenever the inlet vanes are fully open, while a second A3 limit switch (Line 40) is open when the vanes are fully closed.

Anti-Recycle Timer (S4) - This timer (found on Line 34) limits the compressor to one start every 30 minutes, and also provides the "start" signal to the compressor motor starter (K1).

Oil Pump Timer (S9) - With a total timing cycle of four minutes, this control device allows the oil pump to provide a pre-lube cycle of approximately one minute and twenty seconds; at the end of the pre-lube interval, the anti-recycle timer (S4) energizes and the oil pump timer stops timing until the unit shuts down. At that point, S9's timing cycle resumes and will continue until the four-minute cycle is complete, thereby providing a compressor post-lube period of approximately three and one-half minutes.

Electronic Capacity Control Module (U1) - This device modulates the inlet vane actuator (A3; Line 39) by balancing the CONTROL POINT knob setting against the leaving chilled water temperature sensed by the leaving chilled water temperature sensor (U3; Line 38).

The U1 module also serves as a load limiting device as a result of an input signal received from the electronic overload relay (A1); the circuit between the control power fuse (F1) and Terminal 84 (on U1) must be complete before the module can open the compressor inlet vanes.

Compressor Motor Hi-Temperature Cutout (U2) - The M1-M2 contacts of this device (found on Line 35) close shortly after 115-volt control power is provided to Terminals T1 and T2, and will remain closed unless the temperature of the compressor motor windings exceeds 265 ± 5 F. If the motor winding temperature exceeds this level, the M1-M2 contacts will open to shut down the machine; when the winding temperature drops to 235 F, these contacts will automatically reclose.

The motor temperature sensors B1R1, B1R2, and B1R3 are located on the ends of the motor windings at 2, 6, and 10 o'clock positions. These sensors are not replaceable.

Note: Be sure to refer to the legend provided when reviewing the electrical sequence of operation outlined in the paragraphs which follow.

With the chilled water pump starter (K12; Line 13) energized, and the unit ON/OFF switch (S6; Line 26) set at AUTO, 115-volt control power flows through the string of safety controls and safety lockout contacts (Line 16). If all of the safeties are satisfied, the SAFETIES SATISFIED indicator light (DS1; Line 20) illuminates.

Current then flows to the chilled water demand switch (S3; Line 26), whose temperature-sensing element is located in the return water entering the chiller. When the return water temperature rises above the control point, S3 closes; this illuminates the COOLING REQUIRED indicator light (DS2; Line 20) and "feeds" current to the anti-recycle timer contacts (S4; Line 26). If a minimum of 30 minutes has elapsed since the last compressor start, S4's contacts allow the current to pass; this causes the RESTART TIME ELAPSED indicator light (DS3; Line 26) to illuminate, and current flows to the compressor inlet vane actuator (A3). If the inlet vanes are closed and the compressor is off, current flows through the compressor inlet vane end switch and the contacts of relay K7 to Terminal 8. The CHILLED WATER flow indicator light (DS4; Line 20) will then light, provided that the evaporator flow switch (S5; Line 26) verifies chilled water flow.

Notice that positioning switch S6 (Line 26) at AUTO also allows current to energize the condenser pump control relay (K4; Line 19); K4's contacts (Line 16) then close, energizing the condenser water pump starter (K13). If condenser water flow is proven, current flows through condenser flow switch S7 (Line 26), illuminates the CONDENSER WATER flow indicator light (DS5; Line 20), and energizes relay K5 (Line 21). One set of normally-open K5 contacts (Line 43) closes to energize the oil pump timer (S9). After the 40-second timing period has elapsed, S9's contacts (Line 44) close and oil pump motor B2 (Line 45) energizes.

The oil pump utilizes a capacitor-start/induction-run, single-phase motor; its current-sensitive starter relay (K15; Line 45) is wired in series with the pump motor's run winding, allowing it to switch from start to run. When the oil pump motor first starts, it draws locked rotor current; this high current draw causes relay K15 to close its contacts (Line 45). The start capacitor then energizes, and the motor start winding begins its rotation. Once the motor is fully accelerated, the current draw falls, causing K15's contacts (Line 45) to open and drop out of the start winding. The oil pump motor is now in its run configuration.

Once proper oil pressure is established, oil pressure switch S8 (Line 26) closes and the OIL PUMP indicator light (Line 22) illuminates. Relay K6 (Line 23) then energizes, and one set of its single-pole/double-throw contacts (Lines 14 and 15) switch to energize the low oil pressure arming circuit (K3; Line 14). (This occurs when K3's contacts--in Line 16--subsequently close to energize low oil pressure fault indicator CB1.)

A second set of normally-open K6 contacts (Line 34) closes to energize the anti-recycle timer (S4). Within 25 seconds, the S4 contacts in Line 33 close, while another set of S4 contacts in Line 28 closes 20 seconds later. With S4's contacts closed, the SYSTEM operating indicator light (DS7; Line 28) illuminates and relay K9 (Line 26) energizes. A compressor start is then initiated when compressor motor starter relay K1 energizes; one set of K1 "start" contacts (Line 29) closes to maintain power to the compressor starter, while a second set of "start" contacts (Line 34) closes to energize the start pulse signal relay (K10).

Notice that one set of single-pole/double-throw K10 contacts (Lines 32 and 34) switch immediately to ensure the the K10 relay remains energized for the duration of anti-recycle timer S4's timing period. Another normally-closed set of K10 contacts (Line 29) opens to interrupt the "start" signal to the compressor motor through the S4 contacts in Line 26. **Note:** The original "start" signal sent through the S4 contacts in Line 26 is maintained just long enough to energize the "start" contactor of compressor motor starter K1. If K1 drops out of the circuit for any reason, it will remain de-energized until the anti-recycle timer (S4) completes its timing cycle.)

An additional set of normally-open K1 "start" contacts (Line 45) closes to ensure that the oil pump is energized as long as K1's contacts are closed.

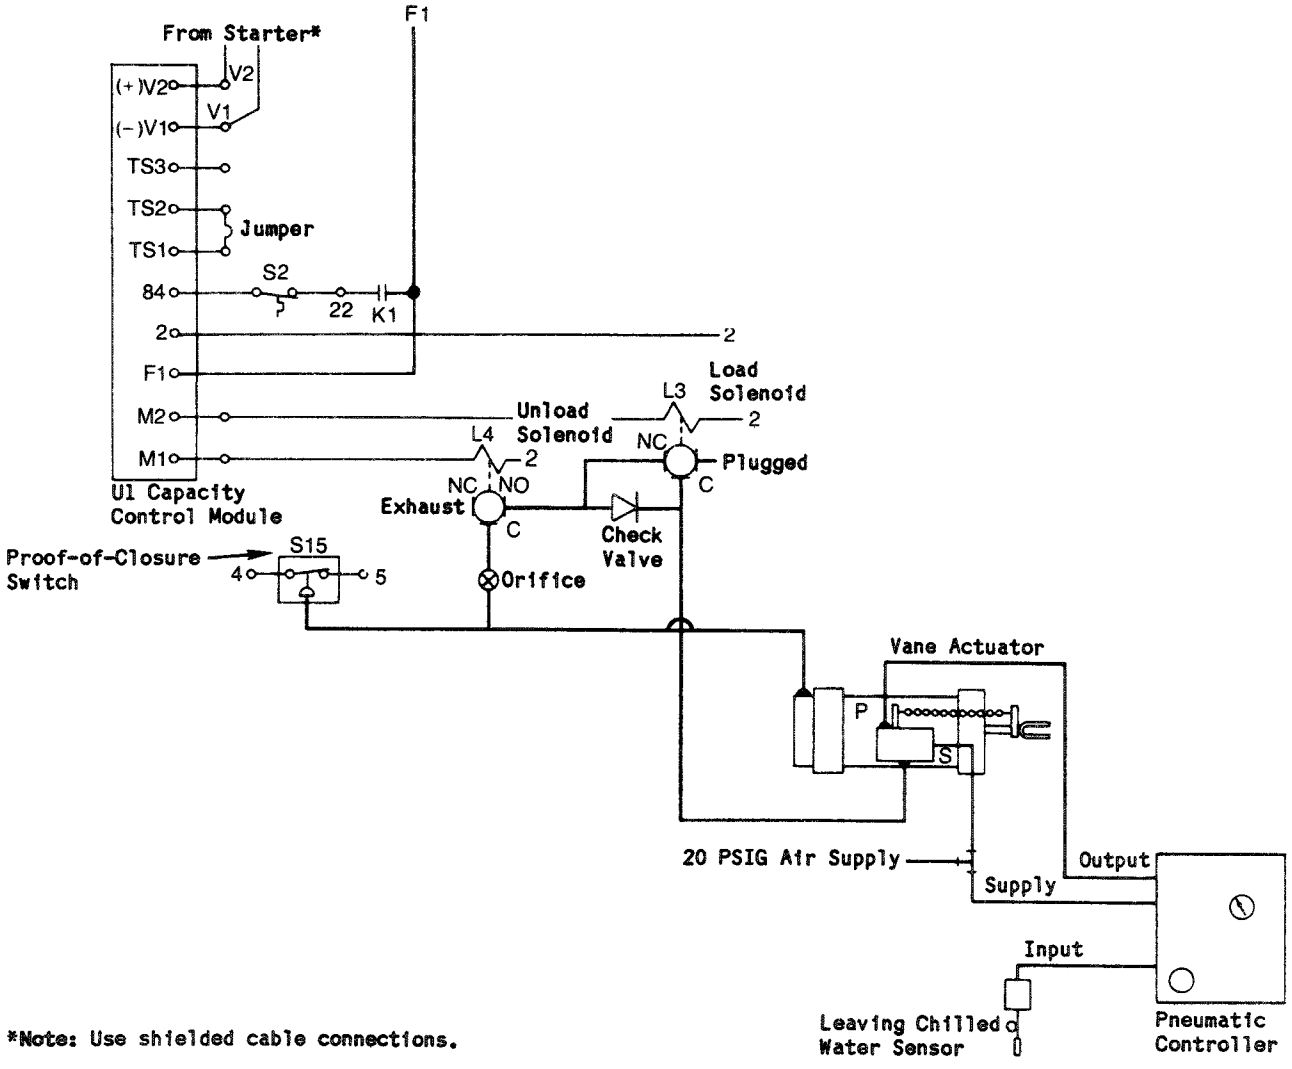
When compressor motor starter K1 "converts" the compressor to the run configuration, K1's normally-open "run" contacts (Line 40) close to supply power to Terminal 84 of the capacity control module (U1). (However, the low refrigerant temperature switch (S2) must be closed for this to occur.) Control module U1 then opens the compressor inlet vanes as needed.

Remember that the "starter fault" safety circuit was armed at the same time that compressor motor starter K1--along with relay K9--was initially energized; a set of normally-closed K9 contacts in Line 25 opened to ensure that relay K8 (i.e., starter fault tripping circuit) remained de-energized. At that point, S4 contacts in Line 26 switched from 13-81 to 13-79 to energize relay K7 (Line 24). Normally-closed K7 contacts in Line 25 then closed, allowing relay K7 to remain energized and completing the arming of the "starter fault" circuit. If compressor motor starter K1 drops out of the circuit for any reason, the K1 contacts in Line 29 will open and relay K9 will de-energize. K9's normally-closed contacts (Line 25) will then reclose to energize the starter fault tripping circuit relay (K8) and cause its normally-open contacts (K8; Line 15) to close. This action trips the starter fault indicator (CB5) and locks the unit off.

When there is no longer a call for cooling--or if a safety opens, compressor starter K1 and relay K5 (i.e., oil pump timer/jump-out start inhibit circuit) are de-energized. A set of S9 contacts (Line 44) ensures that the oil pump timer (S9) and oil pump motor (B2) remain energized for three minutes to provide lubrication during compressor coast-down.

If there is a loss of oil pressure while the compressor is running, oil pressure switch (S8; Line 26) opens; this stops the compressor and de-energizes relay K6 (oil pressure arming circuit/start S4 timer motor; Line 23). Current is then routed from Terminal 12 (Line 26), through the K3 contacts in Line 16 and the normally-closed K6 contacts in Line 14. This trips the low oil pressure fault indicator (CB1), and the compressor is locked out.

Note: Alarm contacts (Line 56) for field connection are factory-wired using a set of auxiliary, normally-closed contacts on each of the control safety lockouts.



Control Options: Pneumatic Capacity Control System

In this control scheme, an analog (proportional) signal from a conventional pneumatic temperature controller (also optional) is fed into the pilot port (labelled "P" in Figure 14) of the pneumatic inlet vane actuator's pilot positioner. Notice that a jumper between Terminals TS1 and TS2 on the capacity control module (U1) is substituted for the electronic leaving chilled water sensor (U3) used in the electronic control scheme described in the preceding section.

When the compressor motor starter assumes the "run" configuration, K1's interlocking contacts close; the continuous circuit between TS1 and TS2 causes the module to transmit a repeated, pulsed loading signal to solenoid valve L3. Unlike the electronic capacity control system, the duration of this pulse is solely the function of motor current in terms of its relationship to the % CURRENT setting of the current limiter. The preselected 10 to 310-second time lapse is observed between successive load pulses.

During the load pulse, the normally-closed (NC) port of solenoid valve L3 opens, permitting the output air pressure from the pilot positioner to be transmitted through the normally-open (NO) and common (C) ports of solenoid valve L4 to the vane actuator. Within the time interval of the load pulse, the pneumatic temperature controller has the authority to open, close or hold the vane position.

Figure 14
CVHE Pneumatic Control Interface

*Note: Use shielded cable connections.

When the system is shut down, opening the K1 contacts--or a low refrigerant temperature condition opens switch S2--control module U1 transmits a continuous unloading signal. This signal closes the normally-open (and opens the normally-closed) ports of valve L4 to exhaust the control air pressure from the actuator and close the vanes.

Load limiting within the pneumatic control system is handled in the same manner as the electronic control scheme: as motor current rises, the duration of the loading pulse decreases. At 100 percent of the % CURRENT setting, the pulse duration drops from 0.25 seconds to zero. At 103 percent, a 0.25-second unloading pulse is initiated, followed by a 10 to 310-second load-delay period; this represents an attempt to return the chiller to 100 percent of the demand limiter setting. Finally, at 105 percent, a continuous unloading pulse is established and is terminated only when the motor current is reduced to 95 percent of the demand limit setting. (Refer to Figure 14; a pressure-relief check valve is connected to the normally-open port of L4 to allow the unit to unload when motor current is between 100 and 103 percent of the % CURRENT setting and the chilled water set-point has been reached. This check valve also enables the pneumatic control to reduce the branch pressure on the actuator when the unit is under current limit and the chilled water setpoint has been reached.)

Notice that control air is supplied to--and exhausted from--the vane actuator through an orifice. This orifice is factory-adjusted to produce the same vane movement rate as that produced by the actuator used in the electronic capacity control system.

Finally, proof-of-closure switch S15, which closes on a drop in pressure, replaces and performs the same function as the end switch of the electric inlet vane actuator (A3; Figure 13 - Line 26).

The remaining circuitry of the pneumatic capacity control system is the same as that used in the electronic control scheme.

Control Options: Sequence Panel

Note: When reviewing the following operational sequence, be sure to refer to the appropriate wiring diagram in the wiring booklet which shipped with the unit. For more comprehensive installation and application information, refer to the submittal information which shipped with the panel.

To ensure that the system operates properly when power is applied, several adjustments must be made to the sequence panel and to the unit controls.

1. On the sequence panel:

a. Select the desired unit operating sequence, and set the sequence switch accordingly.

b. Use the knobs located on the mounting plate within the panel to set the load and unload thresholds.

   Set the load threshold to the percentage of maximum load desired on the lead unit before the lag unit starts; a setting of 90 percent is recommended.

   Set the unload threshold to that percentage of minimum load required with both units operating before the lag unit shuts down. To prevent cycling at this transition point, the setting must be less than half of the load setting; a setting of 40 percent is recommended. As a part of set-up, determine what the minimum current threshold is before adjusting the minimum set-point to insure that the motor will go to 40%.

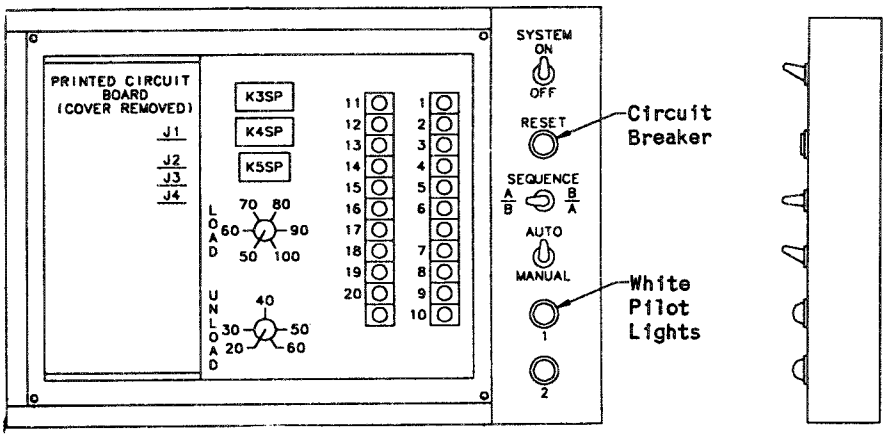
2. Adjust the controls of the lead (A) and lag (B) units. The power switches (labelled AUTO/OFF on the control panel of each unit) should be set at AUTO, and the temperature control adjustments should be set to the same desired control temperature.

Make sure that the knobs on the temperature controls are properly adjusted. The pointer of each should be aligned with the calibration mark on the dial when in the fully counterclockwise position.

In addition, adjust the current limit potentiometers to the fully clockwise position.

These are the only adjustments required for the successful operation of the system.

When control power is applied to a pair of chillers (piped in parallel) utilizing the sequence panel control option, the operational characteristics of the system are the same as those described in the previous sections. Start-up is controlled by the sequence panel OFF/ON switch; refer to Figure 15 for an illustration of the sequence panel and possible panel applications. When the system switch is positioned at ON, its contacts close to the lead unit, and pilot light No. 1 illuminates. If all of the start sequence circuit interlocks are verified, the lead unit will start.



If the current draw of the lead unit exceeds the setting on the load selector, a 15-minute timer energizes. Once the timing cycle is complete, the second (or lag) unit starts and pilot light No. 2 illuminates. At this point, the lead unit begins to unload and the lag unit loads up. After a period of adjustment, the units stabilize, with each carrying half of the cooling load; any further change in cooling demand will be shared equally.

In some applications, the sequence panel is used in conjunction with a pair of chillers piped in series with one chilled water pump; this changes the master/slave control scheme. When both units are on, the "B" (or lag) unit always operates with its temperature control in its current limit mode (i.e., the yellow light is on); its loading, however, tracks that of the "A" (or lead) unit. If the load decreases, the lag unit will shut down 15 minutes after reaching the setting on the unload selector. The remaining unit adjusts to carry the load.

Should it become necessary to run either or both chillers independently from the sequence panel, adjust the OFF/ON system switch on the sequence panel to the OFF position. Then, when the sequence panel's AUTO/MANUAL switch is set at MANUAL, the units will operate in response to their individual control adjustments.

Note: The sequence panel pilot lights indicate a call for the units' operation; they do NOT confirm unit operation.

Control Configurations: Sequence System w/Two Units

Parallel 1 Pump

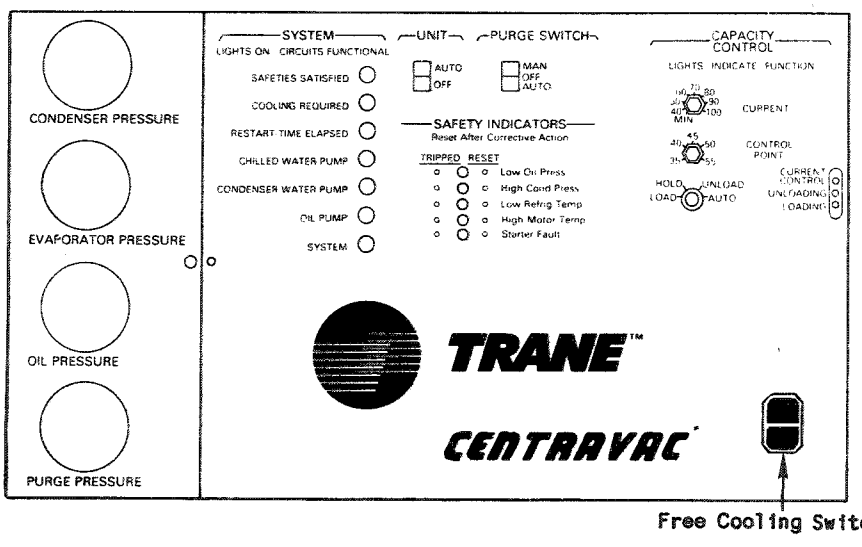
Parallel 2 Pumps

Series

Control Options: Free-Cooling

Free-Cooling, an accessory to CVHE CenTraVacs, adapts the basic chiller so it may function as a simple heat exchanger using refrigerant as the working fluid; however, it does not provide control of the leaving chilled water temperature. When condenser water is available at temperatures lower than the desired chilled liquid temperature, the free-cooling option can provide substantial nominal chiller capacity without operating the compressor, resulting in substantial energy cost savings.

The principle behind the free-cooling option is that refrigerant flows to the area of lowest temperature in the system. When condenser water is available at a temperature lower than the required leaving chilled water temperature, the operator manually stops the compressor and starts the free-cooling cycle by pressing a push button control located in the lower right-hand corner of the unit control panel. See Figure 16. Changeover from the free-cooling cycle to mechanical cooling is accomplished by pressing this same button.



To equip the chiller with the free-cooling option, several components are factory-installed or -supplied: a refrigerant gas line (including an electrically-actuated shutoff valve) installed between the evaporator and condenser; a valved liquid return line (including an electrically-activated shutoff valve) between the condenser sump and the evaporator; a liquid refrigerant storage vessel; additional refrigerant charge; and, a free-cooling selector switch (located on the unit control panel).

When the chiller operator initiates the changeover to the free-cooling cycle, the shutoff valves in the liquid and gas lines open, and a lockout circuit prevents the compressor from energizing. Liquid refrigerant then drains--by gravity--from the storage tank into the evaporator and floods the tube bundle. Since the temperature and pressure of the refrigerant in the evaporator are higher than in the condenser because of the difference in water temperature, the refrigerant in the evaporator vaporizes and flows to the condenser. This gaseous refrigerant then condenses as a result of the effects of the cooling tower water, and flows--again, by gravity--back to the evaporator. Refer to Figure 17 for an illustration of the free-cooling cycle.

The automatic refrigeration cycle described above is sustained as long as a temperature differential exists between the condenser and evaporator liquids. The cooling capacity provided by the free-cooling cycle is determined by the difference in temperature between the evaporator water and the condenser water which, in turn, determines the rate of refrigerant flow between the two shells.

If the system load exceeds the available free-cooling capacity, the operator must manually initiate changeover to the mechanical cooling mode by pressing the free-cooling switch on the unit control panel. The gas and liquid line valves then close and compressor operation begins. Refrigerant gas is drawn out of the evaporator by the compressor, and is then compressed and discharged to the condenser. Most of the condensed refrigerant initially follows the path of least resistance by flowing into the

Figure 16
CVHE Unit Control Panel w/Free-Cooling Option

storage tank. The storage tank is vented to the economizer sump through a small bleed line; when the storage tank is full, liquid refrigerant must flow through the bleed line restriction.

Because the pressure drop through the bleed line is greater than that of the orifice flow control device, the liquid refrigerant flows normally from the condenser through the orifice system and into the economizer.

Note: During the changeover from free-cooling to mechanical cooling, the refrigerant transfer process is completed within three minutes. The loading ramp prevents carry-over by loading the machine slowly.

Control Options: Hot Gas Bypass

The hot gas bypass (i.e., HGBP) control system is designed to minimize machine cycling by allowing the CVHE unit control system to operate stably under minimum load conditions. In these situations, the guide vanes are locked at a preset minimum point and the unit capacity control function is performed by the HGBP valve positioner. Circuits are also provided to allow both the guide vanes and the HGBP valve to close for unit shutdown.

There are four control components associated with the hot gas bypass option:

1. Relay K16: This control device is located in the unit control panel (or mounted in a separate box for retrofit applications), and enables the closure of the HGBP valve and guide vanes at unit shutdown.

2. Switch S12: This single-pole/double-throw limit switch is mounted on the guide vane linkage, and operates when the vanes pass through a particular minimum setting.

3. Switch S: Mounted in the HGBP valve actuator, this single-pole/double- throw limit switch operates when the valve just begins to open. Notice that the "close" limit switch mounted in the valve actuator must be set to operate just after (i.e., valve more closed) Switch S operates.

4. Switch S22: This device is designed to shut the unit down if the discharge temperature exceeds 210 F, thereby preventing the unit from running at extremely low loads for extended periods of time.

Note: When reviewing the sequence of operation provided below, be sure to refer to the hot gas bypass schematic and connection diagrams included in the wiring booklet which shipped with the chiller.

At unit start-up, the HGBP control relay (K16) energizes, and load signals from M2 flow to the "open" terminal of the vane actuator. When the vanes open past the preset minimum operating point, the contacts of limit switch S12 switch so that any unload signals from M1 are routed to the vane actuator. From this point, the unit will load and unload normally throughout the range of guide vane positions. (If the vanes do not open past the preset minimum operating point, however, the unit will remain on inlet guide vane control only.)

Figure 17
Free-Cooling Operation
Vs. Compressor Operatio

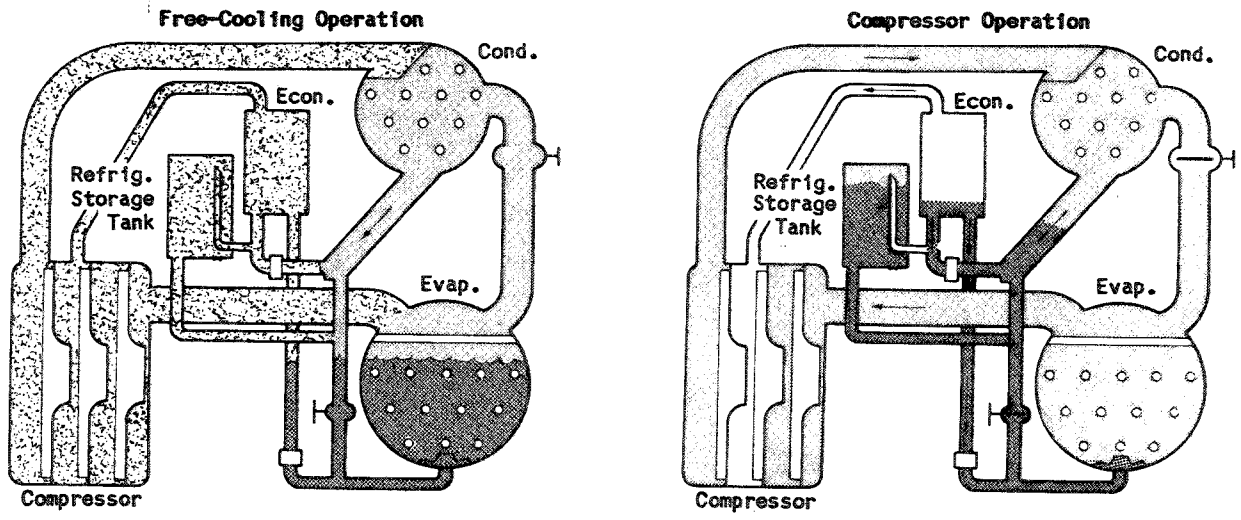


Table 1
Demand-Limit Interface: Input vs. Current

Potentiometer Input	Maximum Current
0 Ohms	100%
200 Ohms	88%
400 Ohms	76%
600 Ohms	64%
800 Ohms	52%
1000 Ohms	40%

When the unit unloads and the guide vanes reach a preset minimum point, Switch S12 energizes and passes unload signals from M1 to the "open" terminal of the HGBP valve actuator. When the HGBP valve opens, Switch S energizes and passes load signals from M2 to the "close" terminal of the HGBP valve actuator. Unit capacity is then controlled by the HGBP valve actuator with the guide vanes held at the minimum position. When the unit again loads, the HGBP valve closes; once it reaches the full-closed position, Switch S energizes and sends additional load signals to the vane actuator.

At unit shutdown, HGBP control relay K16 is de-energized and the unload signal from M1 passes through the normally-closed contacts of K16 to the "close" terminals of the vane and HGBP valve actuators. This operation prepares the unit for restart.

Note: Be sure to contact a qualified service organization for proper adjustment of the HGBP valve actuator limit switches.

Control Options: Demand-Limit Interface

The demand-limit interface control option--whether factory- or field-installed on the unit control panel--is designed to enable the chiller to be demand-limited from an external source. Once the demand-limit module is installed, the CVHE control system can accept a 0 to 1000-ohm potentiometer input (or equivalent). This resistive input limits the maximum current that the compressor motor can draw. Refer to Table 1 to determine the relationship between the potentiometer inputs and the resulting maximum current values. Notice that as the maximum allowable current is decreased, the capacity controller decreases the inlet guide vane opening in an attempt to meet the maximum limit. Current draw with fully closed inlet guide vanes may range from 60 to 30 percent of the rated load amps (RLA), depending on the individual machine amd the operating conditions. Once the vanes are fully closed, any additional signals input to further limit the maximum current will have no effect.

To demonstrate chiller operation during demand-limiting, let's look at the example provided below:

A CVHE unit is drawing 60 percent current, and a 200-ohm potentiometer signal is inputted into the control system. This 200-ohm signal sets the maximum current draw at 88 percent; see Table 1. Since the actual current draw of 60 percent is less than the maximum allowable current draw of 88 percent, the unit will not respond with a capacity reduction at this time.

However, if the load current tries to rise above the maximum allowable current (i.e., 88 percent), demand-limiting will occur. The inlet guide vanes will modulate closed until the actual current draw equals the maximum current allowable.

If the maximum allowable current setting is raised, the inlet guide vanes open slowly, stopping at a position that corresponds to some current draw below the ceiling level.

Note: Make sure that the demand limiter dial on the front of the unit control panel is set at 100 percent. Any demand-limiting initiated with this dial is superimposed onto the external demand-limiting signal (e.g., a dial setting of 75 percent plus a 200-ohm potentiometer input yields a maximum allowable current of 62 percent).

Note: Demand-limiting a centrifugal chiller may cause the machine to temporarily operate in an unstable mode that produces refrigerant gas noise. Since job site conditions vary greatly, it is recommended that the rate of demand-limiting--as well as the maximum amount of demand-limiting--be determined on the job site at start-up.

Control Options: Chilled Water Reset Interface

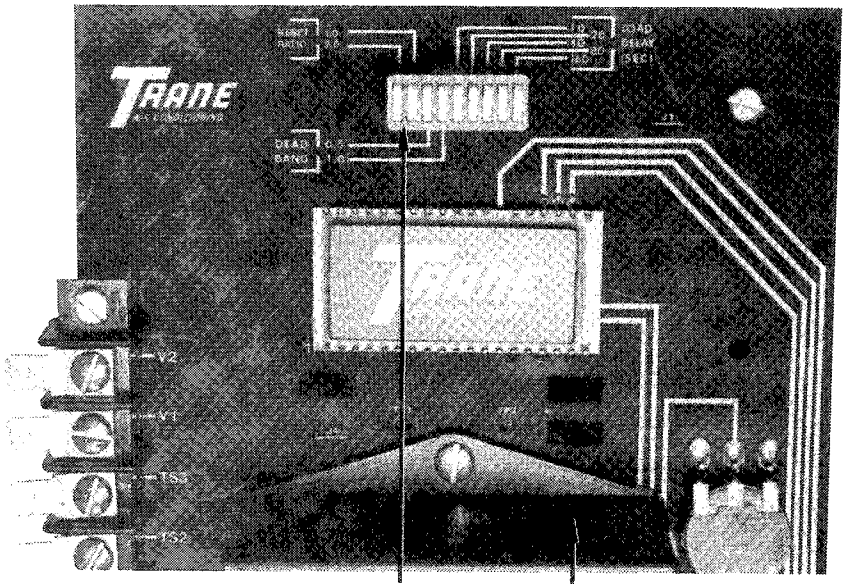
Note: This control option is not compatible with the unit pneumatic capacity control system.

The chilled water reset interface option consists of a control module which is factory- or field-installed on the outside of the unit control panel. When connected to a remote signal device (i.e., field-supplied and -installed), the interface control module will linearly reset the leaving chilled water control point to a maximum of 10 F above the unit control panel setting. (The reset interface control module is designed to accept signals of 0 to 10 VDC, 4 to 20 maDC, or 0 to 1000 ohms.)

Control Options: Chilled Water Reset

Note: This control option is not compatible with the unit pneumatic capacity control system.

Chilled water reset is designed for those applications where the system operates at part load, and does not require design chilled water temperature



at part load. In these cases, the leaving chilled water temperature setpoint can be reset upward using the chilled water reset option.

Using an additional temperature sensor field-installed in the return chilled water piping, the chilled water reset control option enables the capacity control module to sense the cooling load on the chiller. **Note:** Be sure to select the proper sensor, depending upon the full-load delta "T". As the unit unloads, the control module will raise the leaving water temperature according to one of three available ratios; refer to Figure 18. Each of the reset ratios is defined as the change in entering water temperature vs. the change in leaving water temperature. To select the desired reset ratio, adjust the "dip" switches located on the capacity control module found within the unit control panel. See Figure 18.

Once the proper reset ratio has been selected, the chilled water reset option operates automatically, raising the leaving water temperature as the cooling load decreases. No further adjustment or maintenance is required.

Note: The chilled water reset control can be enabled or disabled with the addition of a single, field-supplied, mercury-wetted relay. By short-circuiting the two wires that connect the sensor to the control panel, the capacity control module overrides the reset signal and returns to the control panel setpoint.

Figure 18
Capacity Control Module
Dip Switch Adjustment
for Chilled Water Reset Option

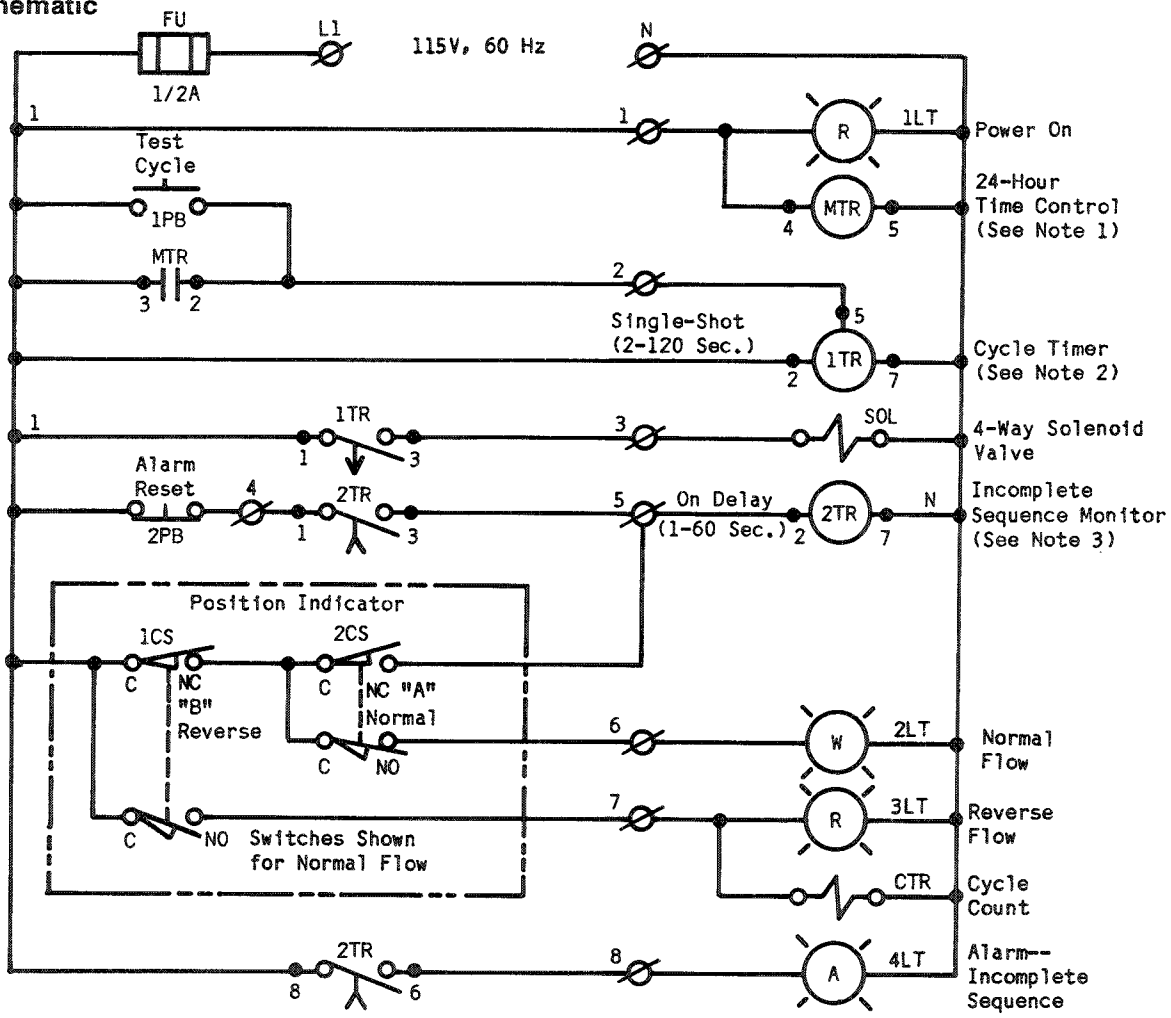
Reset Ration	Dip Switch #1	Dip Switch #2
None	Off	Off
1/2 : 1	On	Off
1 : 1	Off	On
2 : 1	On	On

Notes:
1. These ratios represent the change in entering water temperature vs. the change in leaving water temperature.
2. The actual amount of temperature reset is dependent on 4 parameters: sensor "range", design delta-T, reset ratio, and cooling load.

Automatic Condenser Cleaning System Electrical Sequence of Operation

Before a cycle is initiated, the normal flow light is on as shown in the electrical schematic (Figure 19).

Contact MTR of the 24 HR time control closes at preset times during the day, energizing the single shot timer 1TR. The 1TR contact will close for approximately 30 seconds, energizing the 4-way solenoid valve SOL.



Energizing SOL will reverse the air to the flow diverter actuator (double acting cylinder) causing the flow diverter to move from normal to reverse position. Once the flow diverter plug moves from the normal position, the 2CS contacts (switch A) of the valve position indicator close, turning off the "Normal Flow" light and closing the circuit to the incomplete sequence on-delay relay 2TR, starting the timer.

When the plug reaches the reverse position, the 1CS contacts (switch B of the valve position indicator switch) close, turning the "Reverse Flow" light on and advancing the counter one half count. The circuit to 2TR is opened, resetting it to zero.

After 1TR times out (approximately 30 seconds), it will de-energize, opening the 1TR contact and de-energizing SOL. SOL de-energizing will cause the air to the flow diverter actuator to reverse, and the opposite action just described will occur. The "Reverse Flow" light will go out and the cycle counter will advance another one-half count making one full count. At this point the normal flow light will illuminate.

If diverter transfer time exceeds the time set at the 2TR timer, 2TR will time out and close contacts illuminating the "Incomplete Sequence Alarm". To reset 2TR and turn the "Incomplete Sequence Alarm" light off, push "Alarm Reset". The flow diverter must be in the "Normal" or "Reverse" position to reset.

Figure 19
Automatic Condenser Cleaning System (Option) Electrical Schematic

Notes:
1. Turn outer dial clockwise until white pointer lines up with time of day. Depress one tripper at the time of day each cleaning cycle is desired.
2. Set 1TR to 30 seconds.
3. Adjust time on 2TR to actual valve transfer time + 3 sec.
4. O = Terminal block connections.

WARNING
DISCONNECT ELECTRICAL POWER SOURCE TO PREVENT INJURY OR DEATH FROM ELECTRICAL SHOCK

CAUTION
Use copper conductors only to prevent equipment damage

Unit Start-Up /Shutdown Procedures

Daily Unit Start-Up

1. Check the oil tank oil level; the level must be visible in--or above--the lower sight glass. Also, be sure to check the oil tank temperature; normal oil tank temperature before start-up is 140 ± 5 F.

2. Adjust the unit AUTO/OFF switch to the OFF position.

3. Check for chilled water and condenser water flow.

4. If necessary, readjust the current limit control (labelled % CURRENT) to the desired position.

5. Check the position of the function control switch; it should be set at AUTO.

6. If necessary, readjust the chilled water temperature control (labelled CONTROL POINT) to the desired temperature.

7. Verify that the safety indicators are in the reset position. If any have tripped, be sure to diagnose and correct the cause of the trip-out.

8. Recheck the oil temperature; once it reaches 140 ± 5 F, start the unit by adjusting the unit switch to the ON position.

Daily Unit Shutdown

1. Adjust the unit switch to the OFF position.

2. Shut down the chilled water pump if chilled water service is no longer required.

Seasonal Unit Start-Up

1. Close all drain valves, and reinstall the drain plugs in the evaporator and condenser headers.

2. Service the auxiliary equipment according to the start-up/maintenance instructions provided by the respective equipment manufacturers.

3. Chiller Sizes 036 thru 125 Only: Open the manual valves in the oil cooler water circuit.

4. Vent and fill the cooling tower, if used, as well as the condenser and piping.

Caution: If the chiller is equipped with the automatic condenser cleaning system, take care when filling the condenser to prevent any sudden surge of water which may damage the retainer baskets and brushes. Action of the flow diverter should also be disabled at this time.

At this point, all air must be removed from the system (including each pass). Then install the vent plugs in the condenser water boxes.

5. Close the city water valves to the purge condenser.

6. Open all of the valves in the evaporator and purge condenser chilled water circuits.

7. If the evaporator was previously drained, vent and fill the evaporator and chilled water circuit. When all air is removed from the system (including each pass), install the vent plugs in the evaporator water boxes.

8. Lubricate the external vane control linkage.

9. Check the refrigerant in the unit; to do this, the refrigerant must be drawn off and weighed back into the chiller. (If the unit is low on charge, be sure to contact a qualified service organization.)

10. Check the adjustment and operation of each safety and operating control.

11. Close all disconnect switches.

WARNING: Use care when measurements, adjustments, or other service-related operations must be made with the power on to prevent injury or death due to electrical shock or contact with moving parts.

12. Start the purge system.

13. Verify that each of the safety indicators on the unit control panel is in the reset position.

14. Check the oil tank level; the level must be visible in the lower sight glass. Also, be sure to check the oil tank temperature; normal oil tank temperature before start-up is 140 ± 5 F.

15. Verify that the unit AUTO/OFF switch is positioned at OFF; then energize the water pumps. Check for chilled water and condenser water flow.

16. If necessary, set the current limit control (labelled % CURRENT) at its minimum setting.

17. Check the position of the function control switch; it should be set at AUTO.

18. If necessary, adjust the chilled water temperature control (labelled CONTROL POINT) to the desired temperature.

19. Recheck the oil temperature; once it reaches 140 ± 5 F, start the unit by adjusting the unit switch to the ON position.

The system should now operate automatically.

Seasonal Unit Shutdown

1. Stop the system at the chilled water push button station, or stop the chilled water flow by the means devised for this particular application.

2. Open all disconnect switches except the control power disconnect switch.

WARNING: Use care when measurements, adjustments or other service-related operations must be made with the power on to prevent injury or death due to electrical shock or contact with moving parts.

Caution: The control power disconnect MUST remain closed during the entire shutdown period to allow oil sump and separator (if applicable) heater operation. This will prevent refrigerant from condensing in the oil sump.

Caution: During a shutdown of more than 1 or 2 days, the optional automatic condenser cleaning system should be cycled at least once a day. This will prevent any diverter binding problems and possible unit damage.

3. Drain the condenser piping and cooling tower, if used.

4. Remove the drain and vent plugs from the condenser headers to drain the condenser.

5. If the system will be subjected to freezing temperatures, vent and drain the evaporator, oil cooler, and all connecting piping.

6. Once the unit is secured for winter, perform the maintenance procedures described in the "Annual Maintenance" section of this manual.

Note: During shutdown, be sure to operate the purge unit for a 30-minute period every two weeks. This will prevent the accumulation of air and noncondensibles in the machine. To start the purge, position the water valves to circulate city water through the purge condenser; then adjust the purge switch to the manual (MAN) position.

Periodic Maintenance

This section describes basic chiller preventive maintenance procedures, as well as the recommended intervals for the performance of these procedures. Remember that a periodic maintenance program is important to obtain the best possible performance and efficiency from the CenTraVac chiller. Proper maintenance also assures that minor problems are detected and resolved before they become major.

An important aspect of the chiller maintenance program is the regular completion of the CenTraVac Operating Log; refer to the last page of this manual for an example of this log. When filled out accurately by the operator, the completed logs can be reviewed to identify any developing trends in the chiller's operating conditions. If, for example, a gradual increase in condensing pressure is noted during a month's time, the operator can systematically check–then correct–the possible causes of this condition (e.g., fouled condenser tubes, noncondensibles in the system, etc.).

Daily Maintenance and Checks

1. Check the chiller's evaporator, condenser and purge drum pressure, oil sump temperature, and net oil pressure. Compare the readings obtained with the values provided in Table 2.

2. Check the oil level in the chiller oil sump using the two sight glasses provided in the oil sump head. When the unit is operating, the oil level should be visible in the lower sight glass.

Weekly Maintenance

Check the purge drum sight glass for evidence of condensate. (Water condensed in the purge drum floats on the surface of the liquid refrigerant, creating a visible line of separation in the sight glass.)

To remove water from the drum, operate the purge compressor until a positive pressure of 5 to 10 psig is indicated on the purge drum pressure gauge. Then, shut down the purge compressor and open the manual blow-off valve (located on the water connection end of the drum) to release the water and other noncondensibles.

Caution: If frequent purging is required, identify and correct the source of the air or water leak as soon as possible. Moisture contamination caused by leakage can shorten the life expectancy of the machine.

Note: If the unit is operating in the cooling mode, close the manual shutoff valves on the heating condenser and open the valves on the cooling condenser. Reverse this procedure when the unit is operating in the heat-recovery mode. Be sure to purge only from the active condenser.

Table 2
Normal Chiller Operating Characteristics

Operating Characteristic	Normal Reading
Evaporator Pressure	12 to 18" w.c. Hg (vacuum)
Condenser Pressure[1]	2 to 12 psig
Purge Drum Pressure	0 to 22 psig
Oil Sump Temperature:	
Unit Not Running	140 to 145 F
Unit Running	115 to 150 F
Net Oil Pressure[2]	18 to 20 psid

Notes:
1. Condenser pressure is dependent upon the temperature of the condensing water, and should equal the saturation pressure of R-11 at a temperature 5 to 10 F above that of the leaving condenser water at full load.
2. Net oil pressure (i.e., usable oil pressure) is determined by subtracting the oil sump pressure (i.e., evaporator pressure) from the oil pressure gauge reading.
Example: Oil Pressure Gauge = 10 psig, and the evaporator pressure = 18" Hg (vacuum). First, convert 18" Hg to psig (i.e., -18/2.03 = -8.87 psig).

Then, subtract -8.87 psig from 10 psig (i.e., 10 - (-8.87) = 10 + 8.87 = 18.87 psid). In this example, the net oil pressure of 18.87 psid is within the acceptable limits.

If your chiller is equipped with the factory-installed automatic condenser cleaning system, refer to the following weekly maintenance checks:

[ ] The movement of the diverter valve should be observed (the diverter pointer should rotate 90 degrees between "N" and "S"). Proper movement of the valve should insure that the control and air systems are functioning properly and that the correct transfer time is set.

[ ] Inspect the diverter packing during cycling to insure that no water leakage occurs.

[ ] Insure that the proper air pressure is maintained (70 - 100 psig).

[ ] Check cycle counter to insure that the proper number of cycles are registered.

Every Three Months

WARNING: Open and lock the unit disconnect to prevent injury or death due to electrical shock or contact with moving parts.

1. Clean all water strainers in the CenTraVac water piping system.

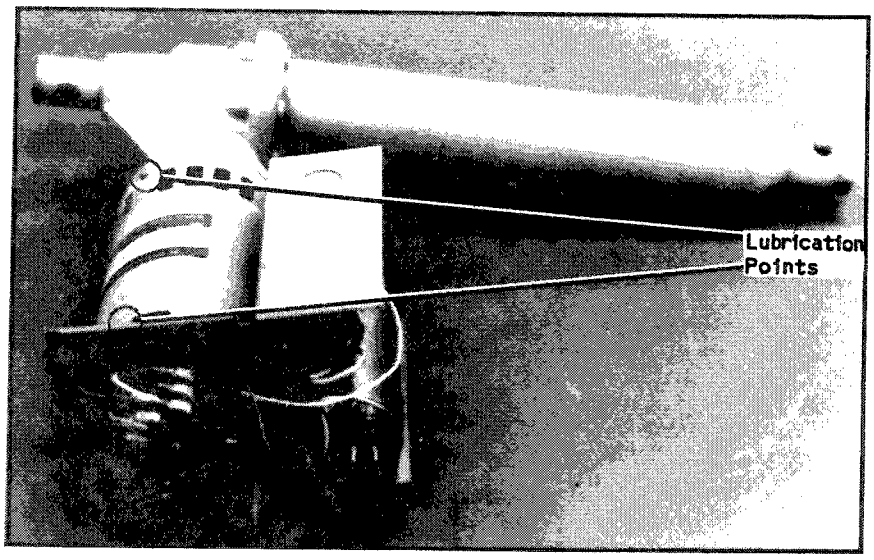
2. Complete all recommended daily and weekly maintenance procedures. (Refer to the previous sections for details.)

If your chiller is equipped with the optional automatic condenser cleaning system lubricate the diverter journal bearings through the grease fittings provided at both the front (actuator end) and rear journal bearings. Use Keystone Nevastane medium grease or equivalent.

Every Six Months

WARNING: Open and lock the unit disconnect to prevent injury or death due to electrical shock or contact with moving parts.

1. Lubricate the vane control linkage bearings, ball joints, and pivot points; a few drops of light machine oil (e.g., SAE-20) is sufficient. Also, apply one or two drops of oil on the vane operator shaft and spread it into a very light film; this will protect the shaft from moisture and rust.



2. Lubricate the actuator motor bearings by inserting a long nozzle into the lubrication ports on the actuator. See Figure 20. Several drops of SAE-20 oil, or equivalent, is sufficient.

Off-Season Maintenance

During those periods of time when the chiller is not being operated, be sure to operate the purge unit for a 30-minute period every two weeks. This will prevent the accumulation of air and noncondensibles in the machine. Since the machine is not providing chilled water, cool water (i.e., less than 80 F) must be supplied to the purge condenser drum by adjusting the water valves to provide alternate water flow through the purge condenser.

Caution: If frequent purging is required, identify and correct the source of the air or water leak as soon as possible. Moisture contamination caused by leakage can shorten the life expectancy of the machine.

Figure 20
Compressor Inlet Vane Actuator

Annual Maintenance

WARNING: Open and lock the unit disconnect to prevent injury or death due to electrical shock or contact with moving parts.

The Trane Company recommends that the chiller be shut down for inspection once each year to check the items listed below; for a more detailed inspection checklist, refer to the "Model CVHE CenTraVac Annual Inspection Checklist and Report" illustrated in Figure 21.

1. Inspect and clean the inside of the purge drum; step-by-step instructions are provided in the "Maintenance Procedures" section of this manual.

2. Change the oil in the oil sump.

Note: If an oil analysis program is being implemented, use the set procedures established with the program. The time between changes can be extended based on the analysis results.

3. Replace the oil system filter. While other methods are commonly practiced in the field, the recommended procedure for removing the oil filter (or element filter in an oil cooler) from a unit under negative pressure requires the use of dry nitrogen to bring the unit up to atmospheric pressure. Once the old filter is replaced and reassembly completed, the unit must be purged.

Note: If the unit is under a positive pressure, the entering and leaving lines at the oil filter (or oil cooler) must be disconnected. Be sure to plug the open end of each line with a flare fitting plug to reduce refrigerant loss during the filter changeout procedure.

4. Inspect the condenser tubes for fouling; clean if necessary.

5. Measure the compressor motor winding resistance to ground; qualified service personnel should conduct this procedure to ensure that the findings are properly interpreted.

6. Contact a qualified service organization to leak-test the chiller; this procedure is especially important if the system requires frequent purging.

Caution: If frequent purging is required, identify and correct the source of the air or water leak as soon as possible. Moisture contamination caused by leakage can shorten the life expectancy of the machine.

Remember that if the system will be off for an extended period of time, the purge unit must be operated for approximately 30 minutes every two weeks to keep the chiller free of air and noncondensibles. Since the machine is not providing chilled water, cool water (i.e., less than 80 F) must be supplied to the purge condenser drum by adjusting the water valves to provide alternate water flow through the purge condenser.

Other Maintenance Recommendations

1. Use a nondestructive tube test to inspect the condenser and evaporator tubes at three-year intervals.

Note: It may be desirable to perform tube tests on these components at more frequent intervals, depending upon chiller application. This is especially true of critical process equipment.

2. Depending upon chiller duty, contact a qualified service organization to determine when to conduct a complete examination of the unit to discern the condition of the compressor and internal components.

Conditions which may dictate shorter intervals between chiller inspections include:

a. chronic air leaks, which can cause acidic conditions in the compressor oil and result in premature bearing wear; and,

b. evaporator or condenser water tube leaks. Water mixed with the compressor oil can result in bearing pitting, corrosion, or excessive wear.

3. Submit a sample of the compressor oil to a qualified laboratory for comprehensive analysis on an annual basis; such an analysis will determine the system moisture content, acid level and wear metal content of the oil, and can be used as a diagnostic tool.

Purge Unit Maintenance

Before conducting the purge maintenance procedures described in the following paragraphs, shut down purge unit operation.

WARNING: Before attempting to perform any maintenance on the purge unit, disconnect the electrical power supply to the purge unit heater and purge compressor drive motor. To prevent injury or death due to electrical shock or contact with moving parts, verify that all power switches are locked or safetied in the "OFF" position.

The compressor in the purge unit has been tested and found to have an acceptable leak rate during the first 1500 hours of normal purge operation. This performance has been obtained through the use of rings specifically designed for this application.

Note: Replacement of the compressor or rings with standard parts will result in refrigerant loss at a rate approximately eight times greater than the Trane version.

The rings will have to be replaced at 1500 hour intervals or excessive refrigerant will be lost. Contact a local Trane service technician for ring replacement.

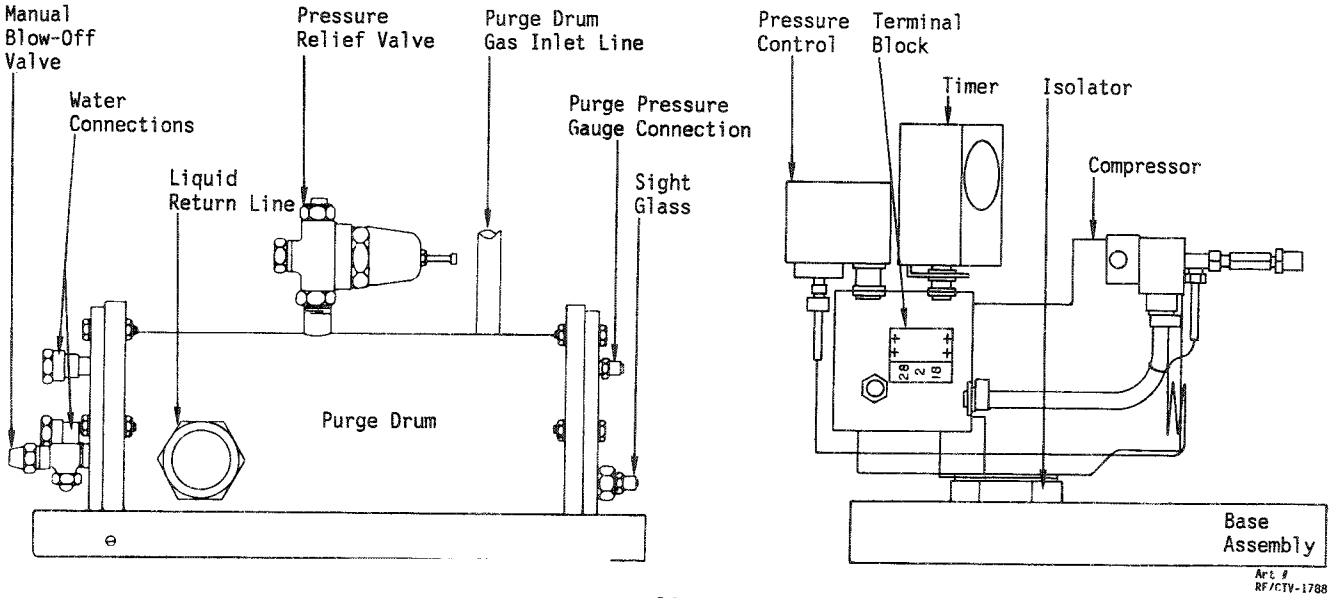
Purge Drum Cleanup

The purge drum should be disassembled annually for cleaning and maintenance. Use the procedure outlined below to remove the purge drum from the chiller.

WARNING: Open and lock unit disconnect to prevent injury or death due to electrical shock or contact with moving parts.

1. Isolate the purge suction line by closing the isolator valve at the condenser.

2. Isolate the refrigerant return line by closing the isolator valve at the evaporator.



3. Close all of the water supply and return valves to the purge drum; then, disconnect the water connections at the drum. Refer to Figure 22 for an illustration of the purge drum.

4. Disconnect the evaporator liquid return line connection at the purge drum.

5. Detach the purge drum gas inlet line.

6. Remove the four purge drum base plate retaining screws.

Figure 22
Purge Unit Components

7. Clean the purge drum water coil using the step-by-step instructions provided below:

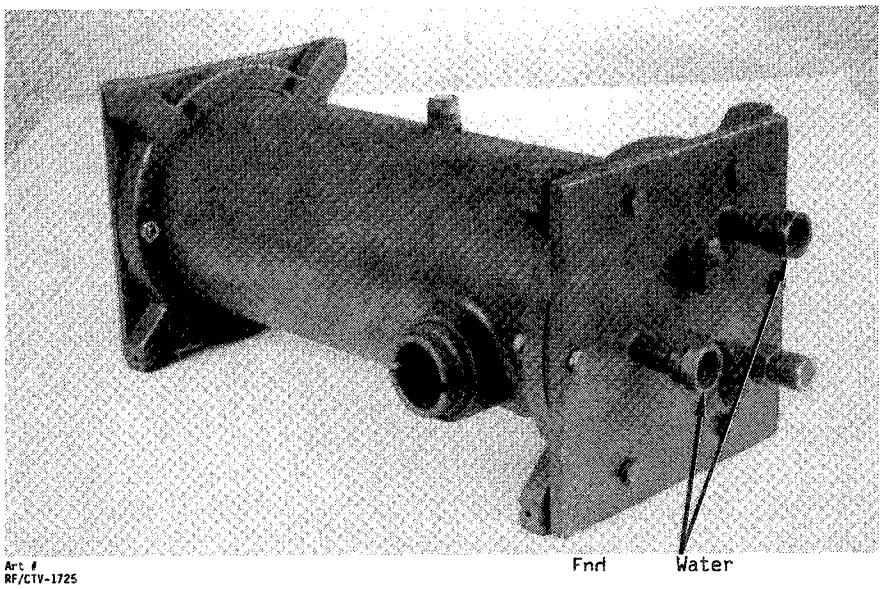
a. Remove the six end plate retaining screws from the water connection end of the purge drum; see Figure 23.

b. Remove the end plate with attached coil and gasket. Refer to Figure 24.

c. Clean the outside of the water coil with a brush or solvent.

Caution: To prevent damage to the water coil, do NOT use a wire brush to clean the coil surface.

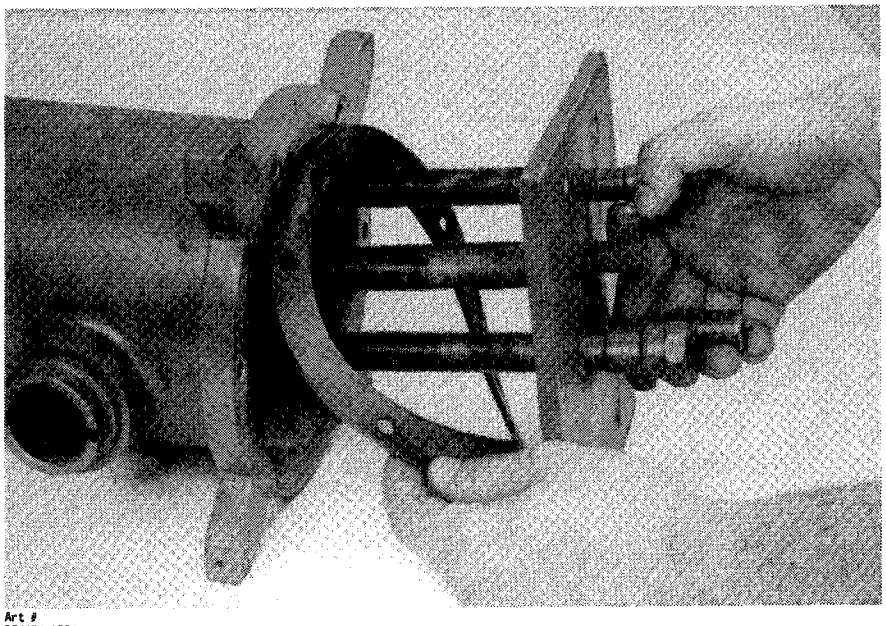
d. Clean the inside of the purge drum with a solvent. (Again, do not use a wire brush or the interior surface of the drum may be damaged.)



e. Clean the small vent hole at the top of the divider plate; this hole must be open. Refer to Figure 25 for vent hole location.

f. Circulate a chemical cleaning solution through the water coil to remove scale from the interior surfaces.

8. Use the procedure outlined below to remove and clean the float valve assembly:



a. Remove the six end plate retaining bolts from the refrigerant connection end of the purge drum.

Figure 23
Purge Unit Assembly

Art #
RF/CTV-1725

Figure 24
Removing Drum End Plate, Including Water Coil and Gasket

Art #
RF/CTV-1726

b. Remove the end plate and gasket shown in Figure 26.

c. Clean the inside of the purge drum with a solvent; do not use a wire brush or the interior surface of the drum may be damaged.

Be sure to check the small hole at the top of the drum divider plate and the slot at the bottom - both should be open.

d. Remove the cotter pin from the float valve assembly; see Figure 26.

e. Clean or replace the float valve seat shown in Figure 27. (To remove the seat, remove the 1/4-inch angle fitting and the float seat retaining nut.)

f. Examine the viton washer identified in Figure 28; if it is cracked or hardened, replace it.

g. Check the condition of the float; if necessary, it can be detached for replacement by removing the retaining screw.

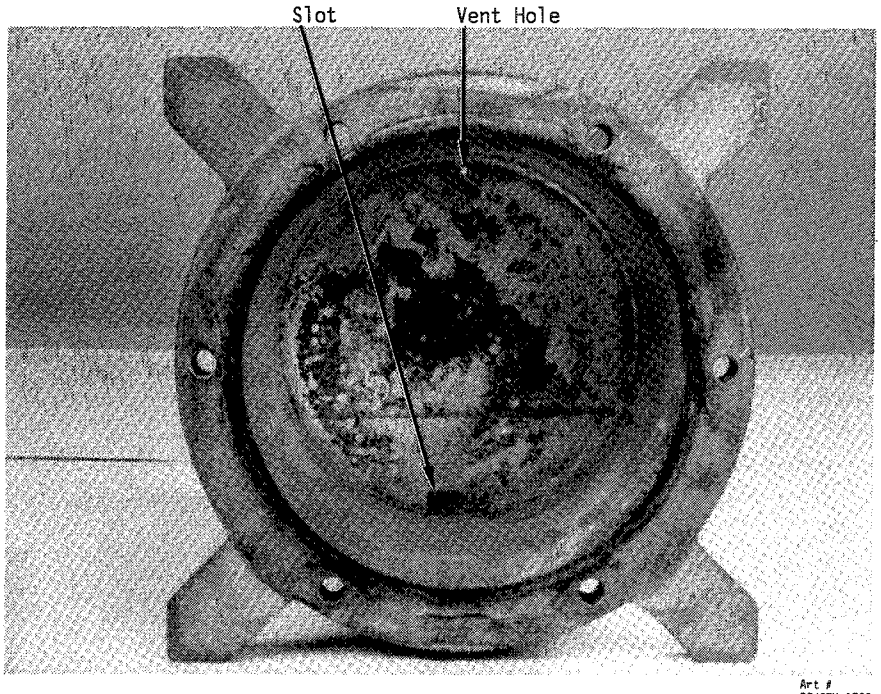
9. Reassemble the purge drum by reversing the order of disassembly. Be sure to use new gaskets on the end plates, but do not use oil or grease on the gaskets and flanges. Tighten the end plate bolts evently until the gaskets just begin to protrude between the flanges.

10. Pressure test all joints at 30 psig using dry nitrogen and R-12 as a tracer.

Purge Drum Water Elimination

Water condensed in the purge drum floats on the surface of the liquid refrigerant. Normally, a line of separation can be seen through the purge drum sight glass.

To remove water from the drum, operate the purge compressor until a positive pressure of 5 to 10 psig is indicated on purge drum pressure gauge. Then turn off the purge compressor and open the blow-off valve (Figure 22) until all of the water has drained away.



Caution: If frequent purging is required, identify and correct the source of the air or water leak as soon as possible. Moisture contamination caused by leakage can shorten the life expectancy of the machine.

Lubrication

The only components of the CVHE CenTraVac that require periodic lubrication are the bearing surfaces of the external vane linkage assembly, and the flow diverter on the optional automatic condenser cleaning system.

Lubricate the vane shaft bearings and the rod end bearings on the vane linkage with a few drops of light machine oil. For flow diverter lubrication, refer to "Periodic Maintenance".

RF/CTV-1728

Figure 26
Purge Drum Float Assembly

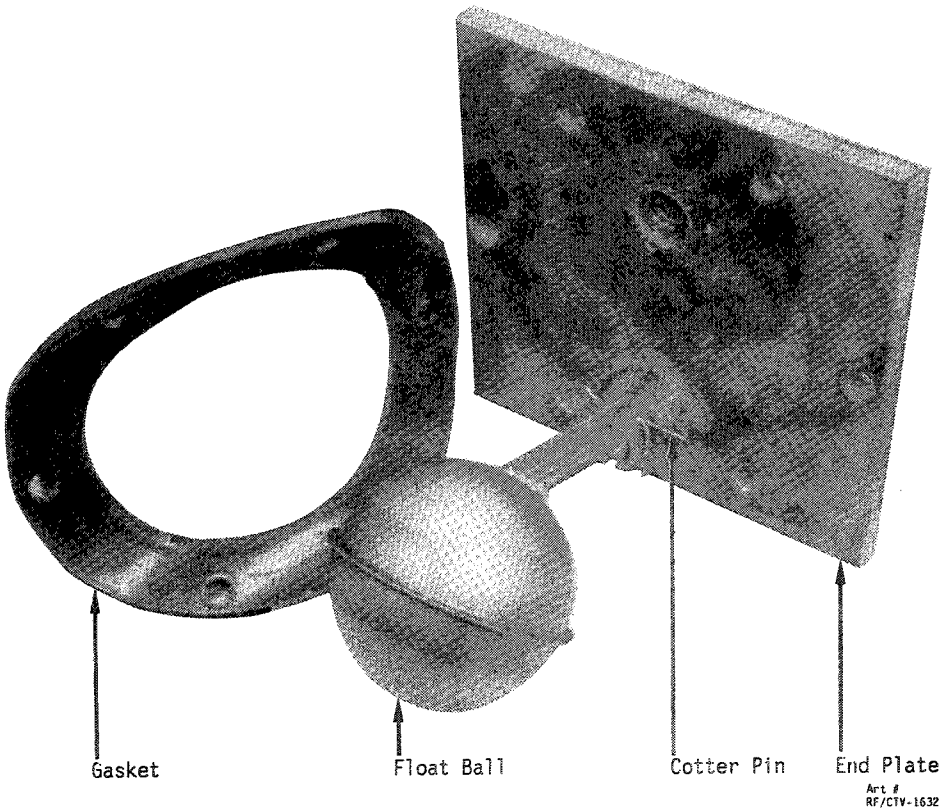

Figure 27
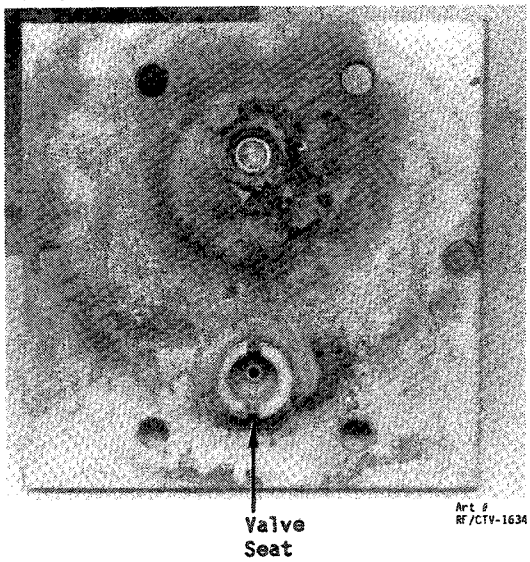
Valve Seat Location



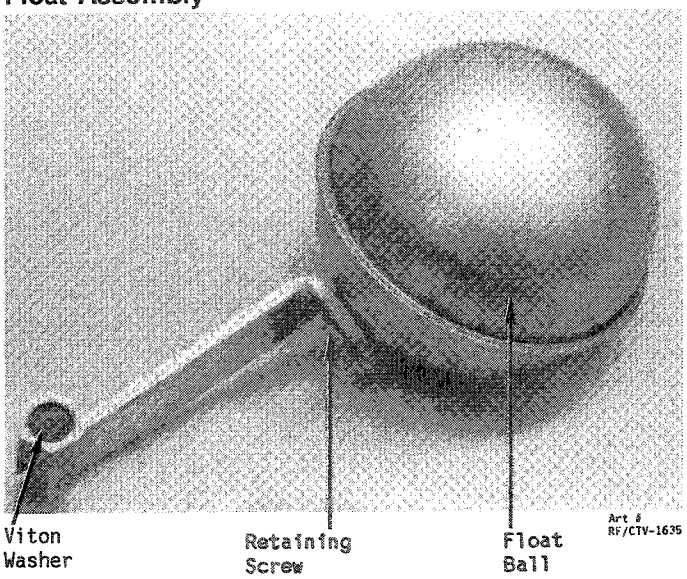


Figure 28
Float Assembly

Refrigerant Charge

To determine the refrigerant charge in the chiller, it is necessary to draw off the refrigerant and weigh it back into the machine. If the unit is low on refrigerant, contact a qualified service organization to ensure that the proper amount of refrigerant is added.

Cleaning the Condenser

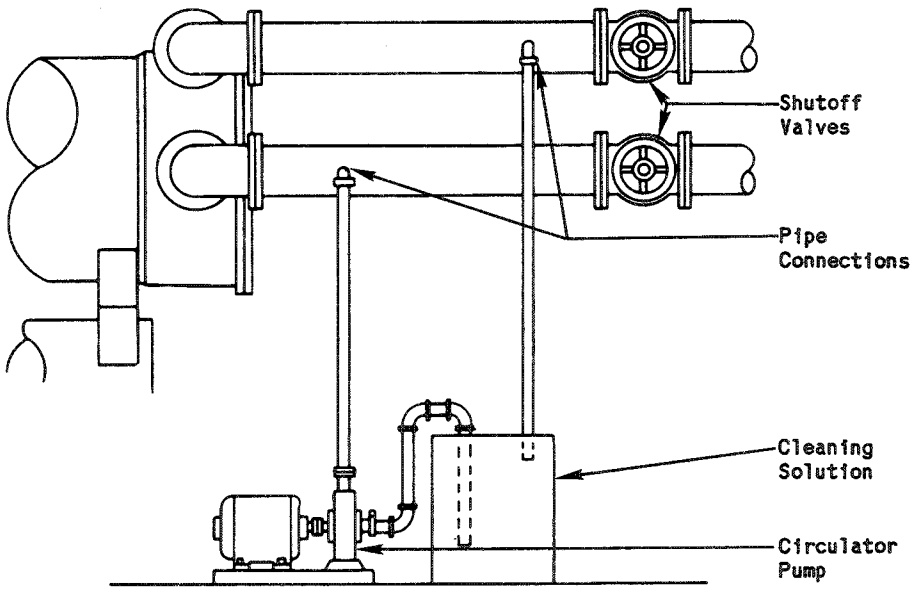
Caution: Do not use untreated or improperly treated water, or equipment damage may occur.

Condenser tube fouling is indicated when the approach temperature (i.e., the difference between the refrigerant condensing temperature and the leaving water temperature) is higher than predicted. If the annual condenser tube inspection indicates that the tubes are fouled, two cleaning methods--mechanical and chemical--can be used to rid the tubes of this foreign matter.

Use the mechanical cleaning method to remove sludge and loose material from the condenser tubes:

1. Remove the retaining nuts and bolts from the water box covers at each end of the condenser. Use a hoist to lift the covers off the water box. (A threaded connection is provided on each water box cover to allow the insertion of an eyebolt.)

2. Work a round nylon or bristle brush (attached to a rod) in and out of each of the condenser water tubes to loosen the sludge.



3. Thoroughly flush the condenser water tubes with clean water.

Scale deposits are best removed by chemical means. Be sure to consult any large chemical house in the area (i.e., since they will know the chemistry of the water) for a recommended cleaning solution suitable for the job. (Remember that the standard condenser water circuit is composed solely of copper, cast iron and steel.) Refer to Figure 29 for an illustration of a typical chemical cleaning setup.

All of the materials used in the external circulation system, the quantity of the solution, the duration of the cleaning period, and any required safety precautions should be approved by the company furnishing the materials or performing the cleaning. Remember, however, that whenever the chemical tube cleaning method is used, it must be followed up with mechanical tube cleaning. The Trane Company assumes no liability for equipment damage caused by improper cleaning procedures.

Note: Since the evaporator is typically part of the closed circuit, it does not accumulate appreciable amounts of scale or sludge. However, if cleaning is deemed necessary, use the same cleaning methods described above for the condenser tube bundle.

Figure 29
Typical Chemical Cleaning Setup

Cleaning the Auxiliaries

If the coils of the purge unit are supplied with water from the same source as that used by the evaporator, they will be subjected to the same type of scaling. When cleaning is required, use the same chemical cleaning method described for the condenser; be sure to thoroughly flush the chemically-cleaned parts with clear water before connecting them to the remainder of the water circuit.

Note: If the auxiliaries are piped into the chilled water circuit only, cleaning is usually not necessary.

Caution: Do not use untreated or improperly treated water, or equipment damage may result.

Compressor Oil

Caution: To prevent the possible burnout of the oil sump heater, be sure to open the control panel disconnect switch before draining the sump.

Approved oils for CVHE CenTraVac chillers are Mobil Whiterex No. 425 and Texaco WF-68; the design oil charge for all units is seven gallons. If these oils cannot be obtained, contact your local Trane representative for recommendations.

Note: An oil transfer pump can be used to change the compressor motor oil incidentally of machine pressure.

Draining the Oil Sump

The saturation pressure of R-11 is less than atmospheric pressure at temperatures below 75 F, and greater than atmospheric pressure at temperatures above 75 F. If the ambient temperature is 75 F or above and the evaporator pressure gauge indicates a positive pressure, open the oil sump charging valve located at the rear of the oil sump and drain the oil into a suitable container.

If the ambient temperature is less than 75 F and the evaporator pressure gauge indicates a negative pressure, the oil must be pumped and drawn from the sump. To do this:

1. Connect a line from an auxiliary oil pump to the oil charging valve located at the rear of the oil sump.

2. Operate the auxiliary oil pump and open the charging valve.

3. After the oil is removed from the sump, close the charging valve.

Note: In lieu of an auxiliary pump, the oil can also be forced from the sump by using dry nitrogen to build a slight positive pressure in the unit.

Filling the Oil Sump

Note: The procedure described below is only applicable if the system is under a vacuum. If the ambient temperature conditions and evaporator pressure gauge reading indicate a positive pressure, pump the oil into the system.

Use the procedure outlined below to fill the oil sump. Be sure to charge the oil directly from the container in which it was shipped to prevent dirt and other foreign matter from entering the sump.

1. Connect a clean piece of clear Tygon vacuum tubing to the oil charging valve.

2. Submerge the open end of the tubing in the container of oil.

3. Open the oil charging valve; if the system is under a vacuum, the oil will be drawn readily from the container.

Caution: To prevent the entry of air into the oil sump make certain that the open end of the tube remains submerged in the oil during the entire charging process. Close the charging valve before raising the tube above the surface of the oil.

4. After the sump is full, close the control panel disconnect switch to energize the oil sump heater.

Control Settings and Adjustments

For your reference, a list of the CVHE controls and their settings is provided in Table 3. For control calibration and checkout procedures, contact a qualified service organization.

Table 3
CVHE Control Settings

Control	Setting
High Pressure Control (S1)[1]	15 psig cutout, 5 psi differential
Low Refrigerant Temp. Control (S2)	Opens as necessary on a fall in refrigerant temperature; adjustable
Chilled Water Demand Control (S3)	As Required
Oil Pressure Control (S8)	Cut-in = 15 psid, Cut-out = 8 psid
Oil Temperature Control (S10)	150 F setpoint, 5 F differential
Purge High Pressure Control (S13)	30 psig cutout, 10 psi differential

Note: If the ASME construction stamp appears on the condenser shell, the HPC cutout point is 25 ± 5 psig.

Trouble Analysis

To use the troubleshooting charts provided on the following pages, use the instructions outlined below:

1. Locate the chart that pertains to the general category of the problem experienced (i.e., Chart A = Unit Start-Up, Chart B = Unit Operation, Chart C = Lubrication System, Chart D = System Temperatures and Pressures, and Chart E = Automatic Condenser Cleaning System Option).

2. After locating the proper chart, determine which of the problem types listed horizontally across the top of the chart is applicable. Notice that the trouble analysis chart for the automatic condenser cleaning system is divided into three columns: "Symptom", "Probable Cause", and "Recommended Action".

3. Use the symptoms listed on the slanted lines to pinpoint the specific problem being experienced. (Legends identifying the control panel lights and circuit breakers are provided on Chart A for your reference.)

4. Trace down the vertical column directly beneath the problem identified in Step 3 to the numbered boxes. The horizontal lines on which the numbered boxes occur indicate the possible causes (left-hand side) and the recommended actions (right-hand side).

The numbers in the boxes indicate the order of probability in which these causes are likely to occur, and the sequence in which the recommended actions should be checked.

Note: These troubleshooting charts are provided solely as a guide for determining the cause of mechanical failure or equipment malfunction. When operational problems do occur, be sure to contact a qualified service organization to ensure proper diagnosis and repair of the unit.

Chart A: Trouble Analysis - Unit Start-Up

Panel Light Legend
DS1 Safeties Satisfied
DS2 Cooling Required
DS3 Restart Time Elapsed

Blocked Orifice Plates								5				**Contact a Qualified Service Organization**
System Water Returning to Unit Too Warm										3		Reduce Current Control Setting if Just Starting Unit. Check Bldg. for Excessive Heat Load
Unit Carrying Over									3		2	See Column On "Unit Carries Over"
Unit Surging											3	See Column On "Unit Surges"
Low Press. Override Faulty or Improperly Set									1			**Contact a Qualified Service Organization**

Chart C: Trouble Analysis - Lubrication

POSSIBLE CAUSE	SYMPTOM: CB1 Trips	Net Oil Pressure Above 35 PSIG	Sump Temp. Below 125 F	Sump Temp. Above 160 F	Oil Level Below Lower Sight Glass	Oil Sump Foams Excessively	RECOMMENDED ACTION
	COMPLAINT: Unit Trips on Low Oil Pressure	Oil Pressure Too High	Oil Sump Too Cold	Oil Sump Too Hot	Unit Loses Oil	Excess Refrig. In Oil	
Oil Filter Dirty	1						Change Filter Element
Oil Cold - Refrig. In Oil	2						Check "Oil Sump Too Cold" Column
Oil Press. Control Faulty Or Out of Adjustment	3						**Contact a Qualified Service Organization**
Oil Press. Regulator Faulty or Out of Adjustment	4						**Contact a Qualified Service Organization**
Low Oil Level In Sump	5						See Column on "Unit Loses Oil"
Faulty Oil Pump	6						Replace
Improper Oil	7	1					Change Oil and Use Recommended Oil Only
Faulty Gauge	8	2	5				**Contact a Qualified Service Organization**
Temp. Control Faulty or Out of Adjustment			1				**Contact a Qualified Service Organization**
Faulty Oil Heater			2				Check Operation of Heater
Excessive Refrig. In Oil			3				See Column on "Excess Refrig. In Oil"
Oil Pump Continues to Run When Unit Stops			4		2	3	If Pump Runs More Than **3** Min., Check for Defective K5 Contacts, S-9 Timer, K-1 Contacts
Oil Sump Too Cold					3	2	See "Oil Sump Too Cold" Column
Loose or Blocked Oil Lines					1		Check External Line For Leaks - Contact a **Qualified Service Organization** To Inspect Internal Lines
Oil Sump Vent Open Too Far	10		7				**Contact a Qualified Service Organization**
Oil Sump Vent Not Open Far Enough				2	5	5	**Contact a Qualified Service Organization**

Chart D: Trouble Analysis - System Temperatures and Pressures

POSSIBLE CAUSE	SYMPTOM: CB2 TRIPS	Condenser Excessively Cool	CB3 Trips	Evaporator Excessively Warm	See Chart C	See Chart C	CB4 Trips	RECOMMENDED ACTION
	COMPLAINT: High Cond. Pressure	Low Cond. Pressure	Low Evap. Pressure	High Evap. Pressure	Low Oil Pressure or Temperature	High Oil Pressure or Temperature	Motor Temp. High	
Condenser Dirty	1							See "Cleaning Condenser"
Air In Water Circuit	2		7					Vent Air From Circuit
High Press. Control Faulty or Out of Adjustment	3							**Contact a Qualified Service Organization**
Safety Control Relay Faulty	4							Replace
Loose Wiring or Connections	5							Check Continuity of Circuits - Repair
Temp. Control Faulty or Improperly Set			1					**Contact a Qualified Service Organization**
Vane Operator Faulty or Out of Adjustment			2					**Contact a Qualified Service Organization**
Low Water Flow Through Evaporator			3					Check Water Pumps, Strainers and Valves
Chilled Water Demand Switch Faulty or Improperly Set			4					**Contact a Qualified Service Organization**
Low Refrigerant Charge			5					**Contact a Qualified Service Organization**
Low Press. Control Faulty or Improperly Set			6					**Contact a Qualified Service Organization**
Blocked Orifice Plates			8					**Contact a Qualified Service Organization**
Light Load on Unit		1		1				Normal Operation
Unit Not Lowering Water Temperature				2				See Chart B "Unit Runs Without Stopping"
Blocked Motor Cooling Line							1	Check Motor Cooling Sight Glass For Flow - Clean Strainer Make Sure Service Valves are Open
Motor Temp. Control Faulty							2	Replace
Voltage Imbalance In Power Circuit							3	Contact Power Company to Correct
Compressor Motor Faulty							4	**Contact a Qualified Service Organization**

Chart E: Trouble Analysis: Automatic Condenser Cleaning System (Optional)

Symptom	Probable Cause	Recommended Action
Incomplete Sequence Alarm light on. Normal and reverse lights illuminate properly.	Inadequate air pressure.	Check supply pressure.
	Choppy movement of diverter plug.	Contact your service company to readjust plug.
	Solenoid valve sticking or exhaust restrictor(s) partially plugged.	Clean solenoid valve/ exhaust restrictor(s); check condition of air.
	Exhaust restrictor screw(s) not set properly.	Reset screws for proper transfer time. Be sure to tighten lock nuts.
	Setting of 2TR timer less than actual transfer time.	Re-adjust setting of 2TR timer to reflect actual transfer time.
	Air leak in: a. Air lines/connections b. Actuator cylinder seals.	Isolate and repair leak. Contact service company to install repair kit.
Incomplete Sequence Alarm light on but normal and reverse lights not lit. Diverter in correct position.	Position indicator switch not being depresssed.	Contact service company for adjustments or repair.
	Faulty position indicator switch.	Replace switch.
	Faulty 2TR timer.	Replace timer.
Normal or Reverse lights not on. Diverter in correct position. Incomplete Sequence Alarm light not on.	Lamp(s) faulty.	Check indicator lights; replace bulb(s) if needed.
No panel lights on.	Fuse blown.	Replace fuse; check incoming power.
	No power at panel.	Check power source.
Diverter won't cycle. Cycle count lower than expected.	24 hour time clock malfunctioning.	Check time clock operation; contact service company for repair or replacement.
	1TR timer malfunctioning.	Check timer operation; contact service company for repair or replacement.
	No/low air pressure.	Check supply pressures.
	Diverter plug stuck.	Contact service company to readjust plug.
	Solenoid valve stuck, or exhaust restrictors plugged.	Clean solenoid valve/ exhaust restrictors; check condition of air.
Water leaking from packing area.	Packing gland loose.	Tighten packing gland.
	Packing needs replacement.	Contact service company to replace packing.
Water hammer occurs during diverter cycling.	Transfer time too fast.	Throttle exhaust restrictors to slow diverter transfer time.

MODEL NUMBER DESCRIPTION

Trane Model Numbers allow the complete description of a machine and its standard options without referring to the serial number. Although all model number information is not required to determine machine performance, all designators must be filled in to enter an order into the Trane order system. Most standard designators are shown below. Other designators for optional or special features or materials may be provided by the factory.

In all cases, the motor to be furnished must have a KW rating equal to or greater than the full load KW determined from the Trane Computer Program. Motor selections must correspond to the available component combinations tabulated in Table 13-1, page 13.

CENTRAVAC CONTROL SYSTEM

The Model CVHE CenTraVac is capable of continuous capacity modulation from 100% to 10% of full load at design conditions. This is achieved through the electronic control panel which is illustrated in Figure 1.

CONTROL PANEL

All safety and operating controls are housed in the CenTraVac control panel. The panel functions are divided into four categories, as indicated by the external panel layout:

1. Pressure indicating gauges have no operating function. They are used only to provide condenser, evaporator, lubricating oil and purge drum pressures.
2. System sequence status lights perform an important diagnostic function. A series of seven lights shows the progress of the CenTraVac starting sequence. As each of the seven circuit interlocks is verified, its individual pilot light comes on. Therefore, the reason for an aborted start can be determined by observing the pilot lights and determining the point at which the sequence was breached.
3. Five fault trip indicators display the status of each safety cutout control. Circuit interrupters are used to open the circuit instead of relays because they will hold their position in the event of power interruption. Therefore, power failure does not require the manual resetting of all safeties. Additional alarm contacts on each of the fault trip indicators are brought to a terminal strip for external connection.
4. The electronic capacity control system consists of three elements:

   a. Demand limiter
   b. Chilled water temperature control
   c. Manual inlet vane control and status

   The demand limiter control can be set to control at any value between 40 and 100 percent of motor full load current. Motor current is sensed by three current transformers and is processed into a proportional DC voltage by the CenTraVac motor overload. This same DC voltage is monitored by the demand limiter. When the set percentage of full load current is reached, the demand limiter prohibits further opening of the inlet vanes. If the setting is exceeded, the inlet vanes are moved toward the closed position.

   The chilled water temperature control module uses a solid state temperature sensor to sense chilled water temperature. Should this temperature vary from setpoint, an electronic controller sends a pulsed signal to the inlet vane actuator. A combination of proportional and floating control is used to provide high accuracy and low sensitivity (hunting).

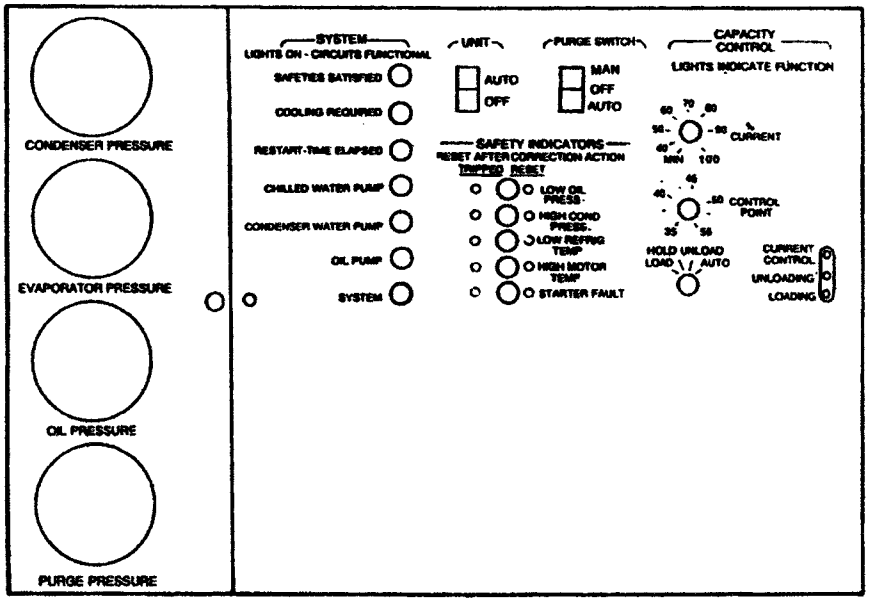

FIGURE 1 - Model CVHB CenTraVac Chiller Control Panel

Electronic Control System
(Refer to Figure 2)

A1 (line 9) is an electronic overload relay. Its purpose is to monitor the current draw of the compressor and to de-energize the compressor starter if the current draw exceeds the setting of A1. (A1 should be set at 105% of FLA.)

A3 (line 39) is the compressor inlet vane actuator electric motor. A3 end switch (line 26) is closed when the inlet vanes are full closed. A3 limit switch (line 38) is open when the inlet vanes are full open. A3 limit switch (line 40) is open when the inlet vanes are full closed.

S4 (line 35) is a multi-program timer. It limits the compressor to one start every 30 minutes and also provides the "start" signal to the compressor starter. S9 (line 43) is the oil pump timer. It keeps the oil pump motor energized for 7 minutes after the compressor starter is de-energized to provide lubrication during compressor coast-down.

U1 (line 37) is the capacity control module. It modules the inlet vane actuator (A3, line 39) in response to leaving water temperature as sensed by sensor U3 (line 38). U1 also serves as a load limiting device thru an input signal from the electronic overload relay. Power must be applied to terminal 84 (line 40) before U1 can open the inlet vanes.

U2 (line 35) is the compressor motor high temperature cut-out. Its M1-M2 contacts will close shortly after 115V is applied to terminals T1 and T2.

Sequence of Operation for Typical Start-Up
(Refer to Figure 2)

Energize the chilled water pump starter K12 (line 13).

Close the circuit breaker CB10 (line 1). Since the contacts of U2 (line 35) do not close instantly, relay K11 (line 36) will not be energized in time to prevent fault trip indicator CB4 (line 16) from tripping. After approximately one second delay, U2 contacts will close energizing K11. Reset CB4. Set switch S6 (line 26) in the "auto" position.

Control power flows thru the safety controls and fault trip indicator contacts (line 16). If all safeties are satisfied, light DS1 (line 20) will light. Power flows on to the chilled water demand switch S3 (line 26) whose temperature sensing element is located in the return water entering the chiller. Upon a rise in return water temperature, S3 closes energizing light DS2 (line 20) and feeding power to timer contact S4. If 30 minutes or more has elapsed since the previous compressor start, timer contact S4 (line 26) feeds power to light DS3 (line 20). Power also flows through compressor inlet vane end switch A3 (if vanes are closed), through relay K7 contacts (if compressor is off) to terminal 8. If chilled water flow is proven, power feeds thorugh flow switch S5 to light DS4 (line 20). Power also feeds through switch S6 energizing relay K4 (line 19). K4 contacts (line 16) close to energize the condenser water pump starter, K13; if condenser water flow is proven, power feeds through flow switch S7 (line 26) to light DS5 (line 20) and also energizes relay K5 (line 21). One set of K5 contacts (line 43) close energizing the oil pump timer S9. A second set of K5 contacts (line 28) close keeping the control circuit complete by jumpering out the start inhibit functions. In 40 seconds timer S9 contacts (line 44) close energizing the oil pump motor B2 (line 45). When oil pressure is established, oil pressure switch S8 (line 26) closes lighting DS6 (line 22) and energizing relay K6 (line 23). One set of K6 SPDT contacts (lines 14 and 15) switch energizing relay K3 (line 14). K3 contacts (line 16) close keeping relay K3 energized and arming the low oil pressure circuit breaker circuit.

A second K6 contact (line 35) closes energizing timer S4 (line 35). In 20 seconds S4 contacts (line 33) close keeping timer S4 energized through its entire timing cycle. 5 seconds later S4 contacts (line 28) close feeding power to light DS7 (line 28 and energizing comrpessor starter K1 (line 29). K1 contacts (line 30) close keeping power on K1. A second set of contact of K1 (line 31) close energizing relay K10 (line 33). K10 contacts (line 31) close keeping K10 energized for the remaining timing cycle of S4. A second K10 contact (line 29) opens removing the "start" signal from the K1 relay circuit. Thus the "start" signal lasts only long enough to energize and close K1 start contactor.

A third K1 start contact (line 45) closes keeping the oil pump motor energized as long as the K1 start contactor remains closed.

When K1 connects the compressor in the run configuration, K1 "run" contacts (line 40) close feeding power to terminal 84 of the capacity control module U1 (line 40) (if refrigerant temperature switch S2 is closed) thus allowing U1 to open the compressor inlet vanes as necessary.

When K1 is initially energized, relay K9 (line 26) is also energized. K9 contacts (line 25) open keeping relay K8 de-energized. This arms the starter fault safety circuit 15 seconds after the initial start pulse is sent to K1. S4 contacts (line 26) switch from 13-81 to 13-79 energizing relay K7 (line 24). K7 contacts (line 26) close keeping K7 energized and completing the arming of the starter fault circuit. If K1 opens for any reason, contacts K1 (line 29) open de-energizing relay K9. K9 contacts (line 26) close energizing relay K8. K8 contacts (line 15) close tripping fault trip indicator CB5 and locking the unit off. When there is no longer a call for cooling or if a safety opens, compressor starter K1 and relay K5 will be de-energized. A contact of timer S9 (line 44) will keep timer S9 and oil pump motor B2 energized for 7 minutes to provide lubrication during compressor coast-down.

If there is a loss of oil pressure while the compressor is running, oil pressure switch S8 (line 26) opens stopping the compressor and de-energizing relay K6 (line 23). Power then feeds from terminal 12 (line 26) through contacts of K3 (line 16) and NC contacts of K6 (line 14) to trip fault trip indicator CB1 locking the compressor off.

Alarm contacts (line 56) are factory wired using NC contacts of the control circuit breakers. NO alarm contacts may be used by moving one wire on each circuit breaker.

FREE COOLING

Free Cooling is an accessory to the Trane Model CVHB CenTraVac Chiller. Free cooling adapts the basic chiller to function as a simple heat exchanger using refrigerant as the working fluid. When condenser water is available at temperatures lower than the desired chilled liquid temperature, Free Cooling can provide up to 45 percent of nominal chiller capacity without operation of the compressor. This feature can result in substantial energy cost savings on many installations.

Operation

Free Cooling operates on the principle that refrigerant flows to the area of lowest temperature in the system. When condenser water is available at a temperature lower than the required leaving chilled water temperature, the operator stops the compressor and starts the Free Cooling cycle by a simple pushbutton control. Changeover back to mechanical cooling is also by simple pushbutton control.

The Free Cooling accessory consists of the following factory-installed or supplied components:

1. A refrigerant gas line, including an electrically actuated shutoff valve, installed between the evaporator and condenser.
2. A valved liquid return line including an electrically actuated shutoff valve, between the condenser sump and evaporator.
3. A liquid refrigerant storage vessel.
4. Added refrigerant charge.
5. Free Cooling changeover controls.

Upon changeover to Free Cooling, the shutoff valve in the liquid and gas lines open and a lockout circuit prevents compressor energization. Liquid refrigerant drains by gravity from the storage tank into the evaporator, flooding the tube bundle. Since the refrigerant temperature and pressure will be higher in the evaporator than in the condenser due to the water temperature difference, the refrigerant vaporized in the evaporator flows to the condenser. The gas then is condensed by the effects of the cooling tower water and flows by gravity back to the evaporator. This automatic refrigeration cycle is sustained as long as a temperature difference exists between the condenser and evaporator liquids.

The difference in temperature between the condenser water and evaporator water determines the rate of refrigerant flow between the two shells and hence the Free Cooling capacity.

If the system load becomes greater than the Free Cooling available capacity, the operator stops Free Cooling operation. The gas and liquid valves close and compressor operation begins. Refrigerant gas is drawn out of the evaporator by the compressor and is compressed and discharged to the condenser. Most of the condensed liquid first takes the path of least resistance by flowing into the storage tank which is vented to the economizer sump through a small bleed line. When the storage tank is full, liquid refrigerant must flow through the bleed line restriction. The pressure drop through the bleed line is greater than that through the orifice flow control device, hence liquid refrigerant flows normally from the condenser through the orifice system and into the economizer.

During changeover to mechanical cooling, the refrigerant transfer process requires less than three minutes. The loading ramp prevents carryover by slowly loading the machine.

Notice

The Trane Company urges that all HVAC servicers working on Trane equipment, or any manufacturer's products, make every effort to eliminate, if possible, or vigorously reduce the emission of CFC, HCFC, and HFC refrigerants to the atmosphere resulting from installation, operation, routine maintenance, or major service on this equipment. Always act in a responsible manner to conserve refrigerants for continued use even when acceptable alternatives are available.

Conservation and emission-reduction can be accomplished by following recommended Trane service and safety procedures published in Trane general service manuals "CTV-SB-81", "CTV-SB-82" and CFC-Guide 2. Copies of these manuals may be obtained by contacting your local Trane commercial product representative.

Product Coding Definition

Introduction

The CVHE 130-1250 and the CVHF 650-1280 is defined using the product definition and selection (PDS) system. This system describes the product offerings in terms of a product coding block which is made up of feature categories and feature codes.

Typical Product Description Block

MODL CVHE	**DSEQ S**
HRTZ 60	**TYPE SNGL**
EVTM IECU	**EVTH 28**
EVWC STD	**EVWP 2**
EVCO FLNG	**EVWA RERE**
CDSZ 080L	**CDBS 800**
CDWT NMAR	**CDPR 150**
CDTY STD	**ORSZ 710**
AGLT NONE	**CNIF MICR**

CVHE/CVHF Product Coding Explanation

The operating components and options for any Model CVHE/ CVHF CenTraVaqc unit can be identified by referring to the alpha-numeric product identification coding block located on the name-plate for the unit. The coding block precisely identifies all characteristics of a unit. Be sure to refer to the service model number when ordering replacement parts or requesting service. An example of a typical product code is given on this page.

Note: Unit-mounted starters are identified by a separate number found on the starter.

NTON 800	**VOLT 4160**
CPKW 650	**CPIM 275**
EVSZ 080L	**EVBS 890**
EVWT NMAR	**EVPR 150**
CDTM IECU	**CDTH 28**
CDWC STD	**CDWP 2**
CDCO FLNG	**CDWA RERE**
PURG HERM	**HGBP W/O**
SRTY RPIR	

MODL
Unit Model

General Information

Literature Change History CVHE-M-6 (February 1993)

Original issue of manual; describes proper operation and maintenance of 60 Hz. CVHE units of "1A " through "1U " design sequences with UCP695 micro-computer-based control systems and CVHF 650 and 1280 "C0 " design sequences with UCP695 micro-computer-based control systems.

About this Manual

This booklet describes the operation and maintenance of 60 Hz. Model CVHE and CVHF CenTraVac chillers equipped with micro-computer-based control systems, whether standard (cooling) or heating-recovery. By carefully reviewing this information and following the instructions given, the owner/operator can successfully operate and maintain a CVHE or CVHF unit.

Diagnostic information is provided at the end of this manual to allow the operator to identify a number of system malfunctions, should any develop. (If mechanical problems do occur, however, contact a qualified service organization to ensure proper diagnosis and repair of the unit.)

Commonly Used Acronyms

For convenience, a number of acronyms are used throughout this manual. These acronyms are listed alphabetically below, along with the "translation" of each:

AMB = Outdoor Ambient Temperature
ASME = American Society of Mechanical Engineers
BAS = Building Automation System

CWR = Chilled Water Reset
DTFL = Design Delta-T at Full Load (i.e., the difference between entering and leaving chilled water temperatures)

ENT = Entering Chilled Water Temperature
FC = Free Cooling
HGBP = Hot Gas Bypass

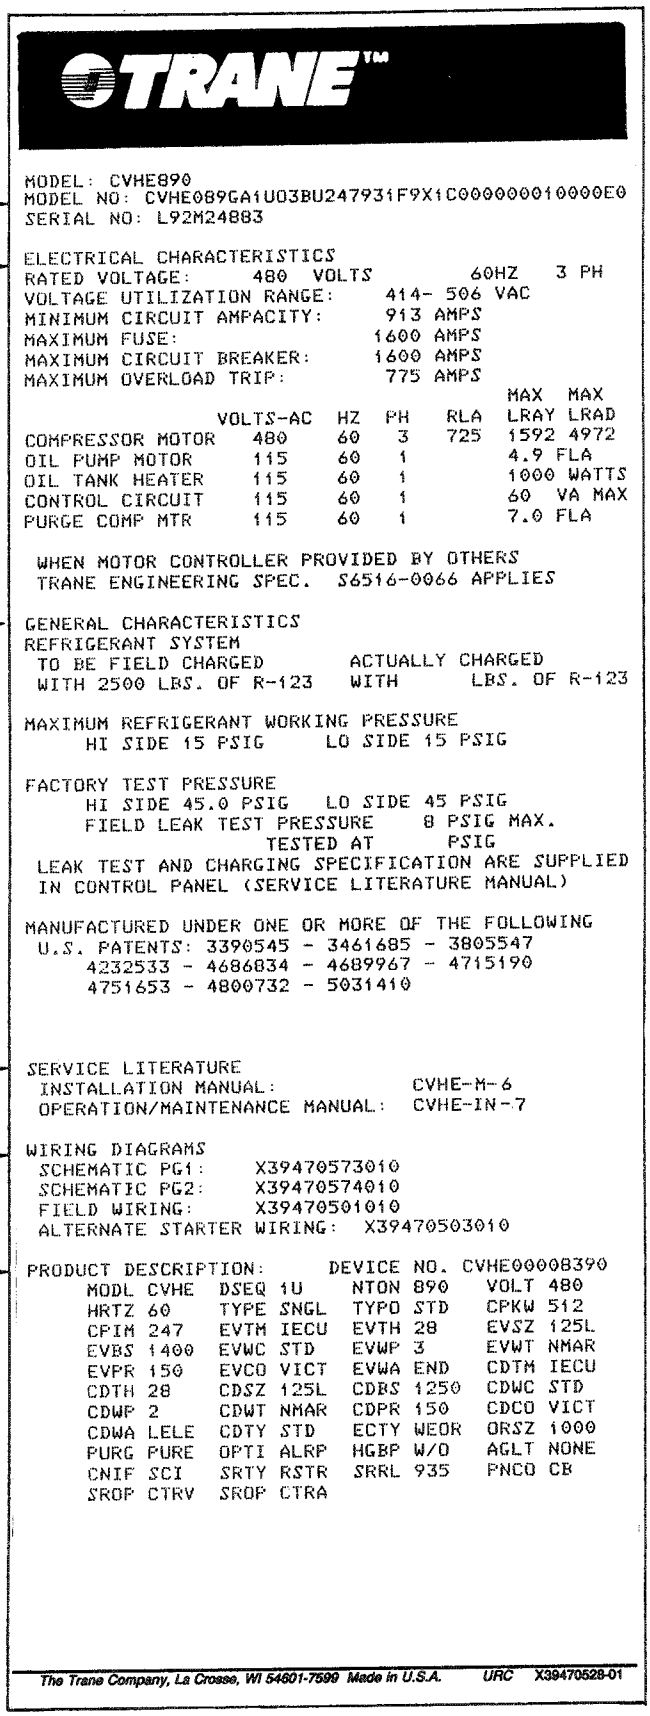
HVAC = Heating, Ventilating, and Air Conditioning
IE = Internally-Enhanced Tubes
LVG = Leaving Chilled Water Temperature

PCWS = Front Panel Chilled Water Setpoint
PSID = Pounds-per-Square-Inch (differential pressure)
PSIG = Pounds-per-Square-Inch (gauge pressure)

SCI = Serial Communication Interface
SCP = Model CVMA System Control Panel (i.e., used to control up to 3 CenTraVacs with UCPs)
UCP = Microcomputer-based, UCP695 Chiller Control Panel for CenTraVacs

Warnings and Cautions

Notice that warnings and cautions appear at appropriate intervals throughout this manual. Warnings are provided to alert installing contractors to potential hazards that could result in personal injury or death, while cautions are designed to alert personnel to conditions that could result in equipment damage.



Your personal safety and the proper installation of this machine depend upon the strict observance of these precautions.

Unit Nameplate

The CVHE or CVHF unit nameplate is located on the left side of the unit control panel (UCP). A typical unit nameplate is illustrated in Figure 1. The following information is provided on the unit nameplate.

- Service model and size descriptor.
- Unit serial number
- Identifies unit electrical requirements
- List correct operating charges of CFC-11 or HCFC-123
- Lists unit test pressures and maximum operating pressures.
- Identifies unit Installation and Operation and Maintenance manual
- Product description block (identifies all unit components and unit "design sequence" (used to order literature and make other inquiries about the unit).
- Lists drawing numbers for unit wiring diagrams.

Mechanical Operation - CVHE

Overview

Each CVHE unit is comprised of 5 basic components: (1) the evaporator, (2) 3-stage compressor for the CVHE unit (3) water-cooled condenser, (4) 2-stage economizer, and (5) related interconnecting piping. A heat-recovery or auxiliary condenser can be factory-added to the basic unit assembly to provide a heat-recovery cycle.

Figure 2 illustrates a typical CVHE chiller.

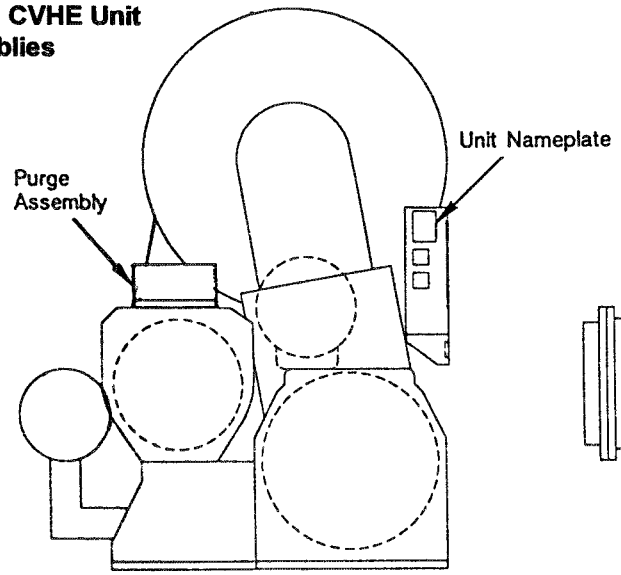
Following are discussions of the unit's cooling-only and heat-recovery modes of operation. A pressure/enthalpy diagram (shown in Figure 3) is provided to further illustrate unit operation.

Cooling-Only Cycle.

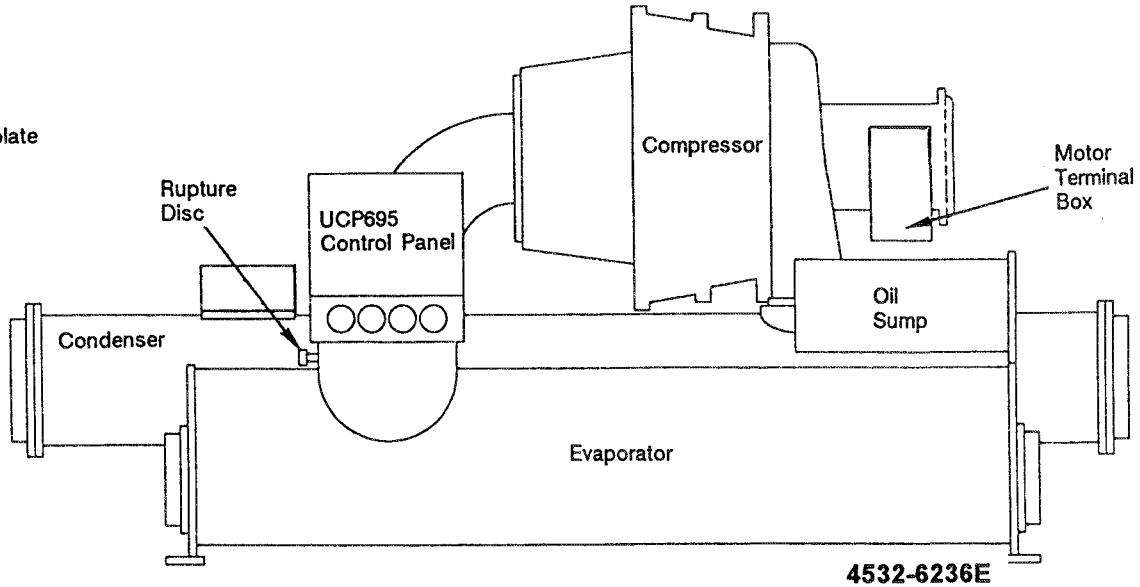
When the CVHE is functioning in the cooling mode, liquid refrigerant is distributed along the length of the evaporator and sprayed through small holes in a distributor (i.e., running the entire length of the shell) to uniformly coat each evaporator tube. Here, the liquid refrigerant absorbs enough heat from the system water circulating through the evaporator tubes to vaporize.

The gaseous refrigerant is then drawn through the eliminators (which remove droplets of liquid refrigerant from the gas) and first-stage variable inlet guide vanes, and into the first stage impeller.

Note: Inlet guide vanes are designed to modulate the flow of gaseous refrigerant to meet system capacity requirements; they also prerotate the gas, allowing it to enter the impeller at an optimal angle that maximizes efficiency at all load conditions.



Compressed gas from the first-stage impeller flows through the fixed, second-stage inlet vanes and into the second-stage impeller. Here, the refrigerant gas is again compressed, and then discharged through the third-stage variable guide vanes and into the third-stage impeller.



Once the gas is compressed a third time, it is discharged into the condenser. Baffles within the condenser shell distribute the compressed refrigerant gas evenly across the condenser tube bundle. Cooling tower water circulated through the condenser tubes absorbs heat from the refrigerant, causing it to condense. The liquid refrigerant then passes through orifice plate "A" and into the economizer.

The economizer reduces the energy requirements of the refrigeration cycle by eliminating the need to pass all gaseous refrigerant through 3 stages of compression. See Figure 4. Notice that some of the liquid refrigerant flashes to a gas because of the pressure drop created by the orifice plates, thus further cooling the liquid refrigerant. This flash gas is then drawn directly from the first (Chamber A) and second (Chamber B) stages of the economizer into the third- and second-stage impellers of the compressor, respectively.

Any remaining liquid refrigerant flows through another orifice plate "C" to the evaporator.

Compressor Lubrication System - CVHE

A schematic diagram of the compressor lubrication system is illustrated in Figure 5; this system supplies oil to the compressor motor bearings.

Oil is pumped from the oil tank (i.e. by a pump and motor located within the tank) through an oil pressure-regulating valve designed to maintain a net oil pressure of 12 to 18 psid. It is then filtered and sent to the compressor motor bearings. On later design CVHE and CVHF models, the oil filter assembly is equipped with refrigeration valves to isolate the filter during filter replacement.

From the bearings, the oil drains back to the oil tank through return lines.

WARNING:
Use caution while working on certain areas of the unit. Surface temperatures may exceed 150°F on the compressor discharge, oil tank (heater), oil filter, and oil lubrication lines.

To ensure proper lubrication and prevent refrigerant from condensing in the oil tank, a 1000-watt heater is secured to the oil tank exterior. Operating in response to a signal from the UCP, this heater energizes as needed to maintain 140° to 145 °F (60-63 C) when the chiller is not running. When the chiller is operating, the temperature of the oil tank is typically 115° to 160° F (46-72 C).

Refer to Figure 5; notice that the oil tank is vented between the compressor inlet vanes and the first-stage impeller suction cover. During normal system operation, motor barrel pressure is greater than that of the oil tank. Therefore, any gaseous refrigerant that enters the motor bearing cavities is drawn toward the oil tank where it is removed by the vent line.

A dual eductor system is used to reclaim oil from the suction cover and from the evaporator, and deposits it back into the oil tank. These eductors use high pressure condenser gas to draw the oil from the suction cover and evaporator back to the eductors, from the eductors the oil is discharged to the top of the oil tank.

Note: CVHEs utilize a time delay relay and solenoid valve that temporarily close the oil sump vent line during the chiller start sequence. This prevents the loss of oil pressure that can occur during start-up by isolating the oil sump from the low-pressure cavity at the opposite end of the sump vent line.

Liquid refrigerant is used to cool the oil supply to the inboard motor bearing on larger units (500-1250). Oil entering the oil cooler assembly from the oil tank (via the regulating valve and filter) flows into a coil inside the cooler shell. See Figure 6. As the oil passes through this coil, it is cooled by a mixture of gaseous and liquid refrigerant that surround the coil exterior.

Once the cooled oil leaves the cooler shell, it flows directly to the inboard motor bearing, and eventually returns to the oil tank.

The oil cooler is piped into the return circuit of the motor cooling system. Part of the refrigerant that is used to cool the compressor motor passes through the oil cooler shell on its way to the economizer.

Motor Cooling System

CVHE compressor motors are cooled with liquid refrigerant; see Figure 5 for a schematic illustration of this pressurized system.

Liquid refrigerant flows from the condenser sump to the bottom of the compressor motor, Figure 7, where it enters the motor chamber through a control orifice. As the liquid refrigerant touches the warmer motor components, a portion of it flashes to a gas and cools the motor. This "flash" gas, along with any excess liquid refrigerant, then drains to the second-stage of the economizer.

Because of the positive pressure differential between the condenser and economizer, proper refrigerant flow through the motor is maintained at all load conditions.

Mechanical Operation - CVHF

Overview

The following description applies to the Trane Model CVHF centrifugal chiller only. Refer to the appropriate operation manual for refrigeration cycle descriptions of other models.

Each CVHF unit is composed of 5 basic components:

-- the evaporator;
-- 2-stage compressor ;
-- water-Cooled condenser;
-- single-stage economizer, and;
-- related interconnecting piping.

A heat-recovery or auxiliary condenser can be factory-added to the basic unit assembly to provide a heat-recovery cycle.

Figure 8 illustrates the general component layout of a typical CVHF chiller.

CVHF cooling-only and heat re-recovery modes of operation are described in the following sections. A pressure/enthalpy diagram (shown in Figure 9) is provided to further illustrate unit operation.

Cooling-Only Cycle

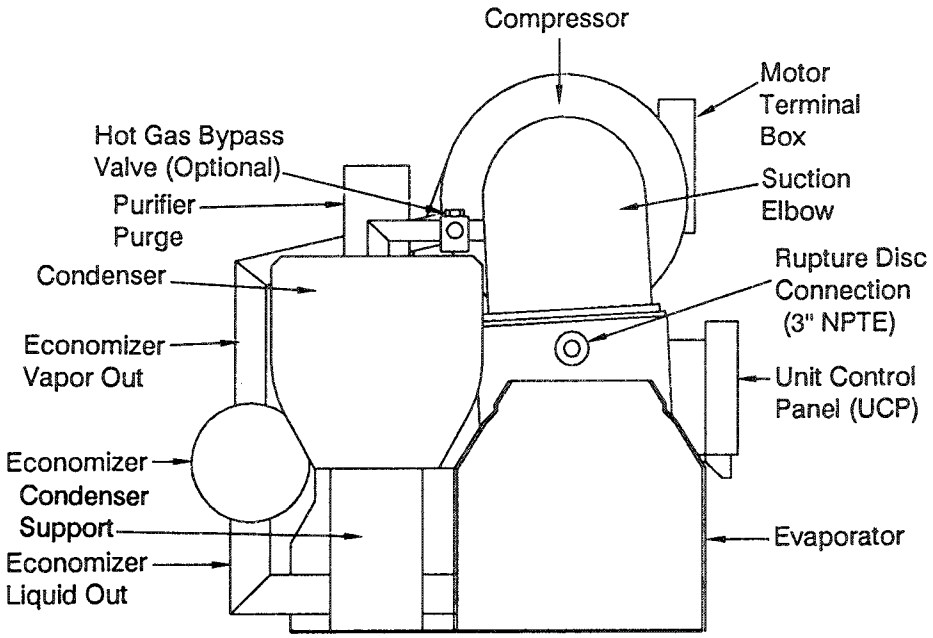
When the CVHF is functioning in the cooling mode, liquid refrigerant is distributed along the length of the evaporator and sprayed through small holes in a distributor (i.e., running the entire length of the shell) to uniformly coat each evaporator tube. Here, the liquid refrigerant absorbs enough heat from the system water circulating through the evaporator tubes to vaporize.

The gaseous refrigerant is then drawn through the eliminators (which remove droplets of liquid refrigerant from the gas), first-stage variable inlet guide vanes, and into the first-stage impeller.

Note: Inlet guide vanes are designed to modulate the flow of gaseous refrigerant to meet system capacity requirements; they also prerotate the gas allowing it to enter the impeller at an optimal angle that maximizes efficiency at all load conditions.

Compressed gas from the first-stage impeller is discharged through the second-stage variable guide vanes and into the second-stage impeller. Here, the refrigerant gas is again compressed, and then discharged into the condenser.

Baffles within the condenser shell distribute the compressed refrigerant gas evenly across the condenser tube bundle. Cooling tower water, circulated through the condenser tubes, absorbs heat from the refrigerant, causing it to condense. The liquid refrigerant then flows out of the bottom of the condenser, passing through an orifice plate and into the economizer.



The economizer reduces the energy requirements of the refrigeration cycle by eliminating the need to pass all gaseous refrigerant though both stages of compression. See Figure 10. Notice that some of the liquid refrigerant flashes to a gas because of the pressure drop created by the orifice plate, thus further cooling the liquid refrigerant. This flash gas is then drawn directly from the economizer into the second-stage impellers of the compressor. The remaining liquid refrigerant flows out of the economizer, passes through another orifice plate and into the evaporator.

Free Cooling, heat Recovery and Auxiliary Condenser Cycles

Refer to the CVHF section of Mechanical Operation.

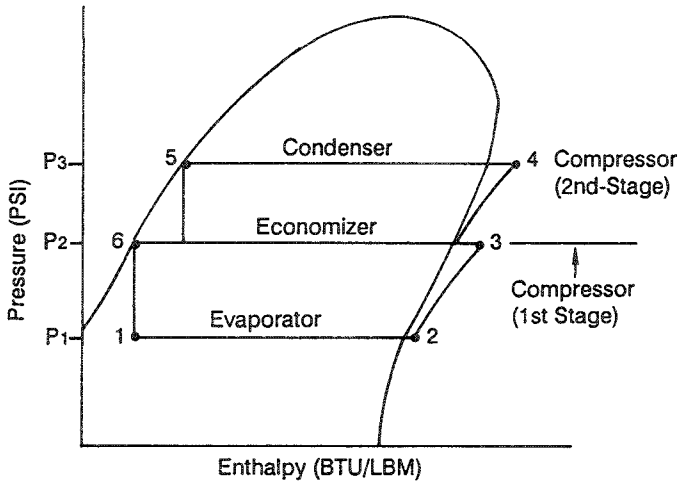
CVHF Pressure/Enthalpy Curve



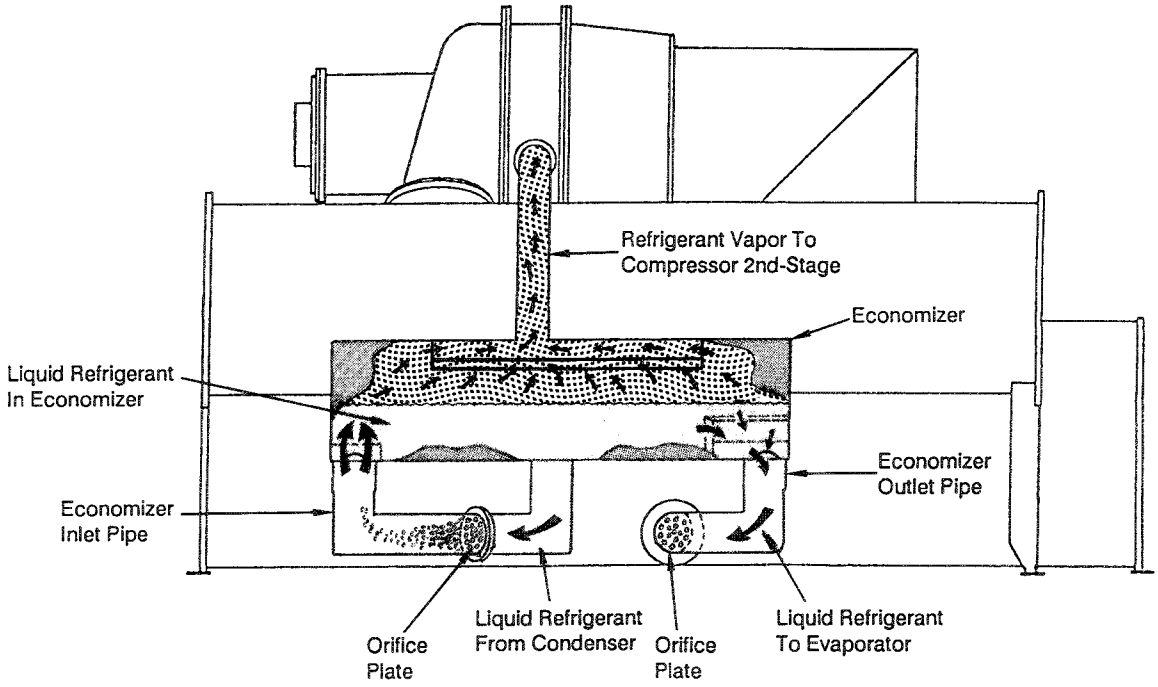


Figure 10
CVHF Economizer Operation

Compressor Lubrication System - CVHF

The CVHF compressor lubrication system, which supplies oil to the compressor motor bearings, is illustrated in Figure 11.

Oil is pumped from the oil tank (i.e., by a pump and motor located within the tank) through an oil pressure-regulating valve designed to maintain a net oil pressure of 12 to 18 psid. It is then filtered and sent to the compressor motor bearings. The oil filter assembly is equipped with refrigeration valves to isolate the filter during filter replacement.

From the bearings, the oil drains back to the oil tank through return lines.

To ensure proper lubrication and prevent refrigerant from condensing in the oil tank, a 1000-watt heater is secured to the oil tank exterior. Operating in response to a signal from the UCP, this heater energizes as needed to maintain an oil tank temperature of 140 to 145 F (60-63 C) when the chiller is not running. When the chiller is operating, the temperature of the oil tank is typical 115 to 160 F (46-72 C).

WARNING:

Use caution while working on certain areas of the unit. Surface temperatures may exceed 150° F on the compressor discharge, oil tank (heater), oil filter, and oil lubrication lines.

The oil tank is vented between the compressor inlet vanes and the first-stage impeller suction cover. During normal system operation, motor barrel pressure is greater than that of the oil tank. Therefore any gaseous refrigerant that enters the motor bearing cavities is drawn toward the oil tank where it is removed by the vent line.

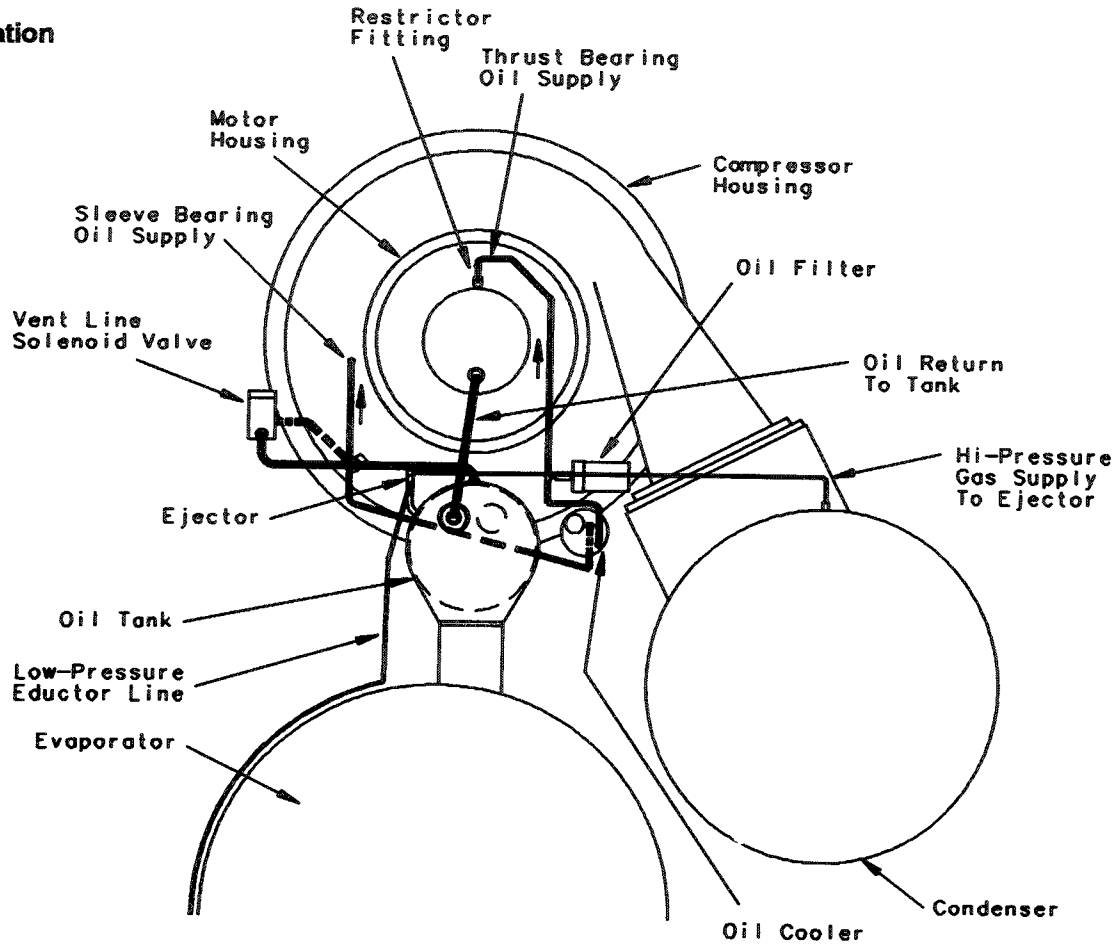
A dual eductor system is used to reclaim oil from the suction cover and from the evaporator, and deposits it back into the oil tank. These eductors use high pressure condenser gas to draw the oil from the suction cover and evaporator back to the eductors, from the eductors the oil is discharged to the top of the oil tank.

Note: CVHFs utilize a time delay relay and solenoid valve that temporarily close the oil sump vent line during the chiller start sequence. This prevents the loss of oil pressure that can occur during start-up by isolating the oil sump from the low-pressure cavity at the opposite end of the sump vent line.

Liquid refrigerant is used to cool the oil supply to the inboard motor bearing. Oil entering the oil cooler assembly from the oil tank (via the regulating valve and filter) flows into a coil inside the cooler shell. As the oil passes through this coil, it is cooled by a mixture of gaseous and liquid refrigerant that surround the coil exterior. Once the cooled oil leaves the cooler shell, it flows directly to the inboard motor bearing, and eventually returns to the oil tank.

The refrigerant-side of the oil cooler is piped into the return circuit of the motor cooling system. Part of the refrigerant that is used to cool the compressor motor passes through the oil cooler shell on its way to the economizer.

Motor Cooling System



CVHF compressor motors are cooled with liquid refrigerant. This pressurized cooling system is illustrated in Figure 12.

Liquid refrigerant flows from the condenser sump to the bottom of the compressor motor where it enters the motor chamber through a control orifice. When the liquid refrigerant contacts the warmer motor components, a portion of it flashes to a gas and cools the motor. This "flash" gas, along with any excess liquid refrigerant, then drains to the evaporator sump.

Because of the positive pressure differential between the condenser and evaporator, proper refrigerant flow through the motor is maintained at all load conditions.

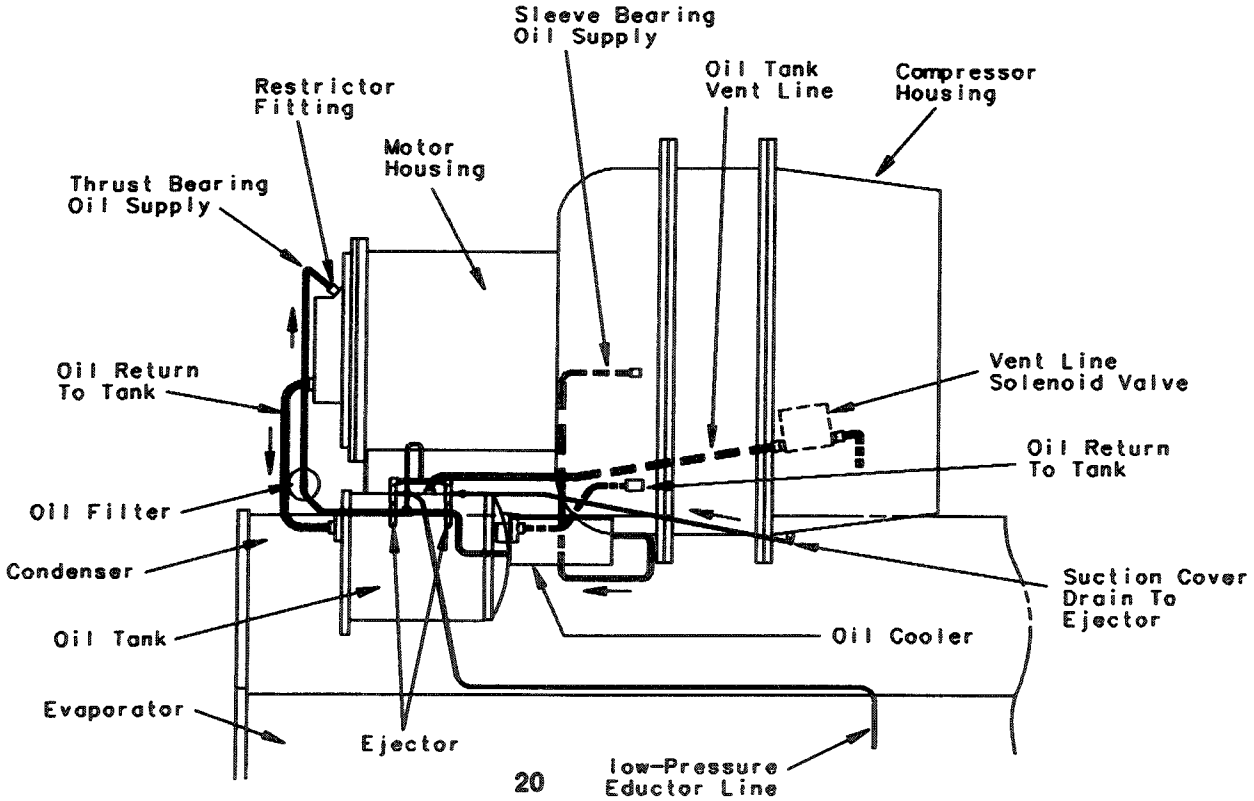

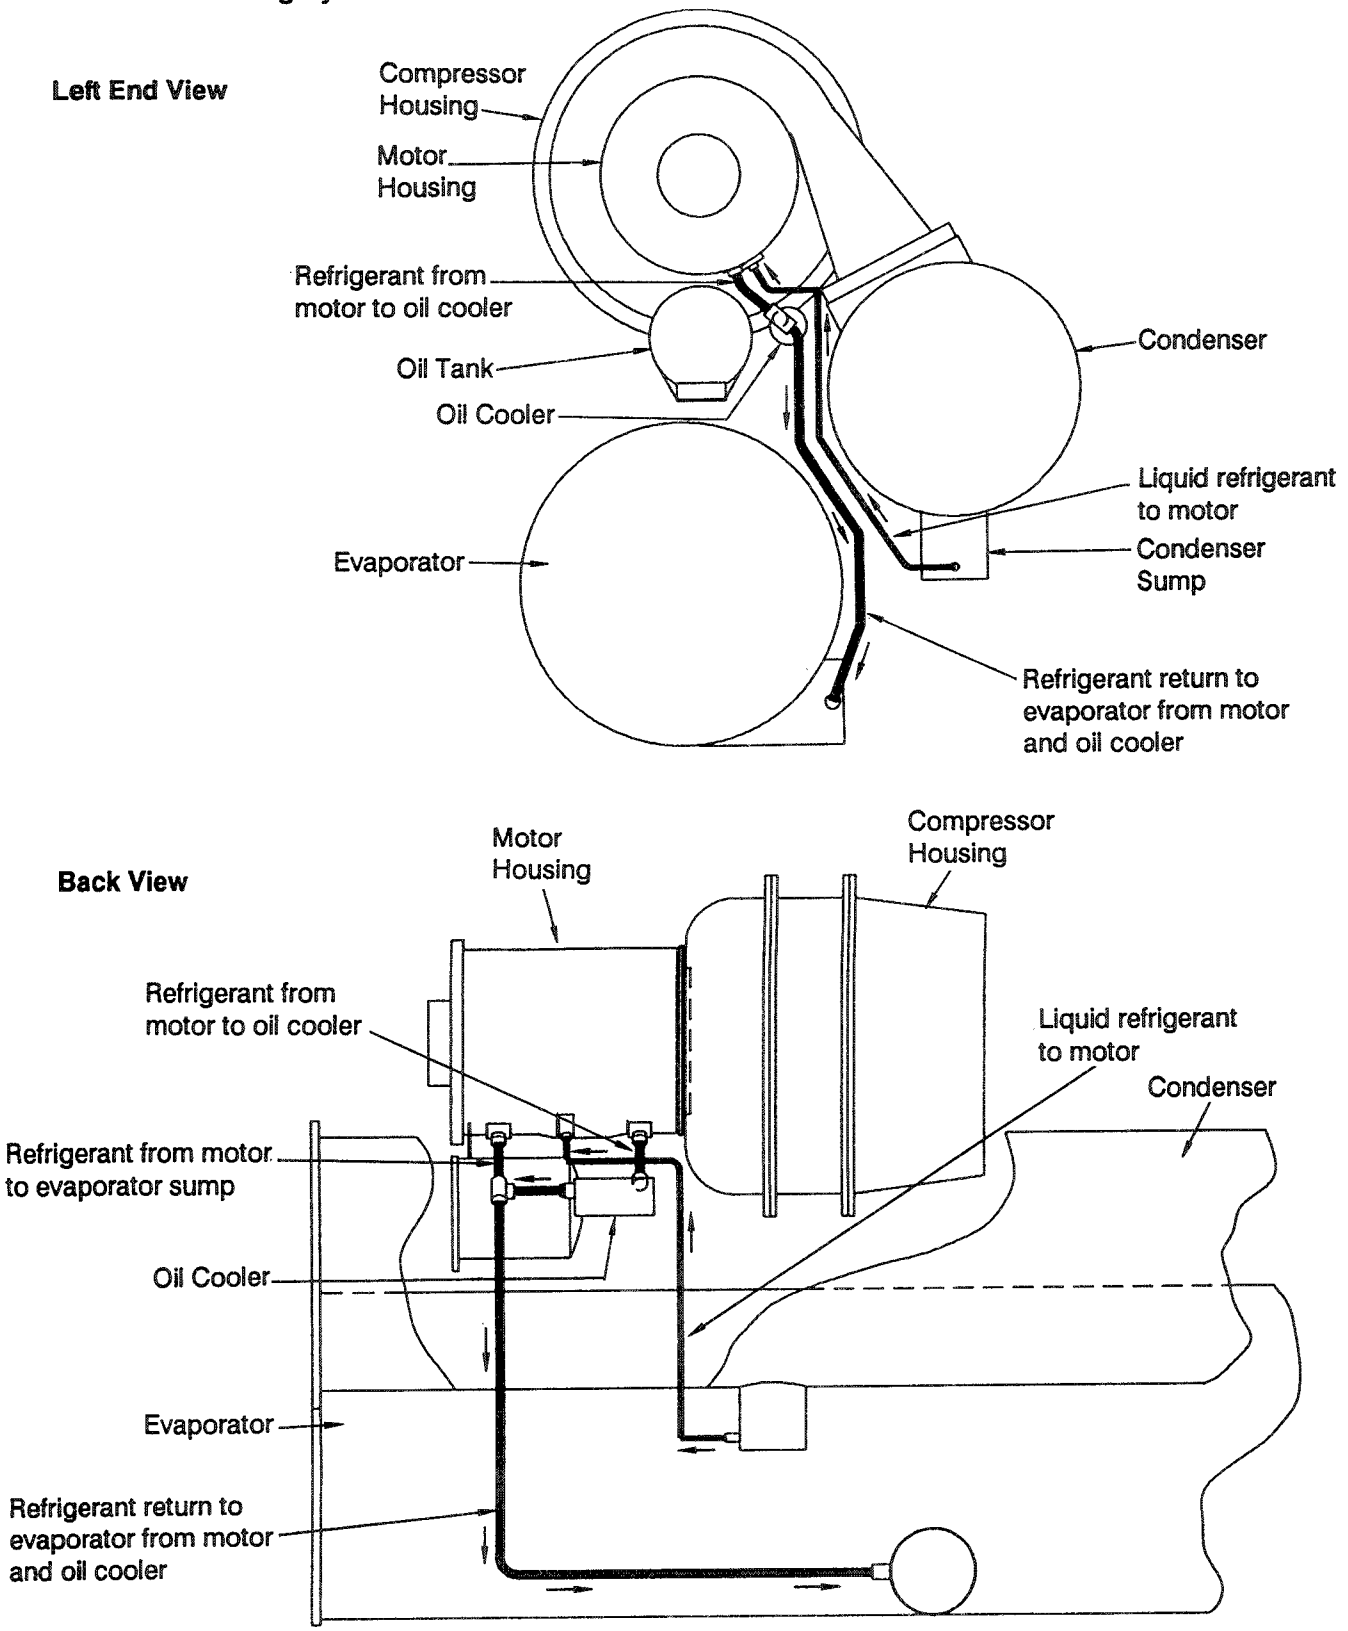

Figure 12
CVHF Motor Cooling System

Free Cooling Cycle (Optional)- CVHE/CVHF

Based on the principle that refrigerant migrates to the coldest area in the system, the free cooling option adapts the basic chiller to function as a simple heat exchanger. However, it does not provide control of the leaving chilled water temperature.

If condenser water is available at a temperature lower than the required leaving chilled water temperature, the operator manually stops the compressor and starts the free cooling cycle by moving the free cooling switch to the "On" position. This optional switch on the unit control panel is illustrated in the "Chiller Control System" manual.

Several components must be factory-supplied or -installed to equip the unit for free cooling operation:

– a refrigerant gas line, including an electrically-actuated shutoff valve, between the evaporator and condenser;

– a valved liquid return line, including an electrically-actuated shutoff valve, between the condenser sump and the evaporator;

– a liquid refrigerant storage vessel;

– additional refrigerant; and,

– a free cooling selector switch on the unit control panel.

When the chiller operator initiates changeover to the free cooling mode, the shutoff valves in the liquid and gas lines open; UCP (i.e., unit control panel) control logic prevents the compressor from energizing. Liquid refrigerant then drains (by gravity) from the storage tank into the evaporator and floods the tube bundle. See Figure 4.

Since the temperature and pressure of the refrigerant in the evaporator are higher than in the condenser (i.e., because of the difference in water temperature), the refrigerant in the evaporator vaporizes and travels to the condenser. Cooling tower water causes the refrigerant to condense, and it flows (again, by gravity) back to the evaporator.

This compulsory refrigeration cycle is sustained as long as a temperature differential exists between condenser and evaporator water. The actual cooling capacity provided by the free cooling cycle is determined by the difference between these temperatures which, in turn, determines the rate of refrigerant flow between the evaporator and condenser shells.

If the system load exceeds the available free cooling capacity, the operator must manually initiate changeover to the mechanical cooling mode by adjusting the free cooling switch to the "Off" position. The gas and liquid line valves then close and compressor operation begins. Refrigerant gas is drawn out of the evaporator by the compressor, where it is then compressed and discharged to the condenser.

Most of the condensed refrigerant initially follows the path of least resistance by flowing into the storage tank. This tank is vented to the economizer sump through a small bleed line; when the storage tank is full, liquid refrigerant must flow through the bleed line restriction. Because the pressure

drop through the bleed line is greater than that of the orifice flow control device, the liquid refrigerant flows normally from the condenser through the orifice system and into the economizer.

Note: During changeover from free cooling to mechanical cooling, the refrigerant transfer process is completed within 3 minutes. The micro-computer-based control system prevents carry-over by not allowing the unit to load for a period of two minutes.

Heat Recovery Cycle (Optional)

"Heat recovery" is designed to salvage the heat that is normally rejected to the atmosphere through the cooling tower, and put it to beneficial use.

For example, a high-rise office building may require simultaneous heating and cooling during the winter months. With the addition of a heat recovery cycle, heat removed from the building cooling load can be transferred to areas of the building that require heat. (Keep in mind that the heat recovery cycle is only possible if a cooling load exists to act as a heat source.)

To provide a heat recovery cycle, a heat-recovery condenser is added to the unit; see Figure 2. Though physically identical to the standard cooling condenser, the heat-recovery condenser is piped into a heating circuit rather than to the cooling tower.

During the heat recovery cycle, the unit operates just as it does in the "cooling only" mode except that the cooling load heat is rejected to the heating water circuit rather than to the cooling tower water circuit.

When hot water is required, the heating water circuit pumps energize. Water circulated through the heat-recovery (or auxiliary) condenser tube bundle by the pumps absorbs cooling-load from the compressed refrigerant gas discharged by the compressor. The heated water is then used to satisfy heating requirements.

Auxiliary Condensers

Unlike the heat-recovery condenser (which is designed to satisfy comfort heating requirements), the auxiliary condenser serves a preheat function only, and is used in those applications where hot water is needed for use in kitchens, lavatories, etc. While the operation of the auxiliary condenser is physically identical to that of the heat-recovery condenser, it is comparatively smaller in size, and its heating capacity is not controlled.

Trane does not recommend operating the auxiliary condenser alone because of its small size.

Chiller Control System

Unit Control Panel

CVHE and CVHF safety and operating controls are housed in the UCP 695 unit control panel. (Panel layout is illustrated in Figure 13.)

Based on control function, the UCP695 panel can be partitioned into 2 major "sections":

1. The "microcomputer-based" controls, which include the relay output module (1U1), power supply output module (1U2) and micro module (1U3); and,

2. The electromechanical control devices (e.g., pressure switches, gauges, counters.)

Major components within each of these control groups are described below.

Relay Output Module (1U1)

Consisting of terminal strip 1TB1, this module allows control of the following electrical circuits using relay contact closures:

-- vanes open;
-- vanes close;
-- condenser water pump;
-- purge;
-- "head relief" request ;
-- alarm relay ; and,
-- free cooling and auxiliary free cooling relays (optional).

Connection points of standard and optional UCP (i.e., Unit Control Panel) output signals are indicated on the typical electrical schematic provided in the Eiectrical Sequence of Operation section of this manual.

Power Supply Output Module (1U2)

Like 1U1, power supply output module 1U2 also uses relay contact closures to enable UCP control of the following electrical circuits on 1TB2:

-- reset relay;
-- stop relay;
-- overload relay;
-- compressor start relay;
-- transition relay; and,
-- oil heater and oil pump relays.

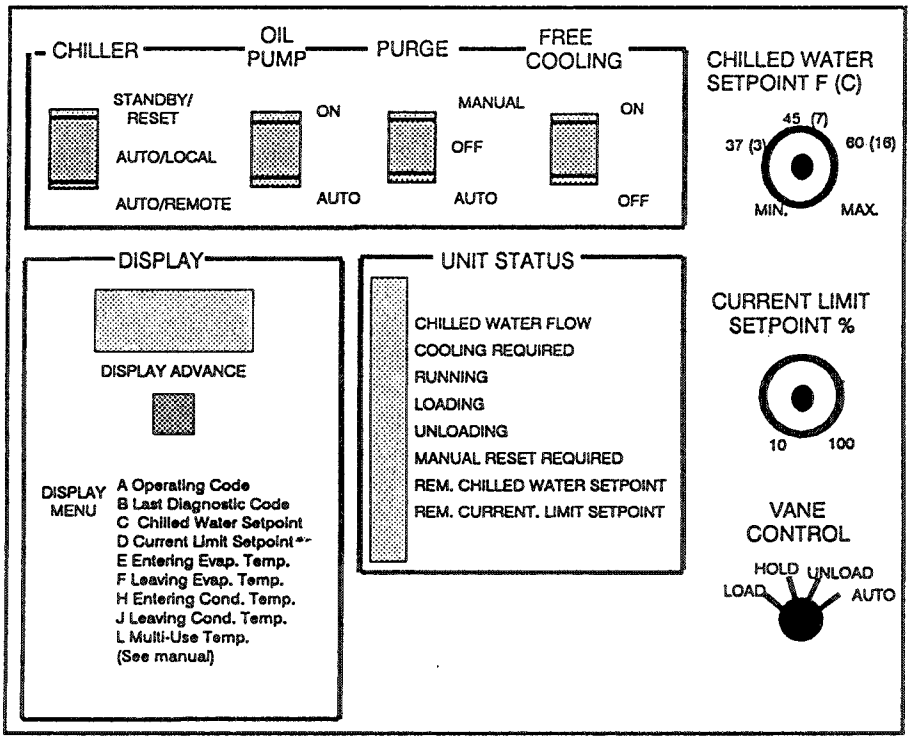

Figure 13
UCP695 Control Panel Layout - CVHE/CVHF

Micro Module (1U3)

Consisting of terminal strips 1TB6, 1TB3 and 1TB4, the input portion of this module "accepts" signals from a variety of standard sensor sources:

-- leaving chilled water and evaporator refrigerant temperature sensors;
-- chilled water and condenser water flow interlock circuits;
-- "vane actuator closed" limit switch;
-- differential oil pressure switch;
-- 3-phase current signals from the auxiliary current transformers;
-- oil and motor winding temperature sensors.

(Figure 14 illustrates the relative locations of the sensors that provide 1U3 with temperature inputs.) Figure 15 shows assembly of Temperature Sensor.

Based on these inputs, micro module 1U3:

a. executes the start and stop sequence;
b. Controls chilled water temperature in response to the setpoint by modulating the position of the inlet guide vanes;

c. Monitor's key chiller operating parameters and "acts" to prevent the chiller from reaching and shutting down on an operating limit;

d. Provide compressor/motor protection.

The human (operator) interface portion of micro module 1U3 is composed of a display window, a display advance pushbutton, status indicator lights, and a series of control knobs and switches. These devices enable the operator to establish chiller control settings, and monitor chiller operating and diagnostic conditions.

Additional information on these components is provided later in this section under "Operator Interface: and "Service Interface".

In addition to the standard micro module features just described, 2 mutually exclusive control options are also available at the micro module level:

1. **Serial Communications Interface Link (SCI). (Optional)** The SCI provides an intelligent interface with a Trane SCP (System Control Panel), allowing the chiller to accept set points and commands from a remote location, and communicate condition and diagnostic information to the SCP.

2. **Chilled Water Reset (CWR). (Optional)** CWR enables the UCP to reset the chilled water setpoint based on load (i.e., evaporator return water temperature) or ambient temperature. (See the Control Options section for further information.)

Electromechanical Controls

Other control devices installed in the unit control panel (but separate from the microcomputer-based controls) are described below.

See Table 1 for control cut-in and cutout points. (Unit time delays and nominal fault time-out periods are also included therefore fore your reference.)

Condenser high Pressure Cutout Switch (1S1)
This 2-position, normally closed switch monitors the pressure in the condenser. (See Table 1 for control set points.)

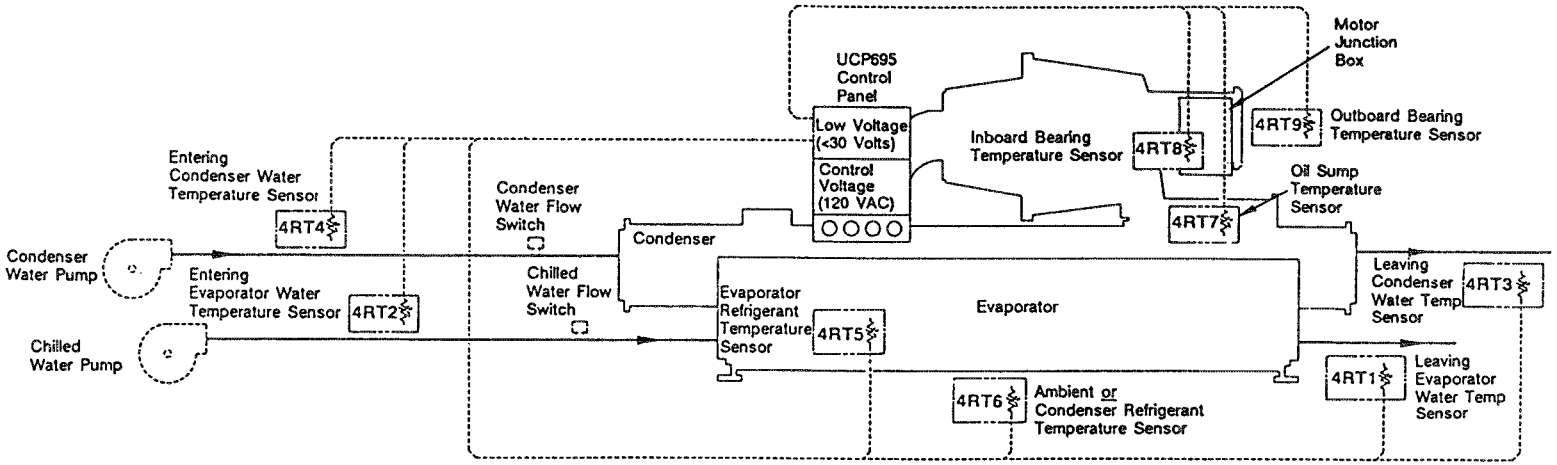
Differential Oil Pressure Switch (1S2) Connected between the down stream side of the oil filter and the oil sump, this SPST, normally open switch closes when the pressure differential reaches the point indicated in Table 1.

Hour Meter (1M1)
Mounted on the left-hand side of the control panel enclosure, the non-resettable hour counter accumulates running hours from the time of initial unit start-up. It displays a maximum value of 99999.9 hours before returning to zero.

Start Counter (1M2)
Accumulating compressor motor starts from the time of initial unit start-up, this nonresettable counter displays a maximum value of 99999 compressor starts before staring over. Like the hour meter, it is mounted on the left-hand side of the control panel enclosure.

Pressure Gauges
Four pressure gauge dials are mounted across the lower front of the unit control panel. These dials enable the operator to monitor oil sump (low), oil supply (high), evaporator and condenser pressures.

Advanced Motor Protection



This control package provides the UCP with the features needed to protect the compressor motor from momentary power losses, phase imbalance, phase reversals, and surge (i.e., see note below) by initiating a unit shutdown whenever one of these situations occurs.

Diagnostic codes for each of these conditions appear at the display window to enable the operator to identify which particular electrical abnormally occurred.

Note: The UCP will allow the chiller to operate under "surge" conditions (operating code A 78) for 15 minutes before shutting it down on latching diagnostic b dA.

Table 1
Unit Time Delays and Safety Control Cutout Settings

Operating Controls: "Timers"	Timing Interval	System Reset	Operating Code (1)
Prelube (2)	15 seconds	n/a	A 72
Restart Inhibit (3):			
Winding Temp. <165 F (74 C)	2 minutes	n/a	A 70
Winding Temp. ≥ 165 F	15 minutes	n/a	A 70
Since Last Start	30 minutes	n/a	A 70
Post-Lube	2 minutes	n/a	A 79
Free-Cool/Vane Open Inhibit (4)	3 minutes	n/a	A 9
Purifier Purge: (purge switch @ AUTO)	Controlled by purge timer (6)	manual (7)	n/a
Sump Vent Line Interval (8)	100 seconds	n/a	n/a
Safety Controls: Fault Time-Outs	**Timing Interval**	**System Reset**	**Diagnostic Code (1)**
Oil Pressure Overdue (2)	33 seconds	manual	b F2
Transition Complete Overdue	2 seconds	manual	b FO
Transition-from-Start Complete	Max. accel. timer setting	manual	b EE
Condenser Water Flow Overdue	3 minutes	manual	b dC
No Evaporator Water Flow	2 seconds max. w/o flutter	auto	b Ed
Vane Closure Overdue	3 minutes	manual	b FA
Free-Cool Valve Closure Overdue	3 minutes	manual	b F9
Surge	15 minutes	manual	b dA
Safety Controls: Unit Cutouts	**Control "Trip" Point**	**System Reset**	**Diagnostic Code (1)**
Winding Temp. Run Inhibit	265 ± 15 F* 130 ± 9 C*	manual	b E7
Low Oil Temp. Run Inhibit	100± 2 F 38+ 1C	auto	b F3
High Oil Temp. Run Inhibit	180± 2 F 83+ 1C	manual	b F4
High Bearing Temp. Run Inhibit (Optional)	180± 2 F 83+ 1C	manual	b EA, Eb
Lvg. Water Temp. Low Limit (Std. Range)	35± 1 F 2+ .5 C	auto	n/a
Differential Oil Pressure Switch — Closes	11.5 - 15 psid	manual	b E8
Differential Oil Pressure Switch — Opens	9+ 1 psid		
High Pressure Cutout Switch — Std. Units	15± 1 psig	manual	b F5
High Pressure Cutout Switch — ASME Units	25+ 1 psig (9)		
Oilless Purge "Extend Run" Press. Switch — Closes	20 psig	n/a	n/a
Oilless Purge "Extend Run" Press. Switch — Opens	25 psig		

Notes:
1. See tables 3 and 4 for complete code listing.
2. Since prelube timing can begin at any point during 33- second "oil pressure overdue" interval, actual elapsed time to "establish oil pressure" and "prelube" can be anywhere from 15 to 48 seconds.
3. The 165 F inhibit applies only when unit is first powered-up, or if chiller switch is turned from STANDBY/RESET to AUTO/ LOCAL or to AUTO/REMOTE. Otherwise, 30 minutes must elapse between compressor starts.
4. Operating code **A 9** will appear on operator display only when free cooling valve limit switches have opened.
5. See "Electrical Sequence of Operation" . Refer to Purifier Purge Operation Manual for details.
6. Reset at 3S6 or 6S6 on purge panel.
7. This timer closes sump vent line during prelube and during unit start sequence.
8. Fixed differential of 3-6 psid for switch closure on a rise in differential oil pressure.

Operator Interface

Monitoring devices and all chiller control components requiring adjustment for normal chiller, operations are accessible without opening the unit control panel door. These components that area part of micro module 1U3 are illustrated in Figure 13 and discussed below.

Chiller Switch

Located above the "Display" block on the UCP, this 3-position switch enables the owner/operator to define chiller control:

Standby/Reset. When power is applied to the unit with the chiller switch set at "Standby/Reset", the UCP is activated but unit operation is prohibited; operating code A 0 appears on the display.

This switch position can be used by all the operator or service technician to clear a latching diagnostic (i.e., fault that requires manual reset), or to shut down the unit.

Auto/Local. This switch position allows the chiller to run automatically, using the operational setpoints set at the unit.

Auto/Remote. With the chiller switch in this position, the unit runs automatically using the setpoints established at a remote device and communicated to the chiller with the optional serial communication-interface (SCI).

If no setpoints are sent by the remote controller, the UCP uses the operational setpoints set at the unit control panel.

Note: When the unit is equipped with the SCI option, a remote device can place the unit in the "Standby/Reset" mode even though the chiller switch is positioned at "Auto/Remote". However, a latching diagnostic condition at the unit cannot be cleared from a remote device.

Oil Pump Switch

A 2-position oil pump switch is located to the right of the chiller switch, above the display window. Switch position functions are described below:

On. This switch position provides continuous operation of the oil pump, even when the chiller switch is positioned at "Standby/Reset".

Note: The "On" switch position is designed for use by service personnel only; do not leave it in this position! Compressor start-up will not occur if the oil pump switch is set at "On" (i.e., latching diagnostic b E8 will flash alternately with operating code A 72 on the UCP's display).

Auto. Oil pump operation is controlled by the UCP, ensuring oil flow when the compressor is running. This is the normal switch operating position.

Purge Switch

Located next to the oil pump switch (see Figure 14), the purge switch enables the owner/operator to select 1 of 3 purge operational modes.

Manual. This switch position provides continuous operation of the purge compressor regardless of centrifugal compressor operation, or the position of the chiller switch.

Off. Purge operation will not occur when the purge switch is set at this position.

WARNING: To prevent injury or death due to electrical shock, open unit disconnect switch before servicing to ensure purge unit is de-energized.

Auto. This is the normal switch operating position. With this switch set at AUTO, the purge will run when the CenTraVac is in powered cooling operation.

If the chiller switch is set at STANDBY/RESET and the purge switch is set at AUTO, the purge unit is also shut down.

Note: On those CVHE/CVHF units equipped with more than one condenser, purge only from the active condenser. Use the manual valves provided to isolate the inactive condenser.

Chilled Water Setpoint

Used to set the leaving chilled water temperature, this manually adjustable potentiometer is located at the right-hand side of the window in the control panel door. See Figure 13, notice that dial settings range from "Min" to "Max", with intermediate To view the front panel chilled water setpoint, adjust the vane control switch to "Hold" and press the "Display Advance" push-button until the " I" code prefix appears on the display. The integer value (in increments of 1F or 1 C) immediately to the right of " I" is the UCP's chilled water setpoint.

Remember that the standard chiller operating range is 37 F to 60 F. (3 to 60.8 C) while the temperature range for extended operation is 20 F to 70 F (-6 to 22 C.)

Note: To view the active chilled water setpoint, check the entry for code prefix "C" of the operator's menu. When the chiller switch is set at "Auto/Remote" and the "Remote Chilled Water Setpoint" status light is lit, the "C" value displayed was entered at a remote system control panel (SCP).

Current Limit Setpoint

Located directly below the chilled water setpoint control, this manually adjustable potentiometer is used to register the desired current limit setpoint. Dial settings range from 40% to 100% of the compressor rated-load-amps. (RLA) value.

To view the front panel current limit setpoint, adjust the van control switch to "Hold" and press the "Display Advance" push-button until the "-" code prefix appears. The integer value (indicated in increments of 1T) at the immediate right of "-" is the UCP's current limit setpoint.

Note: To check the active current limit setpoint, locate the entry displayed for code prefix "d" in the operator's menu. Whenever the chiller switch is set at "Auto/ Remote" and the "Remote Current Limit Setpoint: status light is lit, the "d" value displayed was entered at a remote SCP.

Vane Control Switch

A 4-position, compressor inlet guide vane control switch is located beneath the current limit setpoint control. Each switch position is described below.

Load. As long as the vane control switch remains in this position, the "vanes open" (1U1Q7) relay is continuously energized and automatic vane control is suspended during the "Normal Run" mode (A 74).

Manual loading does not take precedence over the current limit (A 75), condenser limit (A 76) or evaporator limit (A 77) modes of operation.

Hold. With the vane control switch set at "Hold', both the "vanes open: (1U1Q7) and "vanes close" (1U1Q8) relays are de-energized, so the inlet guide vanes remain at their present position. In other words, automatic vane control is suspended when the chiller is operating in the "Normal Run" mode (A 74).

However, keep in mind that a current limit (A 75) condenser limit (A 76), or evaporator limit (A 77) operating mode will override the manual "Hold" setting.

Note: Positioning the vane control switch remains in this position, the "vanes close" relay (1U1Q8) is continuously energized; automatic vane control is suspended regardless of the chiller's operating mode.

Auto. Inlet guide vane position is automatically controlled by the UCP when the vane control switch is set at this normal operating position.

Free Cooling Switch (Optional)

Free cooling enables the chiller to function as a simple heat exchanger, using refrigerant as the working fluid; however, it does not provide control of the leaving chilled water temperature.

When condenser water is available at temperatures lower than the desired chilled water temperature, the free cooling option provides "average selection" chiller capacity without operating the compressor.

A 2-position free cooling switch, located next to the purge switch, allows the operator to select from 1 to 2 operating positions:

On. Placing the free cooling switch in this position forces the chiller to enter the free cooling mode (A 9) ; the compressor shuts down if the unit is operating in the powered cooling mode.

Note: Operating code A 9 appears on the display once the free cooling valves are open. (The unit cannot return to the powered cooling mode until these valves are closed.) Remember, too, that when the UCP is equipped with the SCI option, a remote device can "turnoff" free cooling opera operation while the free cooling switch is set at "On".

Off. This setting enables normal chiller operation within the parameters established for the powered cooling mode.

Unit Status Lights

A series of 8 status indicator lights are located directly below the purge switch. These blue lights along with the operating and diagnostic information found on the display allow the operator to monitor chiller operations. The purpose of each status indicator light is described below.

Chilled Water Flow
Illumination of this light indicates that chilled water flow switch 5S2 is closed.

Cooling Required. This light only illuminates when the UCP proves chilled water flow and detects a cooling requirement (i.e., leaving chilled water temperature exceeds the chilled water setpoint by a value greater than the differential-to-start criteria).

Running. Illumination of this status light indicates that:

-- the unit is running (or is in one of the "run" modes);
-- the chiller switch is set at "Auto/Local" or "Auto/Remote"; and,
-- the start sequence (or , "transition") is complete.

It also remains lit through the chiller's post-lube cycle after the compressor shuts down.

Loading. When this light glows, the UCP is loading the unit (i.e., the vane actuator is driving the vanes open).

Unloading. When this light is on, the UCP is unloading the unit (i.e., the vane actuator is driving the vanes closed).

Note: It is normal for the "Loading" and "Unloading" status lights to flash on and off in short pulses.

Manual Reset Required. Illumination of this light indicates that the UCP detected a "latching diagnostic condition, and shut down the chiller. Operation cannot resume until the UCP is manually reset (i.e., chiller switch is adjusted to "Standby/Reset", then back to "Auto/Local" or "Auto/Remote").

Remote Chilled Water Setpoint. When this light is on, the UCP is ignoring its front panel setpoint, and is using the chilled water setpoint:

-- determined by the optional chilled water reset module, or;

-- entered at a remote source (e.g., an SCP699 system control panel, or a Trane BAS).

If remote communications are severed, the UCP "defaults" to the control value of its chilled water setpoint potentiometer.

Remote Current Limit Setpoint. Illumination of this light indicates that the UCP is using a current limit setpoint communicated from a remote source (e.g., SCP or Trane BAS) , and is ignoring its from panel setpoint.

Again, if remote communications are interrupted, the UCP "defaults" to the control value set with the current limit setpoint potentiometer.

UCP Display

The UCP's display consists of a blue, 4-digit vacuum fluorescent display and a "Display Advance" push-button; both are located to the left of the unit status indicator lights. See Figure 13.

The first letter of the 4-character display identifies the type of data shown in the display window; a list of these indicator codes, along with their meanings, is provided in Table 2. An abbreviated version of this list also appears on the face of the UCP, directly below the "Display Advance" pushbutton. The two remaining alphanumeric characters of the display indicate

characters of the display indicate unit operating mode, diagnostic condition, setpoints or actual temperatures as defined by the code prefix. Refer again to Table 2, as well as to Tables 3 and 4.

Note: If the UCP detects a diagnostic condition, it alternately flashes the appropriate diagnostic code and unit operating mode (at the time of unit shutdown) on the display.

Codes prefixed by a "C" or "d" are followed by the corresponding setpoint value (chilled water or current limit, respectively) presently used to control the chiller. If the chiller switch is set at "Auto/Local", the setpoint values displayed are those set manually at the UCP695 control panel.

however, when the chiller switch is set at "Auto/Remote" and the applicable status indicator lights are on, the displayed setpoint values were established at a remote device (e.g., an SCP699 or Trane BAS).

"E", "F", "H" and "J" code prefixes are followed by an actual measurement of a system parameter (e.g., entering evaporator water temperature). (Code prefixes "E", "H" and "J" represent sensor options: if these sensors are not installed a bar (--) appears on the display.)

Table 2
Display Menus

Operator's Menu		Servicemans's Menu (1, 2)	
Code Prefix	**Parameter Description**	**Code Prefix**	**Parameter Description (and Display Range)**
A	Operating Mode (see Table 16)	A	Operating Mode (see Table 16)
b	Last Diagnostic (see Table 17)	b	Last Diagnostic (see Table 17)
C	Active Chilled Water Setpoint: Std. Range = 37-60 F (3-16 C) Extd. Range = 20-70 F (-6-22 C)	t	Panel Chilled Water Setpoint (---, 20-70 F, ---)(---, -6-22 C, ---)
d	Active Current Limit Setpoint (40% thru 100% RLA)	—	Panel Current Limit Setpoint (---, 40% thru 100% RLA, ---)
E	Entering Evap. Water Temp. (Opt.) (---, 12-91 F, ---)(---, -11-33 C, ---)	_	Evaporator Refrigerant Temp. (3) (b Ad, -4-42 F, ---)(b Ad, -20-6 C, ---)
F	Leaving Evap. Water Temperature (b Ab, 12-91 F, ---)(b Ab, -11-33 C, ---)	L	Control Response Setpoint (1 thru 237)
H	Entering Cond. Water Temp. (Opt.) (---, 28-142 F, ---)(---, -2-62 C, ---)	O	Start Differential Setpoint (2-10 F) ((-17 thru -12 C)
J	Leaving Cond. Water Temp. (Opt.) (---, 28-142 F, ---)(---, -2-62 C, ---)	P	Condenser Limit Setpoint (80-120% HPC)
L	Multi-Use Temperature (4) (---, -5-135 F, ---)	U	Evap. Refg. Trip Setpoint (b A3) Std. Range = 29-34 F (-1 thru 1 C) Extd. Range = 0-34 F (-18 thru 1 C)

Notes:
1. To redefine the "operator's menu" to the "serviceman's menu" turn vane control switch to HOLD.
2. For additional information on any item listed in the "serviceman's menu", contact a qualified service organization.
3. Actual measured evaporator refrigerant temperature.
4. Examples of "Multi-Use Temp." applications are: Cond. Lvg. Refg. Temp.; CWR Ambient Temp.; CWR Temp. from Analog Input.

Figure 16 (Continued)

Adjusting the vane control knob to the "Hold" position redefines the display code prefixes to indicate the "local" (or front panel) chilled water and current limit spiniest, actual evaporator refrigerant temperature, and settings for control response, start differential condenser limit and evaporator refrigerant "trip" point as shown in Table 2.

Important! Do not leave selector knob in "Hold", control of leaving chilled water temperature will be suspended. Only "safeties" are functional!

Note: While in the "serviceman's menu", the integer values displayed for the panel chilled water, condenser limit and evaporator refrigerant trip setpoints represent the entire adjustment range for these potentiometers. Unless the chiller is specifically designed for "extended range" operation, the UCP will adhere to the operating parameters established for "standard range" chillers.

Use the "Display Advance" push-button to scroll from one menu entry to the next. Remember that a blank display marks the end of the "operator's menu"; to return to the top of the menu, simply press this push-button once.

Important! Advancing past the "Last Diagnostic Code" entry in either menu automatically clears, the code registered there from the UCP's memory!

Service Interface

Following is a brief description of UCP control components that can only accessed by opening the control panel door. Each of these divides, as illustrated in "Control Options, is set at initial unit start-up by a qualified service technician.

WARNING: To prevent injury or death due to electrical shock, always open unit disconnect switch before opening control panel door.

CAUTION: To ensure proper chiller operation, never tamper with any UCP controls located behind the panel door without first consulting a qualified Trane service technician.

Table 3
Codes for Unit Operating Modes

3-Character Code	Operating Mode Description
Blank	Power Off
A 0	Standby/Reset
A 1	Auto (Local or Remote)
A 9	Free Cooling
A 70	Restart Inhibit
A 71	Establish Cond. Water Flow
A 72	Start
A 74	Run: Normal
A 75	Run: Current Limit (1)
A 76	Run: Condenser Limit (2)
A 77	Run: Evaporator Limit (3)
A 78	Run: Surge Condition
A 79	Post-Lube
A 88	Reset
A100	External Inhibit (Remote Start/Stop)

Notes:
1. As current limit setpoint is approached, 1U3 restricts further opening of the inlet guide vanes.
2. As condenser limit setpoint is reached, 1U3 restricts additional compressor loading to avoid shutdown on high condenser pres- sure (b F5) and initiates "head relief request" (i.e., optional relay).
3. 1U3 restricts further opening of the inlet guide vanes to avoid unit shutdown on low evaporator refrigerant temperature (b Fb).
4. 1U3 limits compressor loading and initiates "head relief request" (i.e., optional relay) when unit enters a surge condition. An automatic unit shutdown occurs if unit remains in surge for 15 minutes (b dA).

Table 4
Diagnostic Codes

Diag. Code	Diagnostic Explanation	Reset Type	Diag. Code	Diagnostic Explanation	Reset Type
b A3	Evaporator Refrig. Temp. Range	Manual	b E7	High Motor Temperature	Manual
b A4	Motor Temperature Sensor #1	Manual	b E8	Differential Oil Pressure Switch	Manual

b E2	Momentary Power Loss	Auto	b F9	Free-Cooling Valves	Manual
b E3	Phase Imbalance	Manual	b FA	Actuator	Manual
b E4	Phase Loss	Manual	b Fb	Low Evaporator Refrig. Temp.	Manual
b E5	Phase Reversal	Manual	b FF	Unit Control Module	Manual

Notes:
1. Check the "Manual Reset Required" status indicator light to determine if manual reset is necessary.
2. It is not possible to clear a latching diagnostic condition (i.e., one requiring manual system reset) at the unit from a higher-level device (e.g., an SCP699 or Trane BAS).
3. Optional feature.

Clear Restart Inhibit Push-button

By pressing this pushbutton switch (i.e., located to the right of the "Chilled Water Setpoint" potentiometer), the service technician can clear the restart inhibit timer.

CAUTION: The "Clear Restart Inhibit" button is for use only by a qualified service technician. Using this button more than once in 30 minutes may seriously damage the motor.

Control Response Setpoint

(To be set/calibrated by qualified Trane service technician only). Located to the left of the display window, this manually adjustable potentiometer can be set at any position between 1 and 237. (The units used to delimit these settings are arbitrary.)

The control response setting directly affects the vane controller's speed of response to changes in cooling requirements; the lower the control response setting, the slower the response time of the vane controller.

To view the actual control response setting, position the vane control switch at "Hold" and press the "Display Advance" push-button until code prefix" -" appears.

Start Differential Setpoint

(To be set by qualified Trane service technician only). With an adjustment range of 2-10 F (1- 6 C), this manually adjustable potentiometer establishes the number of degrees that the leaving chilled water temperature must rise above setpoint before the unit will start. (It also determines the actual compressor "stop" point; see "Fuse 1F2 Branch Circuit" under Electrical Sequence of Operation for further explanation.)

To display the actual start differential in the display window, position the vane control switch at "Hold" and press the "Display Advance" push-button until code prefix "I I" appears.

Condenser Limit Setpoint (% hpc; Option)

(To be set by qualified Trane service technician only). Optional condenser limit control provides a means for maintaining chiller operation while high head pressure conditions exist.

Notice that the condenser limit potentiometer can be set at any point from 80% to 120% of the rated high pressure control trip point. for standard units with an HPC cutout is 20 to 30 psig.

Once established, the UCP compares this value with condenser refrigerant (head) pressure. As the head pressure approaches the condenser limit setpoint, the UCP either slows/prohibits van opening, or initiates a regulated van closure.

Remember that the condenser high pressure cutout switch (1S1) remains active, and will shut down unit operation on latching diagnostic b F5 (i.e., "high condenser refrigerant pressure") if its trip point is exceeded view the actual condenser limit setpoint on the UCP's display, adjust the vane control knob to "Hold" and press the "Display Advance" push-button until " -" code prefix appears.

Evaporator Refrigerant Trip Setpoint

(To be set by qualified Trane service technician only). With a standard adjustment range of 29 to 34 F (-2 C to 1C), this manually adjustable potentiometer is used to establish the chiller's low refrigerant temperature trip point. An optional "extended range" is also available which provides an adjustment range of 0 to 34 F (1 to 18 C.)

To view the actual control setting, adjust the vane control knob to "Hold" and press the "Display Advance" push-button until the "-" code prefix appears.

Note: Attempting to adjust the evaporator refrigerant trip point below the minimum range value results in a latching diagnostic. (Diagnostic code b A3 will flash alternately on the display with the operating code at the time the minimum range value was violated.)

CAUTION: to assure proper chiller operation, adjustment of this control must always be service technician.

UCP "Summary Sheet"

A summary of UCP operating and diagnostic codes, display menus, timing functions, control cutout points and terminal strip connections along with an illustration of micro module 1U3 is provided of this manual.

Electrical Sequence Of Operation

Overview

This section will acquaint the operation with the control logic governing CVHE /CVHF chillers equipped with UCP695-based control systems. Be sure to refer to the typical wiring schematic shown in Figure 16 when reviewing these step-by-step electrical sequences of operation. Available starter electrical configurations are illustrated by Figure 17.

Note: The typical wiring diagrams in Figures 16 and 17 are representative of standard CVHE/ CVHF units and are provided only for general reference. They may not reflect the actual wiring of your unit. For specific electrical schematic and connection information, always refer to the wiring diagrams that shipped with the chiller.

With the supply power disconnect switch or circuit breaker (2CB1) closed, 120-volt control power is provided through control power transformer 2T4 and a 30-amp starter panel fuse (2F4) to terminal 1TB5-1 in the UCP control panel. From this point, control voltage flows to:

Fuse 1F2, supplying power to micro module 1U3 and the starter control, oil heater, and power supply transformer (1T1) circuits.

Fuse 1F3, supplying power to the oil pump and inlet vane actuator circuits; and,

Fuse 1F4, supplying power to the purge control system. Although these 3 branch circuits energize simultaneously, the functions occurring in each circuit are described separately in the following paragraphs.

Fuse 1F2 Branch Circuit

120-Volt control power passing through fuse 1F2 travels to 5 separate subcircuits:

1. Low-voltage power is provided to micro module 1U3, relay output modul9e 1U1 and power supply output mode 1U2 through fuse 1F5 and power supply transformer 1T1.

2. Oil tank heater 4HR1 may be energized via the normally-open K6 contacts of power supply output module 1U2. (The status of these contacts open or closed is based on input from oil sump temperature sensor 4RT7.)

Note: UCP control logic is designed to energize the oil tank heater as required to maintain a sump temperature of 140° F to 145° F (60 C to 63 C) when the chiller is not running. Micro module 1U3 also monitors sensor 4R7 while the chiller is operating, and will shut down the unit on latching diagnostic b F4 if oil sump temperature reaches 180°F (83 C).

3. Condenser water flow interlock circuit.

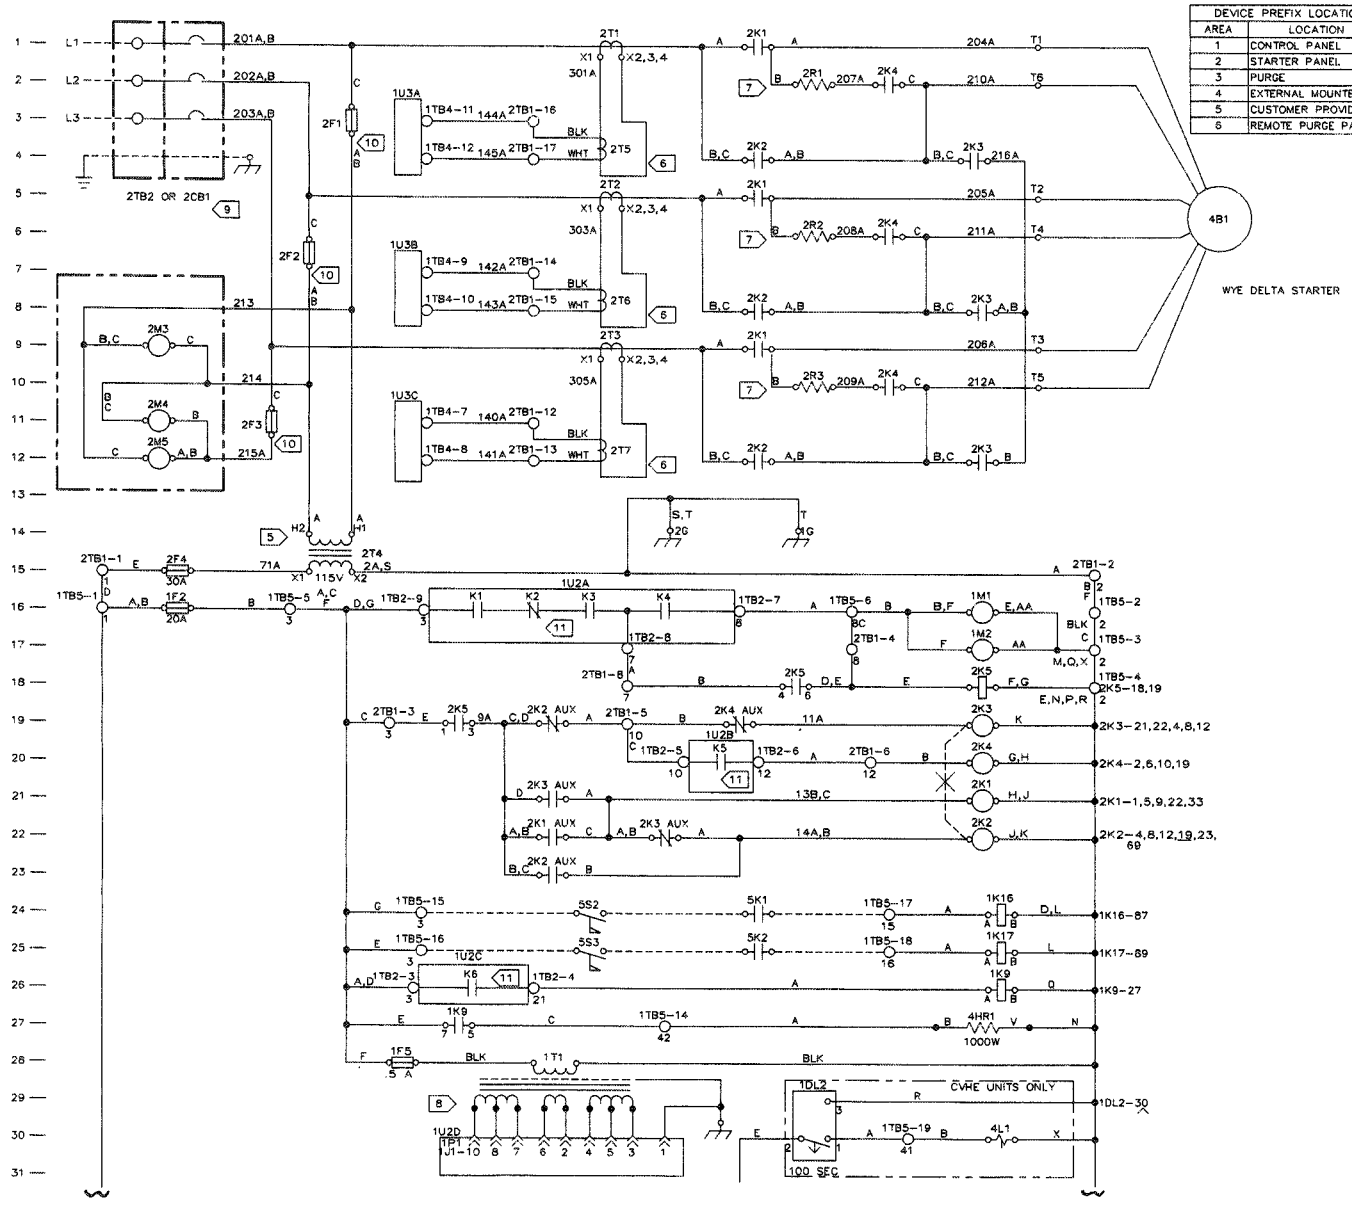
4. Chilled water flow interlock circuit.

5. Starter control circuit.

Chilled and Condenser Water Flow Interlock Circuits

Control voltage passing through fuse 1F2 also energizes the chilled and condenser water flow interlock circuits. Closure of flow switches 5S2 and 5S3 along with the auxiliary contacts of water pump contactors 5K1 and 5K2 in the interlock circuits energizes the chilled and condenser water pump relays (1K16, 1K17). Notice that chilled water pump relay 1K16's normally-open, "proof-of-flow" contacts are connected between Terminals 1TB5-12 and 1TB5-13 in the high-voltage section of the UCP control panel. (See Line 41 in Figure 16.)

Closure of the normally-open set of 1K17 contacts (Figure 16, Line 89) is the UCP's "proof-of-flow" signal for the condenser water circuit. Notice that this set of contacts is located in a low voltage (< 80V) input circuit connected to Terminals 1TB3-22 and 1TB3-23 on micro module 1U3.



Micro Module and "Wye-Delta" Starter Control Circuits

While branch circuit fuse 1F2's micro module and "wye-delta"-type starter control subcircuits are separate, their functions are closely coordinated and are discussed together in the following paragraphs.

120-Volt control power enters power supply output module 1U2 at Terminal 1TB2-9. (See Line 16 of Figure 16.) Logic circuits within micro module 1U3 determine the "net" contact status (open or closed) of reset relay K1, stop relay K2 and overload relay K3 based on input signals sent to 1U3 and its timers.

Individual access to the K1, K2 and K3 relays is not possible; however, the "net state" of all 3 relays is available between Terminals 8 and 9 on terminal block 1TB2. When the "net state" of the K1, K2 and K3 contacts along with condenser high pressure switch 1S1 is closed,

USE COPPER CONDUCTORS ONLY TO PREVENT EQUIPMENT DAMAGE. UNIT TERMINALS ARE NOT DESIGNED TO ACCEPT ANY OTHER WIRING

ATTENTION

UTILISER SEULEMENT DES CONDUCTEURS EN CUIVRE POUR EVITER D'ENDOMMAGER L'EQUIPMENT. LES BORNES NE SONT PAS PREVUES POUR AUTRES TYPES DE FILS CONDUCTEURS.

NOTES:

1. DASHED LINES INDICATE FIELD WIRING BY OTHERS. PHANTOM LINES INDICATE ALTERNATE CIRCUITRY OR AVAILABLE SALES OPTION. CHECK S.O. TO DETERMINE IF WIRING IS REQUIRED FOR SPECIFIC OPTIONS.
2. ALL FIELD WIRING MUST BE IN ACCORDANCE WITH THE NATIONAL ELECTRIC CODE (NEC). STATE AND LOCAL REQUIREMENTS. OTHER COUNTRIES APPLICABLE NATIONAL AND/OR LOCAL REQUIREMENTS SHALL APPLY. ALL WIRING TO 1TB3, 1TB4 & 1TB6 IS LOW VOLTAGE (30 VOLTS MAX) ONLY.

[3] MANUAL RESET IS ACCOMPLISHED BY MOVING THE CHILLER SWITCH, LINE 61, FROM "STANDBY/RESET" TO "AUTO". MANUAL RESET IS ALSO REQUIRED FOR A TRIP-OUT DUE TO THE RUNNING EXTERNAL INTERLOCK, LINE 67.

[4] AUXILIARY TERMINAL CONNECTIONS FOR A CUSTOMER SPECIFIED OR INSTALLED OPERATING STATUS INPUT. TERMINALS 1TB3-16 AND 1TB3-17 MUST BE JUMPERED IF THIS EXTERNAL INPUT IS NOT USED.

5. THE FOLLOWING CAPABILITIES ARE OPTIONAL - THEY ARE IMPLEMENTED AND WIRED AS REQUIRED FOR A SPECIFIC SYSTEM APPLICATION.

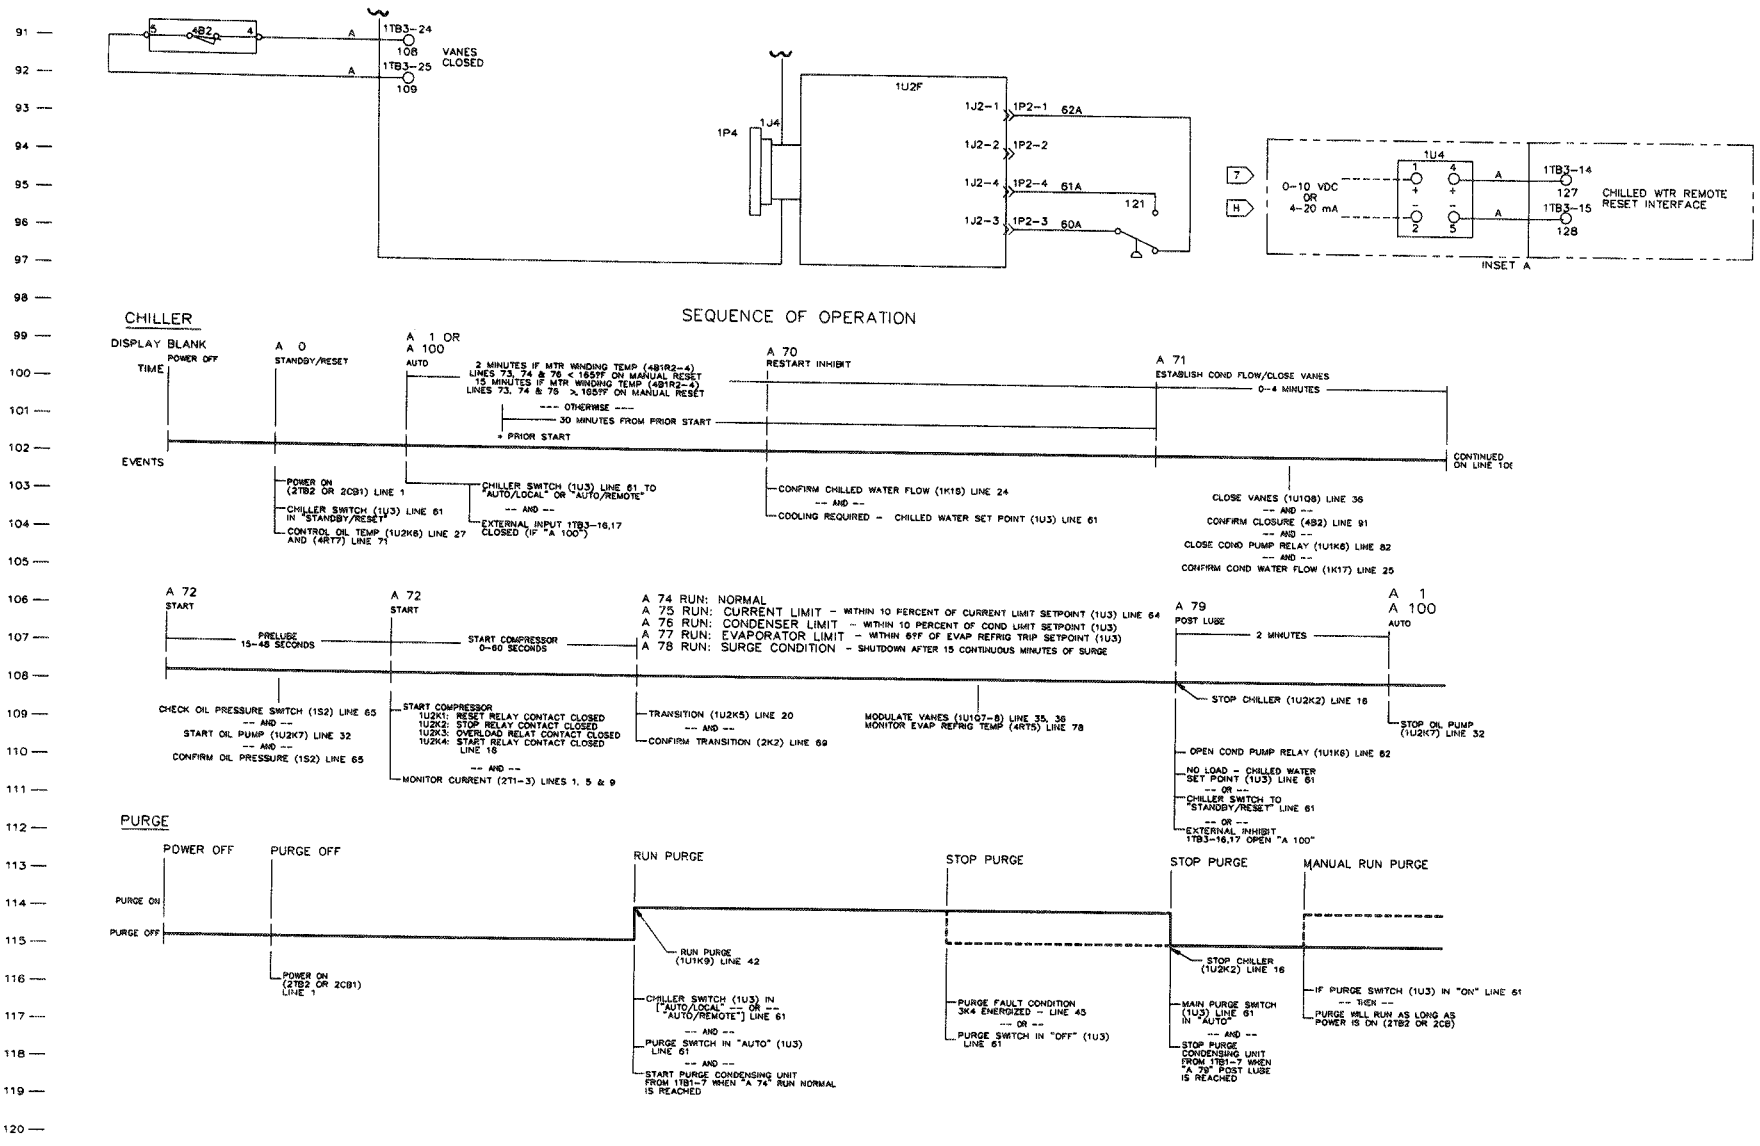
[A] CHILLED WATER RESET- REQUIRES MATCHED PAIR OF THERMISTORS FOR 4RT1 & 4RT2, LINES 67 & 69. IF AMBIENT TEMP BASED CHILLED WATER RESET IS REQUIRED, USE STD SUPPLIED LEAVING EVAP WATER TEMP SENSOR (4RT1 LINE 67) FOR 4RT6 LINE 80 AS AN AMBIENT TEMP SENSOR.

[C] CONDENSER LIMIT CONTROL - FACTORY WIRED AND MOUNTED IN CONTROL PANEL.

[D] BEARING TEMPERATURE SENSORS - FACTORY INSTALLED THERMISTOR, 4RT8 & 4RT9 LINES 77 & 79.

[E] ENTERING EVAP TEMP SENSOR - REQUIRES MATCHED PAIR OF THERMISTORS 4RT1 & 4RT2, LINES 67 & 69.

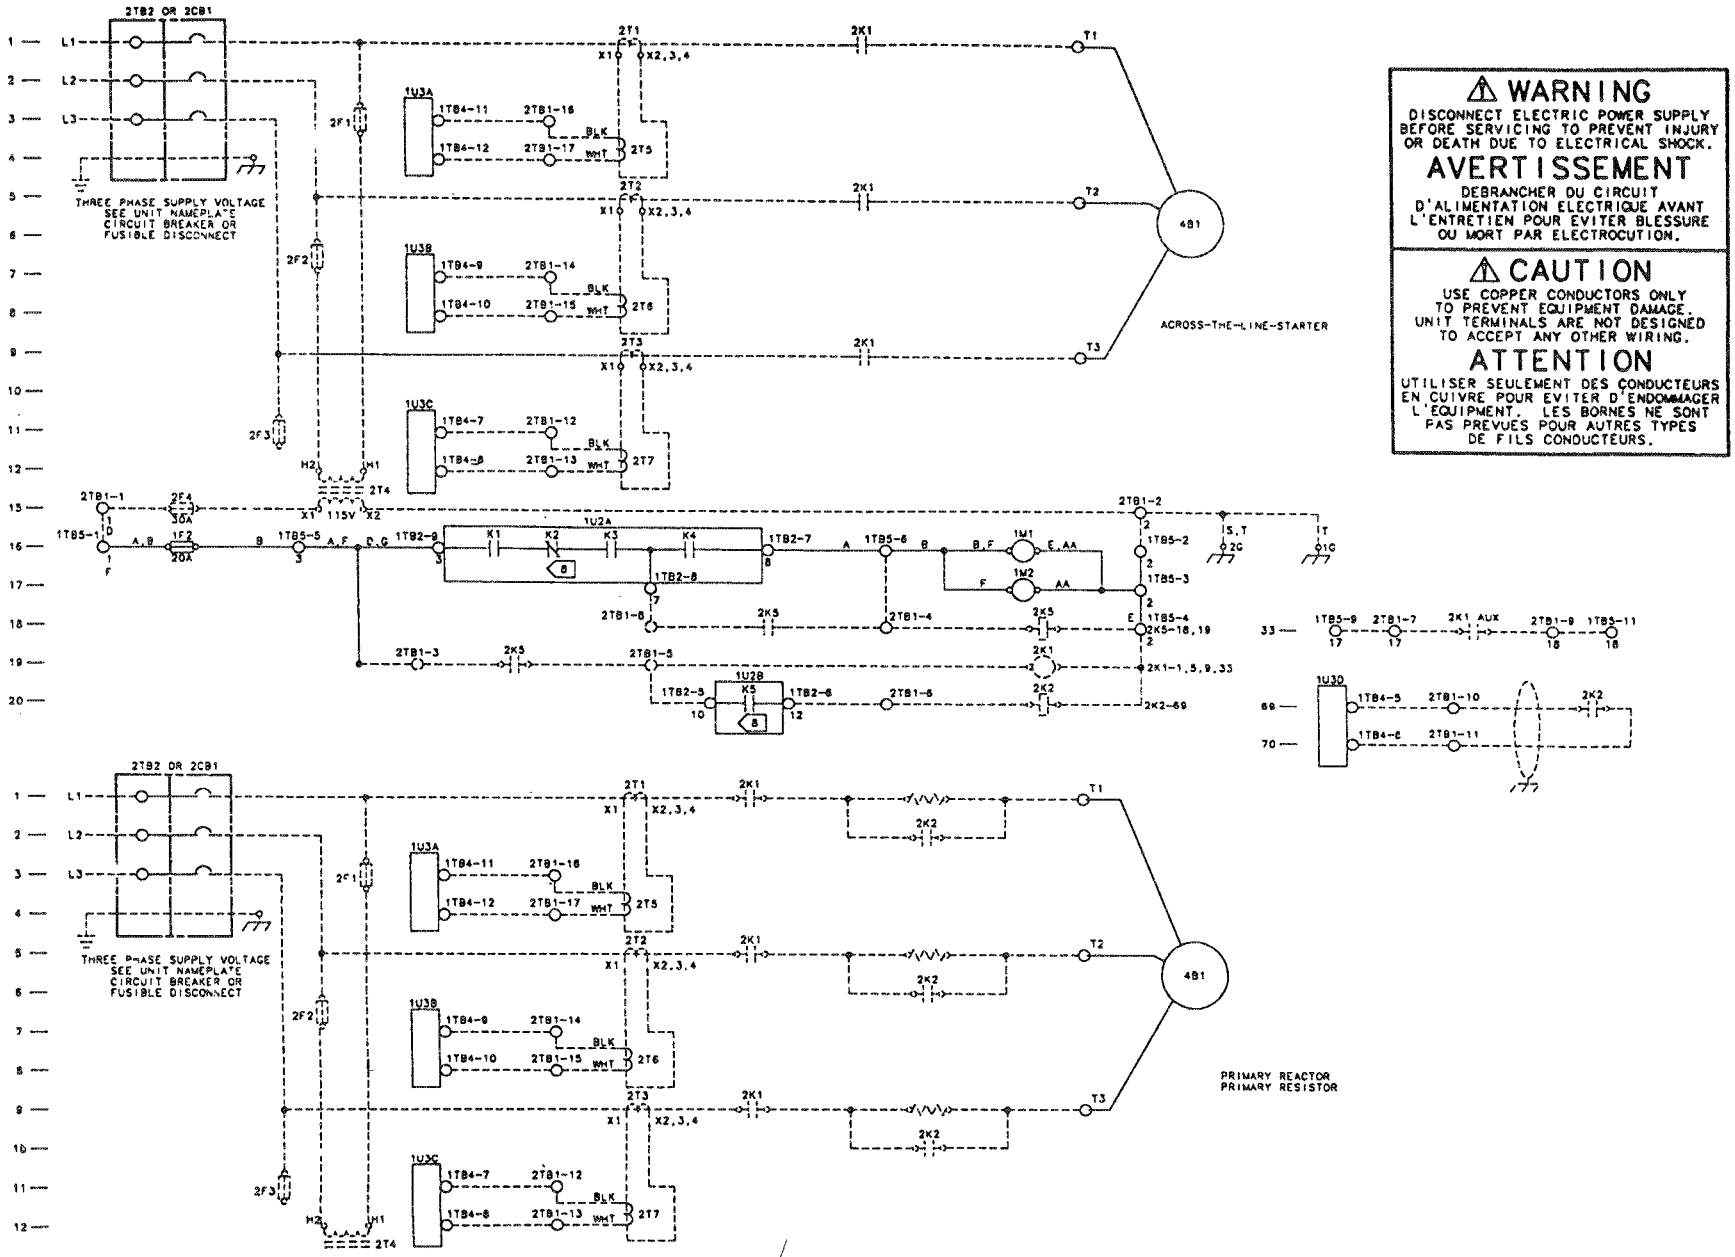
[F] ENTERING AND LEAVING CONDENSER WATER TEMP SENSORS MATCHED PAIR OF THERMISTORS FOR 4RT3 & 4RT4 LINES 71 & 73.



[G] TRACER MONITORING PACKAGE INCLUDES OPTIONS D, E AND F PLUS THERMISTOR FOR 4RT6 LINE 80 TO BE USED AS CONDENSER REFRIGERANT TEMP SENSOR.

[H] REMOTE GENERIC BAS CHILLED WTR RESET INTERFACE--MAY BE FACTORY OR FIELD INSTALLED. CAN NOT BE USED WITH OPTION G.

[6] RELAY COILS NOT SHOWN. CONTACTS ARE CONTROLLED BY THE LOGIC OF THE MICRO-MODULE (1U3). SEE SEQUENCE OF OPERATION LINES 102 - 115.



[7] NEGATIVE SIGNAL INPUTS ARE GROUNDED TO UCP ENCLOSURE. FOR CORRECT OPERATION, EXTERNAL EQUIPMENT SIGNALS SHALL BE ISOLATED OR FLOATING WITH RESPECT TO UCP ELECTRICAL SERVICE GROUND AND ISOLATED FROM EACH OTHER. SPECIAL CONSIDERATION MUST BE GIVEN TO 4-20 mA SIGNALS. IF THE CURRENT SOURCE REGULATES CURRENT FLOW ON THE NEGATIVE LEAD, USE A SEPERATE POWER SUPPLY FOR EACH CHANNEL. IN SOME APPLICATIONS IT MAY BE NECESSARY TO INSTALL A LOOP ISOLATER IN EACH CHANNEL TO PREVENT LOOP INTERFERENCE.

Figure 17 (Concluded)

X39470503C

If cooling is required and all of the conditions required for start-up are met, micro module 1U3 sends a signal to power supply output module 1U2 to close the K4 contacts. This allows control voltage to flow to hour meter 1M1 and start counter 1M2; at the same time, a "start" signal is sent to pilot relay 2k5.

Notice that pilot relay 2K5 has 2 sets of normally-open contacts. The first set (Line 18; Figure 16) closes to lock the pilot relay into the control circuit around the K4 contacts.

Closure of the second set of 2K5 contacts (Line 19) allows control voltage to flow through the normally-closed auxiliary contacts of run contactor 2K2 (2M) and transition contactor 2K4 (1A) to the coil of shorting contactor 2K3 (S).

When shorting contactor 2K3 energizes, its normally-open, auxiliary contacts (Line 21) close; this allows control voltage to flow to the coil of start contactor 2K1.

With 2K1 now energized, its normally-open, auxiliary contacts (Line 22) close; this locks start contactor 2K1 into the control circuit around the auxiliary 2K3 contacts in Line 21 (Figure 16). Power is now supplied to the "wye" ("star") windings of compressor motor 4B1 through start contactors 2K1 and 2K3,

As the compressor accelerates, motor current draw decreases. When current draw drops to 85% of RLA, micro module 1U3 sends a signal to power supply output module 1U2 to close the normally-open contacts of compressor transition relay K5.

This energizes the coil of transition contactor 2K4 and causes its normally-closed set of auxiliary contacts (Line 19) to open.

With the circuit to shorting contactor 2K3 now open, 2K3 de-energizes and its normally-closed., auxiliary contacts (Line 22) reclose to allow control power to reach the coil of run contactor 2K2. Once the auxiliary set of normally-open 2K2 contacts in Line 23 closes, run contactor 2K2 is locked into the control circuit around the auxiliary, normally- open 2K3 and 2K1 contacts (Lines 21 and 22).

A normally-closed set of auxiliary 2K2 contacts also opens in Line 19 to interrupt control voltage to transition contactor 2K4.

Now that the "delta" motor windings are energized, compressor 4B1 is operating in its normal "run" mode; it will continue to do so until the "net state" of the k1, K2 and K3 contacts (Line 16) is open . Once this "open" condition occurs, voltage to pilot relay 2K5 is lost and its contacts reopen.

Any of the following events will result in a "net state" of "open" for contacts K1, K2 and K3, and stop compressor operation:

1. Adjusting the chiller switch to "Standby/Reset";

2. UCP detection of a latching or non-latching diagnostic condition; or,

3. Satisfaction of the cooling requirement (i.e., building load drops to the point where machine operation is no longer practical).

Determination of an actual compressor "stop" point based on satisfaction of cooling demand hinges on the start differential setpoint. the relationship between this setpoint and the UCP's "shutdown" criteria is illustrated in Table 5.

Table 5
CVHE/CVHF
Compressor "Stop" Points

Chiller Delta-T ° F	Rec. Start Differential Setpoint ° F	Chiller Shutdown Point (Degree below Setpoint) ° F
4 or less	2.0	2.0
5 or 6	3.0	2.0
7 or 8	4.0	2.0
9 or 10	5.0	2.0
11 or 12	6.0	2.0
13 or 14	7.0	2.0
15 or 16	8.0	2.0
17 or 18	9.0	2.0
19 or more	10.0	2.0

Note: "Chiller shutdown point" refers to actual leaving chilled water temperature with [illegible] the chilled water setpoing (CWS).

Fuse 1F3 Branch Circuit Oil Pump Circuit

120-Volt control power from control power transformer 2T4 flows through branch circuit fuse 1F3 and Terminal 1TB5-10 to a 6.2 amp fuse (1F1). Fuse 1F1 protects the oil pump motor (4B3) from overamperage conditions.

Current passing through fuse 1F1 reaches 2 normally-open, parallel sets of contacts those of oil pump relay K7 and start contactor 2K1. K7's are located on power supply output module 1U2, but contact status open or closed is governed by micro module 1U3.

Note: While the K7 contacts are automatically closed by 1U3 as a part of the start sequence, they can also be closed manually by adjusting the oil pump switch from "Auto" to "On".

With the K7 contacts closed, vent-line interval timer 1DL2 energizes and closes its set of normally-open contacts for 90 seconds. During this period, closure of vent-line solenoid valve 4L1 isolates the oil sump from the compressor to prevent loss of oil pressure. When the 90-second interval expires, 1DL2's contacts reopen and solenoid valve 4L1 de-energizes to reopen the oil sump vent line.

Closure of the K7 contacts also allows current to pass through the coil of oil pump starter relay 1K8 to the "run" windings of oil pump motor 4B3.

When motor 4B3 first starts, current draw is high; this causes current-sensing relay 1K8 to close its normally-open contacts (Line 31; Figure 16) and "pull in" of pump capacitor 1C1. With this circuit complete, current now flows to the "start" windings of the oil pump motor.

As the pump motor accelerates, its amp draw eventually falls below the "capacitor-enable" threshold of relay 1K8. Once this occurs, 1K8 reopens its normally-open contacts, and power is supplied only to the "run" windings of motor 4B3.

The normally-open, auxiliary 2K1 contacts (Line 33) that parallel those of oil pump relay K7 (Line 32) are located on start contactor 2K1. As soon as 2K1 energizes, these auxiliary contacts close. Notice that completion of this circuit assures that voltage is provided to the oil pump motor as long as the compressor motor is operating.

Oil pump operation ceases when both the K7 (Line 32 and auxiliary 2K1 (Line 33) contacts open.

Vane Actuator Circuit

Control power passing through branch circuit fuse 1F3 and Terminal 1TB5-10 not only energizes the oil pump circuit, but also provides power to the inlet vane actuator circuit. See Figure 16, notice that current enters van actuator motor 4B2 at Terminal 2. (Inset D of this schematic indicates typical, internal actuator wiring.)

Voltage entering the actuator at Terminal 2 passes through a thermal overload protection device to the "open" and "close" sets of actuator motor windings. A capacitor is connected to the opposite ends of these windings to provide the capacitance needed to start and run the vane actuator motor.

Current flowing from the "open" motor winding passes through an end switch and out of the actuator at Terminal M2, while current flowing through the "close" motor winding passes through another end switch and out of the actuator at Terminal M1.

CAUTION: To prevent actuator damage resulting from overheated motor windings, actuator motor end switches must be adjusted to open the motor circuits before the actuator drive arm reaches the end of its travel.

Control of the inlet vane actuator is achieved via 2 Triac switches (Q7, vanes open; Q8, vanes closed) located in relay output module 1U1. Functionally, Q7 and Q8 each operate like a simple set of contacts.

While the operation of both Triacs is automatically governed by micro module 1U3, manual control is possible by positioning the vane control switch at "Load", "Hold" or "Unload".

Note: Manual loading or holding does not take precedence over the current limit (A 75), condenser limit (A 76) or evaporator limit (A 77) modes of operation.

Purge System

Because some sections of the chiller's-refrigeration system operate at less-than-atmospheric pressure, the possibility exists that air and moisture may leak into the system. If allowed to accumulate, these non-condensibles become trapped in the condenser; this increases condensing pressure and compressor power requirements, and reduces the chiller's efficiency and cooling capacity.

The Trane Purifier Purge is the only purge system available for the CVHE/CVHF chiller. The purge is designed to remove non-condensible gasses and water from the refrigeration system. Purifier Purge unit operation, maintenance and troubleshooting is covered by a separate operation and maintenance manual (PRG-OM-4).

Control Options

Note: The typical wiring diagrams show in Figures 18 and 19 are provided only as a general reference. They may reflect the actual wiring of your unit. For specific electrical schematic and connection information, always refer to the wiring diagrams that shipped with the chiller.

Free Cooling

As described in Mechanical Operation, this control option adapts the basic chiller to function as a simple heat exchanger without controlling leaving water temperature.

Free cooling must be initiated manually by adjusting the free cooling switch (Figure 13) to the "On" position. When this is done (and the compressor is running), the UCP issues a "stop" signal and the chiller enters post-lube (operating code A 79).

Note: As soon as post-lube is initiated, the compressor motor and condenser water pump starters de-energize; oil pump operation continues until the 2-minute post-lube cycle expires.

Once post-lube is complete, operating code A 1 appears on the display and micro module 1U3 sends a "close" signal to inlet guide vane actuator 4B2. (Latching diagnostic b FA occurs if vane closure is not established within 3 minutes.)

If the vanes close within 3 minutes, a "start" signal is sent to the condenser water pump; condenser flow switch 5S3 must then close within 3 minutes, or the UCP will shut down chiller operation on latching diagnostic b dC.

See Figure 18 for typical schematics of the free cooling electrical circuits. When the inlet guide vanes are closed and condenser water flow is established, the UCP energizes 4 sets of K1 free cooling relay contacts (Lines 36 through 39) and a set of K2 free cooling relay contacts (Line 90) in relay output module 1U1.

Note: The normally-open K2 contacts (Line 90) provide the owner with the electrical access needed to control auxiliary equipment during the free cooling cycle (e.g., water flow through the cooling tower during the free cooling mode). Actual use of the K2 contacts may vary with any given chiller application.

Two sets of normally closed K1 contacts (Lines 36 and 38) now open while the 2 normally open sets of K1 contacts (Lines 37 and 39) close. This completes the "open" circuits of the free cooling liquid (4B12) and gas (4B23) -line valve actuators. Remember that both valves must open within 3 minutes, or unit operation is locked out on latching diagnostic b F9.

Operating A 9 (free cooling) appears on the display when the UCP verifies that the free cooling valves are open.

Note: UCP control logic prevents the compressor from starting when the chiller is operating in the free cooling mode. Manual control of the inlet guide vanes (via the vane control switch) is also disabled at this time.

Once the chiller functioning in the free cooling mode, powered e cooling switch is adjusted to "Off" and the UCP verifies that the free cooling valves are closed.

Hot Gas Bypass

The hot gas bypass (HGBP) control option is designed to minimize machine cycling by allowing the chiller to operate stably under minimum load conditions. In these situations, the inlet guide vanes are "locked" at a preset minimum position, and unit capacity is governed by the HGBP valve actuator.

Control circuitry (see Figure 19) is designed to allow both the inlet guide vanes and the HGBP valve to close for unit shutdown.

Four control components are associated with the hot gas bypass option:

HGBP Relay 1K15. Located in the UCP695 panel (Figure 13), this relay enables the HGBP valve and inlet guide vanes to close at unit shutdown.

HGBP Transfer Switch 4S4. This single-pole/double-throw (SPDT) limit switch is mounted on the actuator shaft (near the first-stage inlet guide vane linkage), and operates when the vanes pass through a particular minimum setting. It is field adjustable for optimum performance.

HGBP Valve Switch 4B5. Mounted on the hot gas bypass valve actuator, this SPDT limit switch operates when the valve just begins to open. Notice that the "close" limit switch mounted on the HGBP valve actuator (4B5) must be set to operate just after damper end switch 4S4 operates.

Discharge Temperature Switch 4S5. This device is designed to shut down the unit on latching diagnostic b F1 if the discharge temperature exceeds 210 F; (99 C) this prevents the chiller from running at extremely low loads for extended periods of time.

As soon as the power supply disconnect switch or circuit breaker 2CB1 is closed, 120-volt control power is supplied to the HGBP circuit through branch circuit fuse 1F3. Notice that this circuit includes both vane actuator motor 4B2 and HGBP valve 4B5.

Before the compressor "start" signal is sent, micro module 1U3 issues a "vane close" signal by closing Triac switch 1U1Q8. This, in turn, causes both the inlet vane (4B2) and HGBP valve (4B5) actuators to drive closed via the normally closed contacts of HGBP relay 1K15.

Once the inlet guide vanes are closed and the remainder of the start sequence is complete, the auxiliary contacts of start contactor 2K1 (Line 32) close and HGBP relay 1K15 energizes.

Machine start-up is usually followed by a series of "vanes open" signals issued by the UCP through successive closures of Triac switch 1U1Q7. (See "Fuse 1F3 Branch Circuit" in Electrical Sequence of Operation for an explanation of vane actuator operation.) Notice that the "vanes open" signal passes through HGBP valve motor end switch 4B45 (Line 36); this end switch remains closed as long as the HGBP valve is closed.

Continued loading eventually causes Transfer Switch 4S4 to change position so that it closes between vane actuator 4B2's M1 Terminal (Line 34) and Terminal 1TB7-3 (Line 37). Vane actuator 4B2 is now connected "directly" to Triac switches 1U1Q7 and 1UQ8 through 4S4; therefore, any additional loading or unloading dictated by the UCP is performed by 4B2 acting independently of HGBP valve actuator 4B5.

As the unit unloads and the inlet guide vanes again reach the preset minimum position, transfer switch 4S4 closes between Terminal 2 on 4B5 and Terminal 1TB7-3. This completes the HGBP valve actuator's "open" circuit so that any unload signals from the UCP will now drive the HGBP valve open. As soon as this occurs and the HGBP valve opens 4B5's end switch (Line 36) reverses its position and completes the "close" circuit of the HGBP valve actuator.

See Figure 18. Any load signals generated by the UCP must now pass through the "close" circuit of valve actuator 4B5 (Terminals 1-to-3) and through 4B5's end switch (Line 36 to "vanes open" switch 1U1Q7. In this manner, unit capacity is controlled by the HGBP valve actuator, with the inlet guide vanes held at their minimum position.

Once the UCP determines that additional cooling capacity is required, it issues a load signal that causes valve actuator 4B5 to drive the HGBP valve closed.

When the valve reaches the full-closed position, 4B5's end switch (Line 36) returns to its original position and inlet guide vane control is restored to valve actuator 4B2.

If the inlet guide vanes do not open past the minimum position (at start-up) before an unload signal is sent, the unit will use the HGBP valve actuator to control vane movement.

Note: Contact a qualified service technician for proper adjustment of the end switches on HGBP valve actuator 485 and HGBP transfer switch 4S4.

Relay Package

On modules prior to 1991 this UCP control option consists of the addition of 2 relays built into relay output module 1U1; alarm relay K4 and "head-relief request" relay K3. After February 1991 all 1U1 modules have the additional relays and are not an option.

Alarm Relay 1U1K4 activates whenever the UCP detects a latching diagnostic condition (i.e., one that requires manual reset), and provides the electrical access needed for field-installation of a customer-supplied alarm.

See Lines 84 through 87 in Figure 16. Notice that the customer-provided alarm relay (5K3) can either be field-connected between Terminals 1TB1-9 and 1TB1-10 for normally open contacts, or between Terminals 1TB1-8 and 1TB1-10 for normally closed contacts.

'Head-relief" request relay 1U1K3 is designed to be used in conjunction with the UCP's standard surge protection feature, as well as with the condenser limit control option. Its' normally open relay contacts (Figure 16, Line 88) are field-accessible at Terminals 1TB1-11 and -12, and can be used to control or signal for a reduction in entering condenser water temperature.

Designed to prevent high refrigerant pressure trip-outs during critical periods of chiller operation, this UCP option consists of: (1) the manually adjustable condenser limit potentionmeter on micro module 1U3; (2) pressure transducer 1R1; and (3) the associated inter-connecting piping and wiring.

The UCP monitors the condenser pressure registered by pressure transducer 1R1, and then com-press this value to the manually adjusted setting of the condenser limit potentiometer.

Based on these inputs, the UCP modulates inlet guide vane posi-tion accordingly to keep the chiller on-line as long as possible (as the high pressure safety limit is approached).

Note: If the optional relay package option is installed, the head relief request relay may also energize to signal further corrective action (e.g., lowering entering condenser water temperature).

Keep in mind that the UCP's condenser limit control option supplements the protection already provided by condenser high pressure cutout switch 1S1.

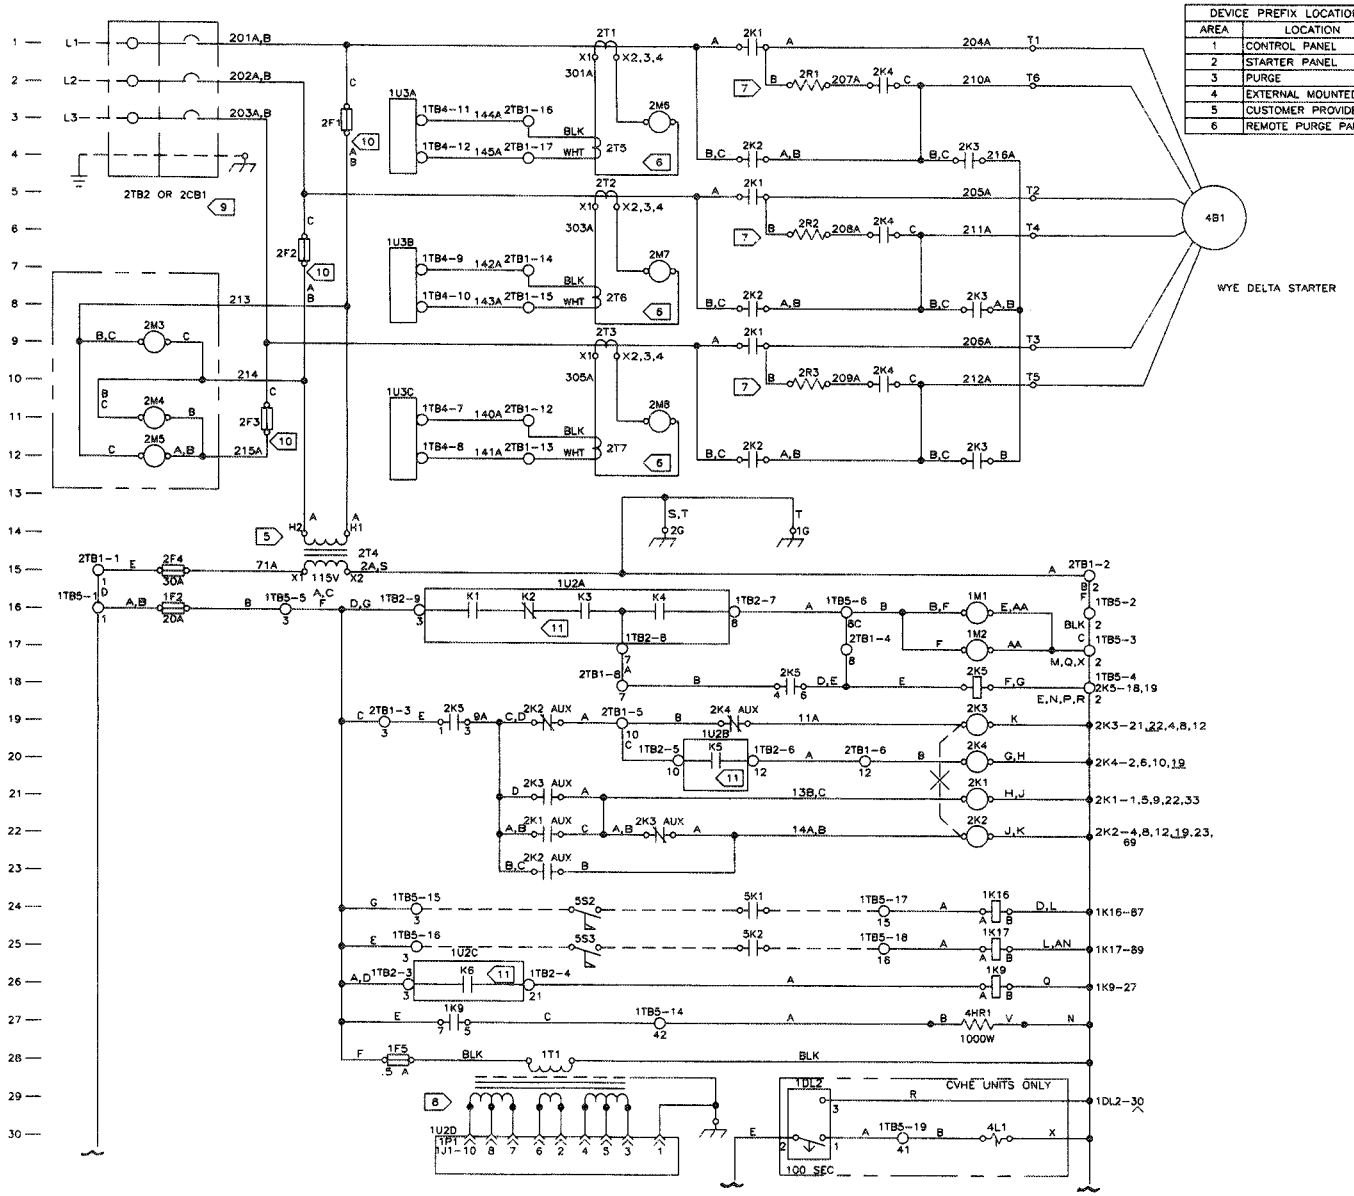
Bearing Temperature Sensors (4RT8, 4RT9)

When this UCP control option is specified, temperature sensors 4RT8 and 4RT9 are factory-installed in the oil return lines of the inboard and outboard compressor motor bearings.

If the temperature registered by either of these sensors reaches or exceeds 180 F (83 C), the UCP shuts down chiller operation on latching diagnostic B EA (high bearing temperature at "Sensor # 1"), or b EA (high bearing tem-perature at "Sensor # 1"), or b EB (high bearing temperature at "Sensor # 2".

Note: 4RT8 is designated as "Sensor # 1". Its sensing element is installed in a well in the inboard bearing oil return line, and the leads are connected to Terminals 1TB4-19 and -20 on micro module 1U3. Designated as "Sensor # 2," 4RT9's sensing element is installed in a well in the oil return line of the outboard bearing; the sensor leads are connected to Terminals 1TB4-21 and -22. (Alternatively, these sensors may be epoxied to the underside of the oil return lines.)

Sensor Options



Along with the factory-installed bearing temperature sensors just described, the following Sensors are available to add at any time.

Entering Evaporator Water (4RT2). Sensor 4RT2 is installed in the water piping entering the evaporator, and is connected between Terminals 1TB3-3 and 1TB3-4 on micro module 1U3.

Entering (4RT3) and Leaving (4RT4) Condenser Water. Sensor 4RT3 is connected between Terminals 1TB3-5 and -6, and registers the temperature of the water entering the condenser. Field-installed in the water piping leaving the condenser, sensor 4RT4 is connected to Terminals 1TB3-7 and -8.

Condenser Refrigerant (4RT6). Sensor 4RT6's sensing element is epoxied to the refrigerant line located between the condenser and condenser/economizer flange, and the sensor leads must be field-connected to Terminals 1TB3-14 and 1TB3-15 on micro module 1U3. Required if controlled by SCP. Read-out is only enabled at a Tracer.

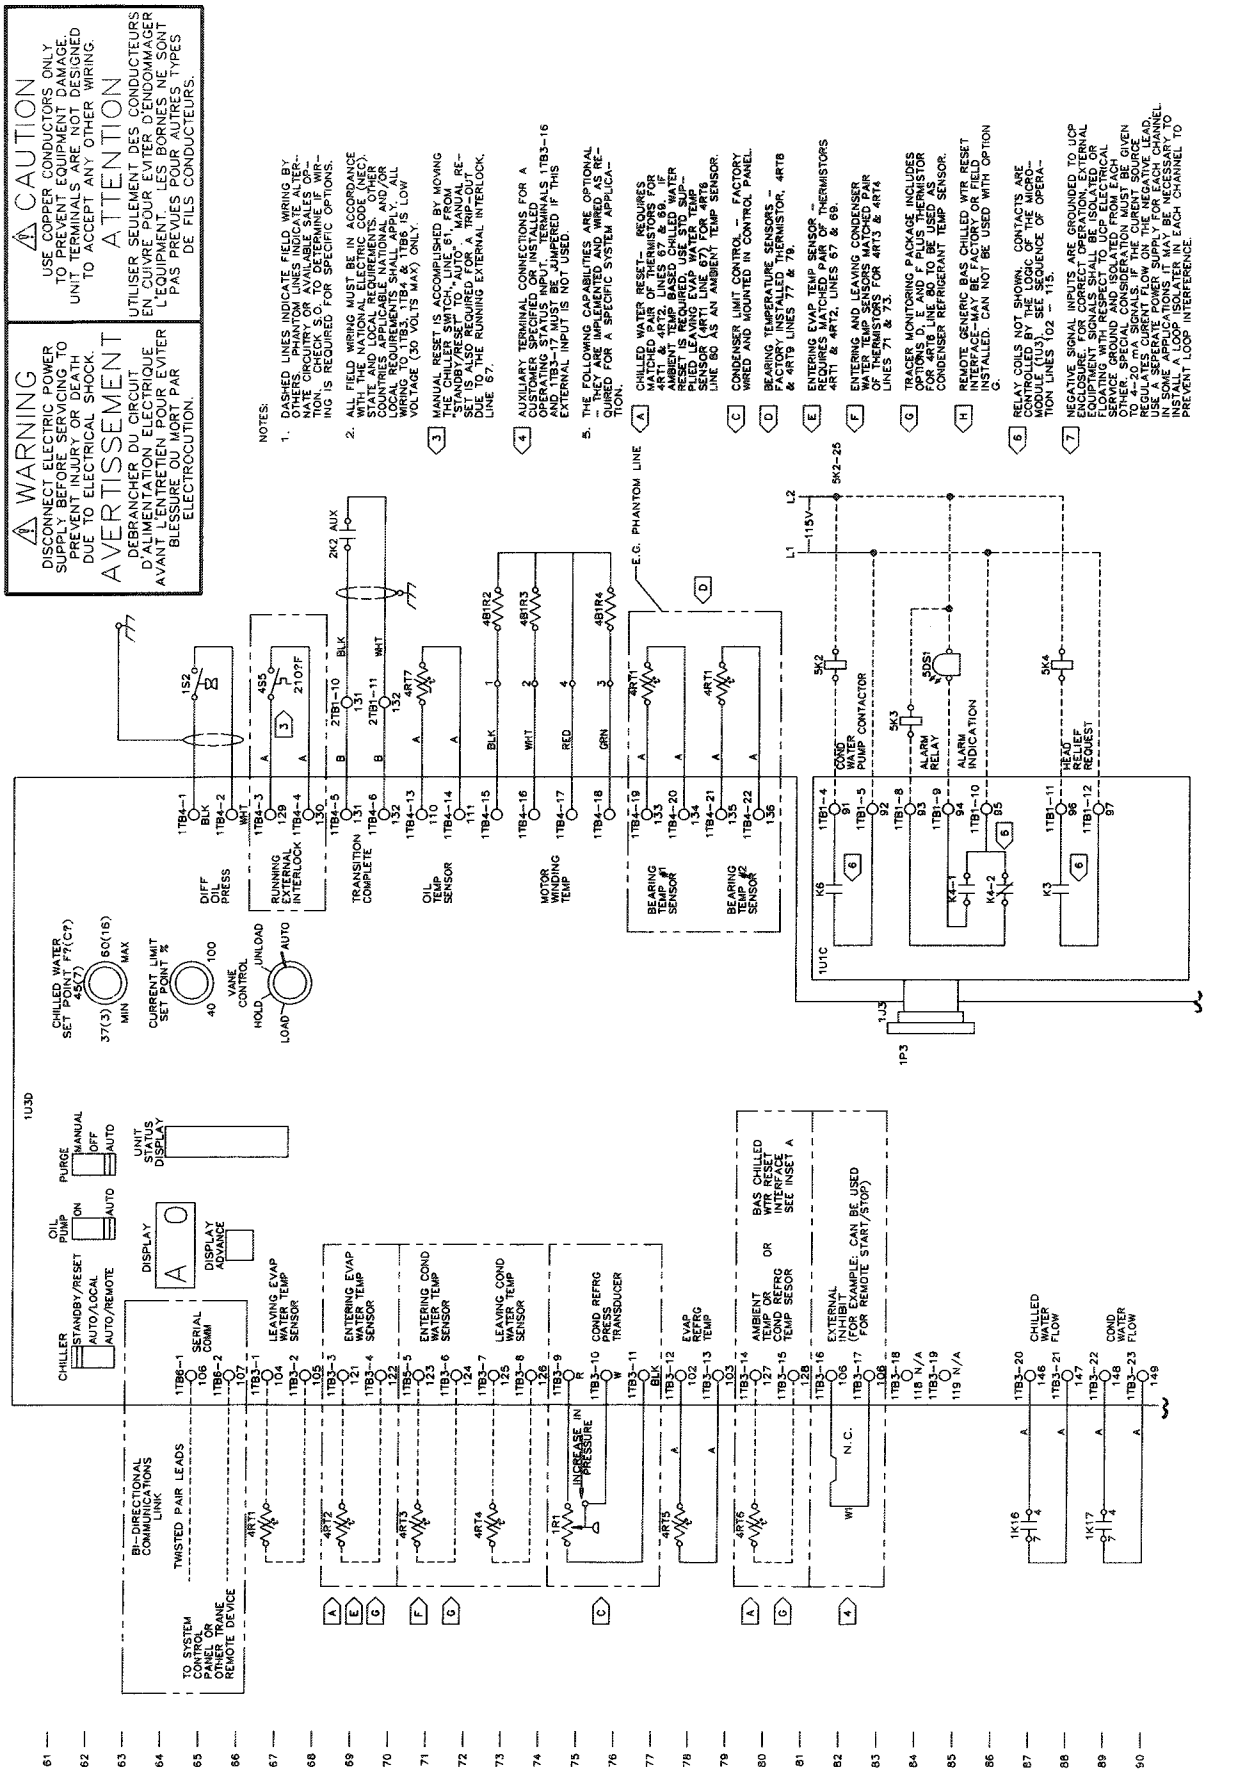
Figure 19 (Continued)



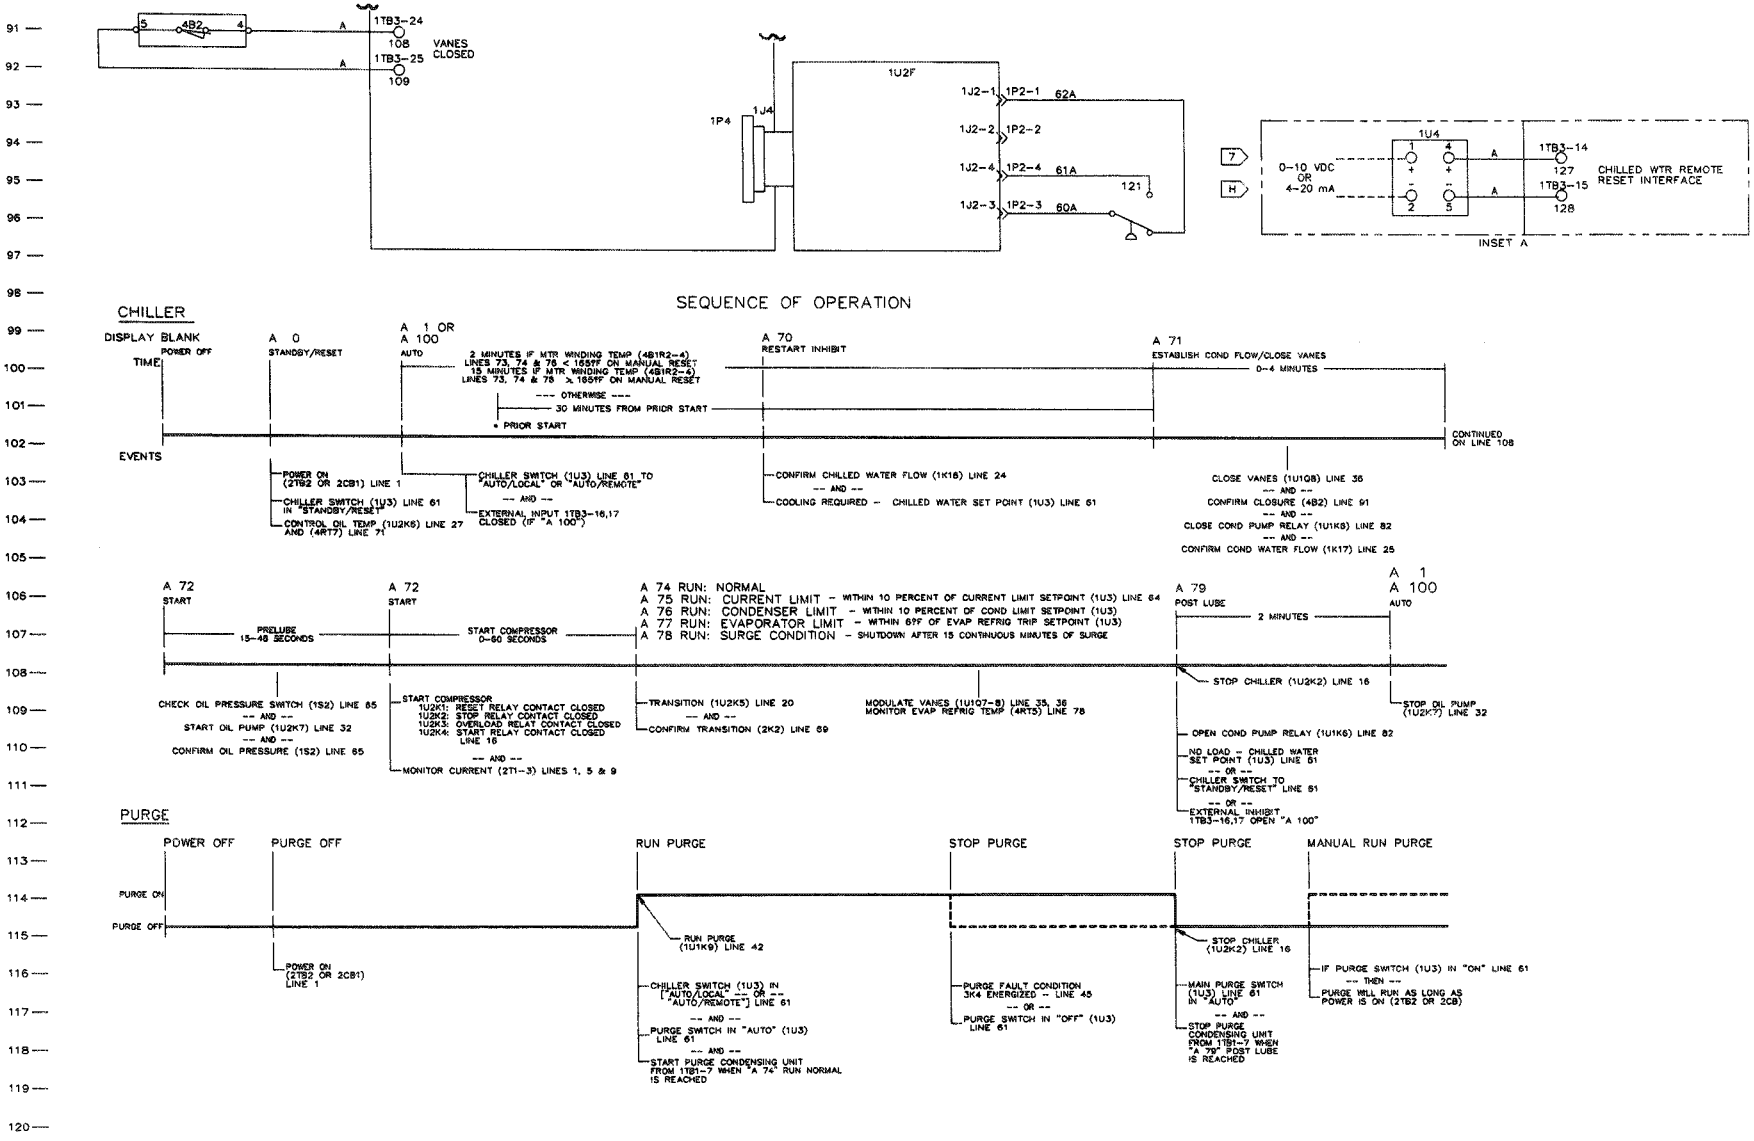


Figure 19
(Concluded)

X39470580C

Serial Communication Interface (SCI)

This UCP control option allows micro module 1U3 to exchange information (e.g., operating parameters, setpoints and commands) with an SCP699 System Control Panel. Figure 20 illustrates how such a communication control network might appear. Notice that twisted-pair connectors are used to establish the communication link between the unit(s) and the SCP.

Additional information about this control option is provided in the installation manual and operator's guide that ships with the SCP699 System Control Panel.

Note: The SCI and chilled water reset (CWR) options are mutually exclusive; that is, a CVHE/CVHF unit cannot be equipped with both SCI and CWR.

Chilled Water Reset (CWR)

Chilled water reset is designed for those applications where the design chilled water temperature is not required at part load. In these cases, the leaving chilled water temperature setpoint can be reset upward using the chilled water reset option.

Optional chilled water reset (CWR) consists of a factory-installed module in the unit control panel and a field-installed temperature sensor. Sensor location is dependent on whether "load" or "ambient" chilled water setpoint rest is desired:

If "load" CWR is selected, the CWAR sensor is field-installed in the return chilled water piping, and connected to Terminals 1TB3-3 and -4 of micro module 1U3.

With selection of "ambient" CWR, the sensor is connected to 1U3 terminals 1TB3-14 and -15, and is typically field-installed just inside the building's fresh air intake duct, or on the north exterior wall of the building. In either case, shelter the sensor from direct sunlight and the elements.

Operator selection of the type of chilled water reset desired for a given application is accomplished at the unit control panel. To access the chilled water reset controls, open the control panel door; the CWR reset type, action and reference knobs are located at the far left of micro module 1U3. See Figure 21.

WARNING: To prevent injury or death due to electrocution, use care when performing control set-ups, adjustments or other service-related operations with power on.

Notice that the conversion tables needed to determine CWR control settings (i.e., Tables A and B) are provided on the face of the micro module, at the immediate right of the current limit setpoint potentiometer. (Both tables are also shown in Figure 21) for your convenience.

Note: There are several important points to consider when using the UCP's optional chilled water reset (CWR) function:

a. To enable the CWR module, be sure to set the chiller switch at "Auto/Remote". (Notice that the "Remote Chilled Water Setpoint" status indicator light is illuminated when the CWR function is active.

b. Once the CWR module sends micro module 1U3 a new chilled water setpoint, it will not issue another setpoint change until the actual leaving chilled water temperature is within 1 F(-17 C) of setpoint for 75 seconds.

c. As long as the chiller switch is set at"Auto/Remote", the CWR function remains active even while the unit is idle!

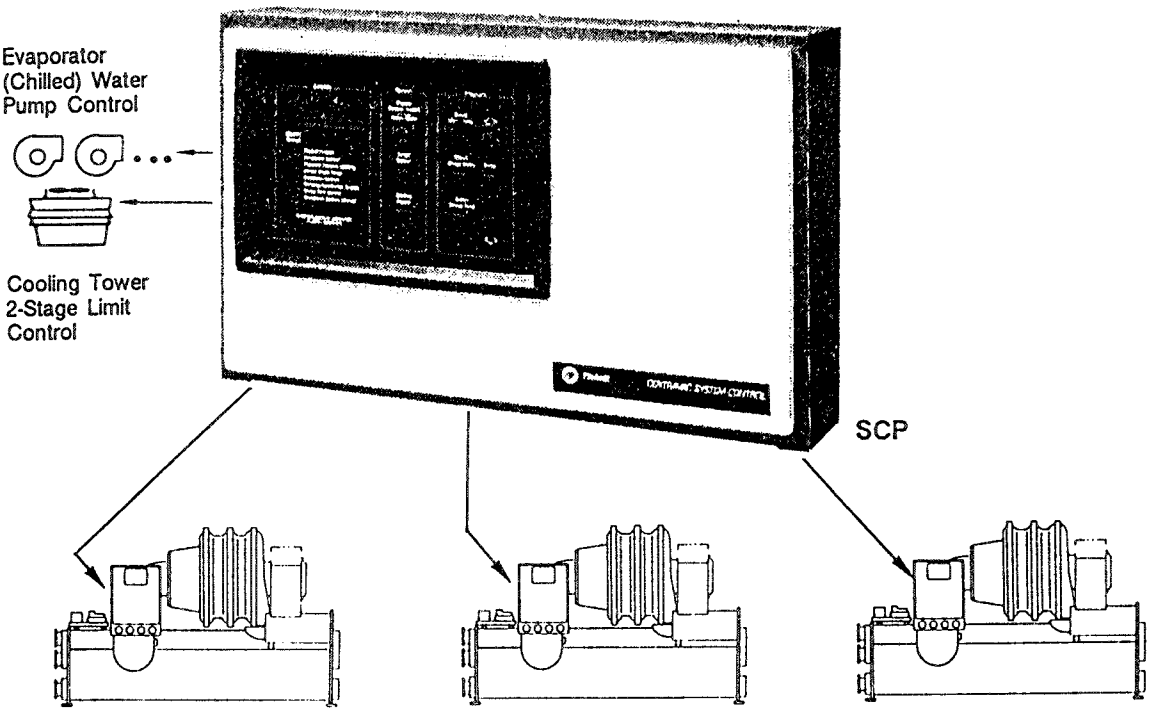
Load-Based CWR

1. Reset Type Knob: Set at "Evap. Delta-T".

2. **Reset Reference Knob:** Set at the design delta-T (DTFL) for the unit. Use Table B (Figure 20) to convert the unit DTFL to a letter code ("A" through "H").

Note: In those instances where the DTFL value falls between the values listed, always use the next lower value.

Example: Chiller A is designed to operate with an entering chilled water temperature (CWT) of 56 F (14 C), and a leaving chilled water temperature of 44 F (8 C).



a. **Determine Chiller A's design Delta-T.**

DTFL = Design Ent. CWT - Design Lvg.
CWT
DTFL = 56 F - 44 F (14 C - 8 C)
DTFL = 12 F (-11 C)

b. **Convert Chiller A's DTFL to a letter code.** Locate 12 F (-11 C) DTFL in Table B under "Evap. Delta-T"; 12 F (-11 C) DTFL = "E".

c. Adjust the reset reference knob to control setting "E".

Figure 21
Micro Control Module (1U3) w/Chilled Water Reset Option

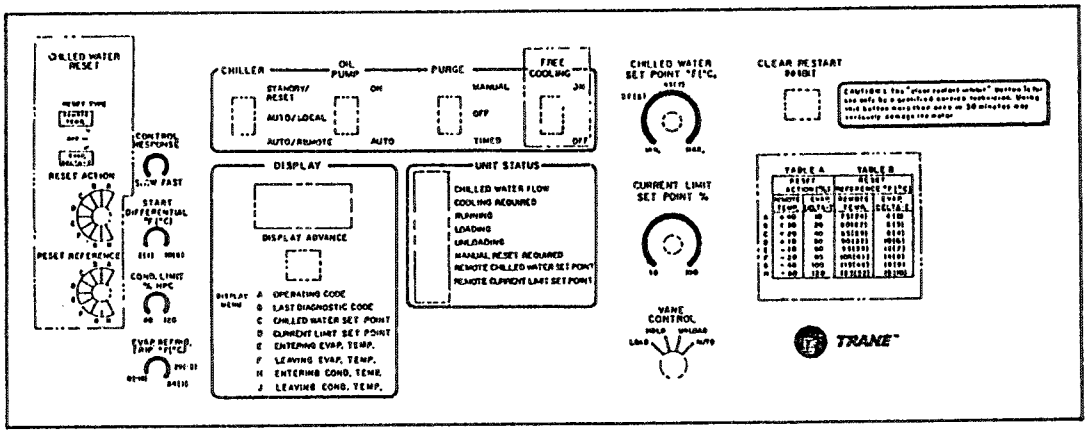

Table A Table B

	Reset Action (%)		Reset Reference F (C)	
	Remote Temp.	Evap. Delta-T	Remote Temp.	Evap. Delta-T
A	+ 40	10	75 (24)	4 (2)
B	+ 30	20	80 (27)	6 (3)
C	+ 20	40	85 (29)	8 (4)
D	+ 10	50	90 (32)	10 (6)
E	- 10	60	95 (35)	12 (7)
F	- 20	80	105 (41)	14 (8)
G	- 40	100	115 (46)	16 (9)
H	- 60	120	125 (52)	18 (10)

Notes:

1. Control option features (i.e., free cooling and chilled water reset) shown above are enclosed in phantom-line boxes.
2. Tables A and B on the above illustration are reproduced in larger type at left.

3. **Reset Action Knob:** Set at the amount of reset desired. Use the following equation and Table A (Figure 21) to determine the amount of reset desired; then convert this amount to a letter code (i.e., "A" thru "H").

RCWS = PCWS + RAS [DTFL - (ENT-LVG)]

Where:

RCWS = Reset Chilled Water Setpoint
PCWS = Front Panel Chilled Water Setpoint
RAS = Reset Action Setpoint
DTFL = Design Delta-T at Full Load
ENT = Entering Chilled Water Temperature
LVG = Leaving Chilled Water Temperature

Notes about this equation:

a. To convert the reset action values in Table A from percentages to decimal values, divide by 100. Decimal values must be used for the RAS variable in the equation.

b. System control will not allow chilled water reset downward even though it is possible in this equation.

c. Increasing the reset action setpoint (RAS) to a larger number results in more reset.

d. If you know how many degrees of chilled water reset are desired (i.e., (RCWS), as well as the DTFL, ENT and LVG, the equation can be rearranged to solve for the reset action setpoint (RAS):

RAS = RCWS - PCWS
[DTFL - (ENT - LVG)]

Review Examples 1 and 2 below to ensure that you understand both: (a) how to calculate a load-based reset chilled water setpoint; and, (b) how this reset value changes with the selected reset reference and reset action control settings.

Example # 1:

DTFL = 10.0 F (-12 C)
PCWS = 45.0 F (8 C)
RAS = 0.5 (i.e., "50" in Table A)

When the unit is operating at full load, ENT is 55F (13 C) and LVG is 45 F (8 C), so:

RCWS = 45 F + 0.C [10 F - (55 F - 45F)]
RCWS = 45 F + 0 F
RCWS = 45 F (8 C)

Since LVG and RWCS are equal (i.e., both are 45 F) (8 C), there is no reset at this full load condition.

If this same unit is only half loaded (i.e., ENT - LVG = 5F) (-15 C), then:

RCWS - 45 F + 0.5 [10 F - 5 F]
RCWS = 45 F = 2.5
RCWS = 47.5 F (9 C)

Example # 2:
DTFL = 10.0 F (-12 C)
PCWS = 45.0 F (8 C)
RAS = 1.0 (e.e, "100" in Table A)

Chiller B is operating at full load, and the delta-T across the evaporator (ENT - LVG) is 10 F (-12 C) , so:

RCWS = 45 F + 1.0 [10 F - 10F]
RCWS = 45 F = 0 F
RCWS = 45 F (8 C)

Under this full load condition, LVG and RWCS are again equal (i.e., both are 45 F) (8 C), so there is no reset.

If this same unit is only half loaded (i.e., ENT - LVG = 5 F) (-15 C), then:

RCWS = 45 F + 1.0 [10 F - 5 F]
RCWS = 45 F + 1.0 [5]
RCWS = 50 F (10 C)

In this situation, the chilled water setpoint will be rest 5 F (-15 C) will be reset 5 F (-15 C) upward, and the chiller will operate with an entering chilled water temperature of 55 F (13 C) and a leaving chilled water temperature of 50 F (10 C).

Notice that an RAS of 1.0 yields a constant return temperature; as unit load varies, the leaving chilled water setpoint is reset so that the entering chilled water temperature is always 55 F (13 C).

Ambient-Based CWR

When ambient-based chilled water reset is desire, the CWR controls must be adjusted as described below:

1. **Reset Type Knob:** Set at "Remote Temp".

2.**Reset Reference Knob:** This knob is used to set the temperature below or above which reset begins (i.e., design ambient). Use Table B (Figure 21) to convert the desired design ambient temperature to a letter code (i.e., "A" through "H").

Example: Chiller A's design ambient temperature is 90 f (33 C) (i.e., chilled water reset is desired if the ambient temperature falls below 90 F) (33 C).

a. Convert Chiller A's design ambient to a letter code. Locate 90 F (33 C) in Table B under "Remote Temp."; 90 F = "D".

b. Adjust the reset reference knob to control setting "D".

3. **Reset Action Knob:** Set at the amount of reset desire. Use the following equation and Table A (Figure 21) to determine the amount of reset desired; then convert this amount to a letter code (i.e., "A" through "H").

RCWS = PCWS + RAS (RRS - AMB)

Notes about this equation:

a. To convert the reset action values in Table A from percentages to decimal values, divide by 100. Decimal values must be used for the RAS variable in the equation.

b. Increasing the RAS to a larger number results in more reset.

c. Using a negative RAS causes the chilled water setpoint to be reset upward whenever the ambient temperature exceeds the design ambient. System control will not allow the chilled water setpoint to be reset downward even though it is possible in this equation.

Review Example 3 to ensure that you understand the correlation between the reset action setting and the reset chilled water setpoint in ambient-based chilled water reset.

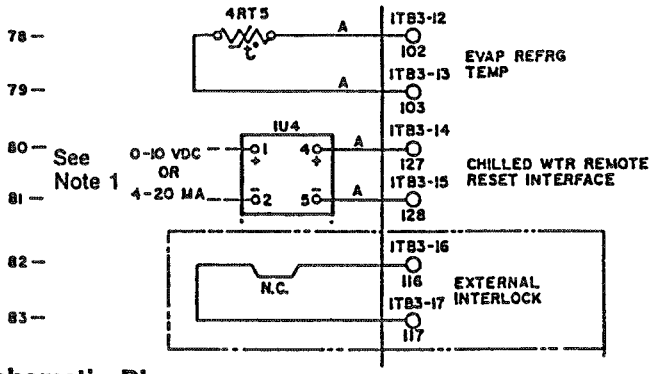
Example # 3

PCWS = 45.0 F (8 C)
RAS = 0.2 (e.e., "20" in Table A)
RRS = 90.0 F (33 C)

When the outdoor air temperature is 80 F (27 C), then:
RCWS = 45 F + 0.2 (90 F - 80 F)
RCWS = 45 F = 2 F
RCWS = 47 F (9 C)

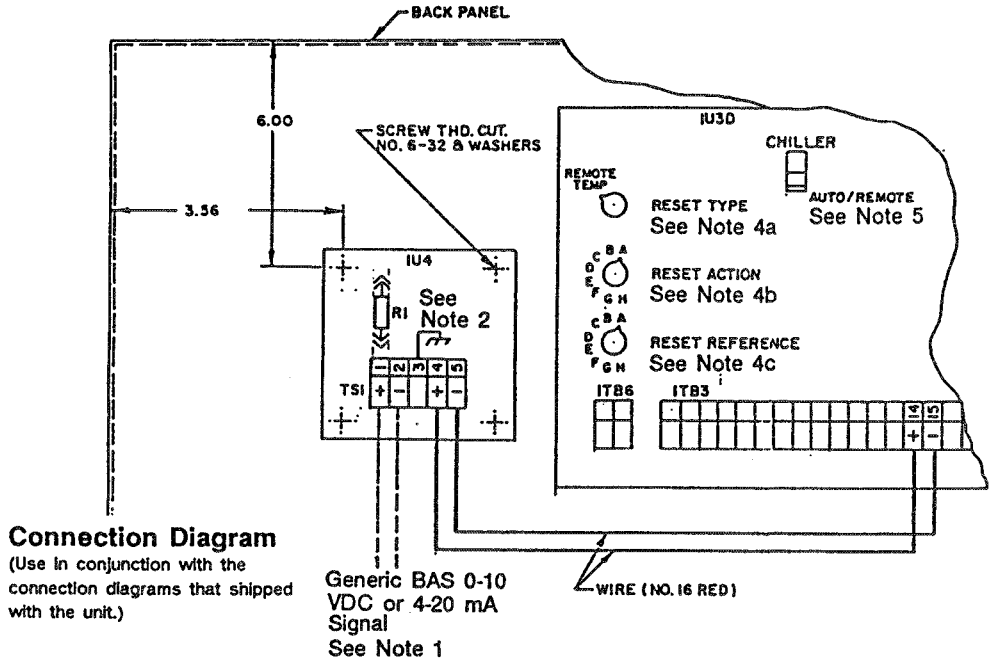
If the outdoor air temperature drops to 70 F (22 C), then:
RCWS = 45 F + 0.2 (90 F - 70 F)
RCWS = 45 F + 4 F
RCWS = 49 F (33 C0

Thus, a RAS of 0.2 (i.e., + 20%) provides 2 F of reset for every 10 F drop in outdoor air temperature below the design ambient.



Remote Generic BAS/CWR Interface

In CVHE applications where the operator wishes to use a generic building automation system (BAS) to reset the chilled water setpoint, a "chilled water reset interface" module (1U4) must be either factory- or field-installed inside the UCP enclosure.



Once installed, the interface module "converts" a 0-10 VDC (or a 4-20 mA) output signal from the generic BAS to a usable input for the CWR module.

A special "customer information" drawing accompanies each CVHE/ CVHF unit equipped with the generic BAS/CWR interface option. the wiring information operational data included on this drawing are shown in Figure 22.

0.45 (0.25)	0.90 (0.50)	1.35 (0.75)	1.80 (1.00)
0	0	0	0

Note: The chilled water setpoint will be reset in integer F only.

RCWS = Reset Chilled Water Setpoint
PCWS = Front Panel Chilled Water Setpoint

(1) RCWS = PCWS

(2) RCWS - PCWS = Reset Action x (-18.3 ÷ 9.50 VDC)
or
RCWS - PCWS = Reset Action x (-18.3 ÷ 4.75 mA)

(3) RCWS - PCWS = Reset Action x (-9.9 ÷ 6.010 VDC)
or
RCWS - PCWS = Reset Action x (-9.9 ÷ 3.005 mA)

Notes:
1. Negative signal inputs are grounded to the UCP's enclosure. For correct operation, external equipment signals must be isolated or floating with respect to the UCP's electrical service ground.
2. Remove resistor R1 when a 0-10 VDC input is used.
3. Dashed lines (- - - -) represent field-installed wiring.
4. To activate the remote generic BAS/CWR interface, complete these micro module (1U3D) control adjustments:
   a. Set "Reset Type" at the "Remote Temp." position.
   b. Set "Reset Action" to "A", "B", "C" or "D". (Refer to the chart at left to determine the appropriate setting.)
   c. Set "Reset Reference" to the "A" position.
5. To enable the remote generic BAS/CWR interface, the UCP's chiller switch must be set at "Auto/Remote".
6. Maximum continuous input = 15 VDC (30 mA); minimum continuous input = -4 VDC (-8 mA). (Below these values, diagnostic code b AE will appear on the micro module [1U3D] display.)
7. When the chiller is not running, the micro module (1U3D) setpoint "steps" toward the desired generic BAS setpoint at a rate of approximately 1 F (0.55 C) per second.

When the chiller is running, 1U3D's setpoint is changed by 1 F (0.55 C) only when chilled water temperature is "in control" for 75 seconds. ("In control" is defined as the 1U3 setpoint ± X, where X varies from 0.8 to 1.6 F (0.44 to 0.88 C) based on the micro module's differential-to-start setting.

4533-2379-0A

Unit Start-up Procedures

Daily Unit Start-Up

Note: Refer to Figures 23 and 24 for UCP Start-Run-Shutdown sequence and UCP timing functions.

1. Start the chilled water pump if it was turned off at the end of the previous day.

While the chiller switch is positioned at "Standby/Reset", the UCP checks for closure of the chilled water flow switch (5S2). Illumination of the "Chilled Water Flow" status indicator light indicates that flow is established.

If flow switch 5S2 fails to close or if it reopens following a closure diagnostic b ED appears on the display.

2. Check the oil tank oil level; the level must be visible in or above the lower sight glass. Also, be sure to check the oil tank temperature; normal oil tank temperature before start-up is 140°F to 145° F (60 to 63 C).

Note: the oil heater is energized whenever power is supplied to the unit and the oil temperature is less than 140°F (60 C).

3. Verify that the vane control knob and oil pump switch are positioned at "Auto", and that the purge switch is set at "Timed".

Note: Unit start-up will not occur if the oil pump switch is in the "On" position.

4. If the chiller is equipped with the free cooling option, ensure that the free cooling switch is in the "Off" position.

5. Check the chilled water setpoint and readjust it, if necessary. (Setpoint value can be observed by pressing the advance menu button until code prefix "C" appears on the display.)

6. If necessary, readjust the current limit setpoint. (To determine the setpoint value, press the advance menu push-button until code prefix "d" appears on the display.)

7. Adjust the 3-position chiller switch from "Standby/Reset" to "Auto/Local" or "Auto/Remote". (The operating code appearing on the display changes from A 0 to A 1.) the UCP operation and timing functions are illustrated in Figures 23 and 24.

As state goes from A0 to A1 or A70, the logic passes through A88 briefly. As A88 is flashed all safety sensors are checked for short circuits and open circuits. If a sensor is bad, a latching diagnostic will occur indicating which sensor.

The UCP also checks compressor motor winding temperature, and a 4-minute delay is initiated if the winding temperature is less than 165° F. If it is greater than 165° F, however, a 15-minute delay period begins.

Next, the UCP checks the leaving evaporator water temperature and compares it to the chilled water setpoint. If the difference between these values is less than the start differential setpoint, cooling is not needed.

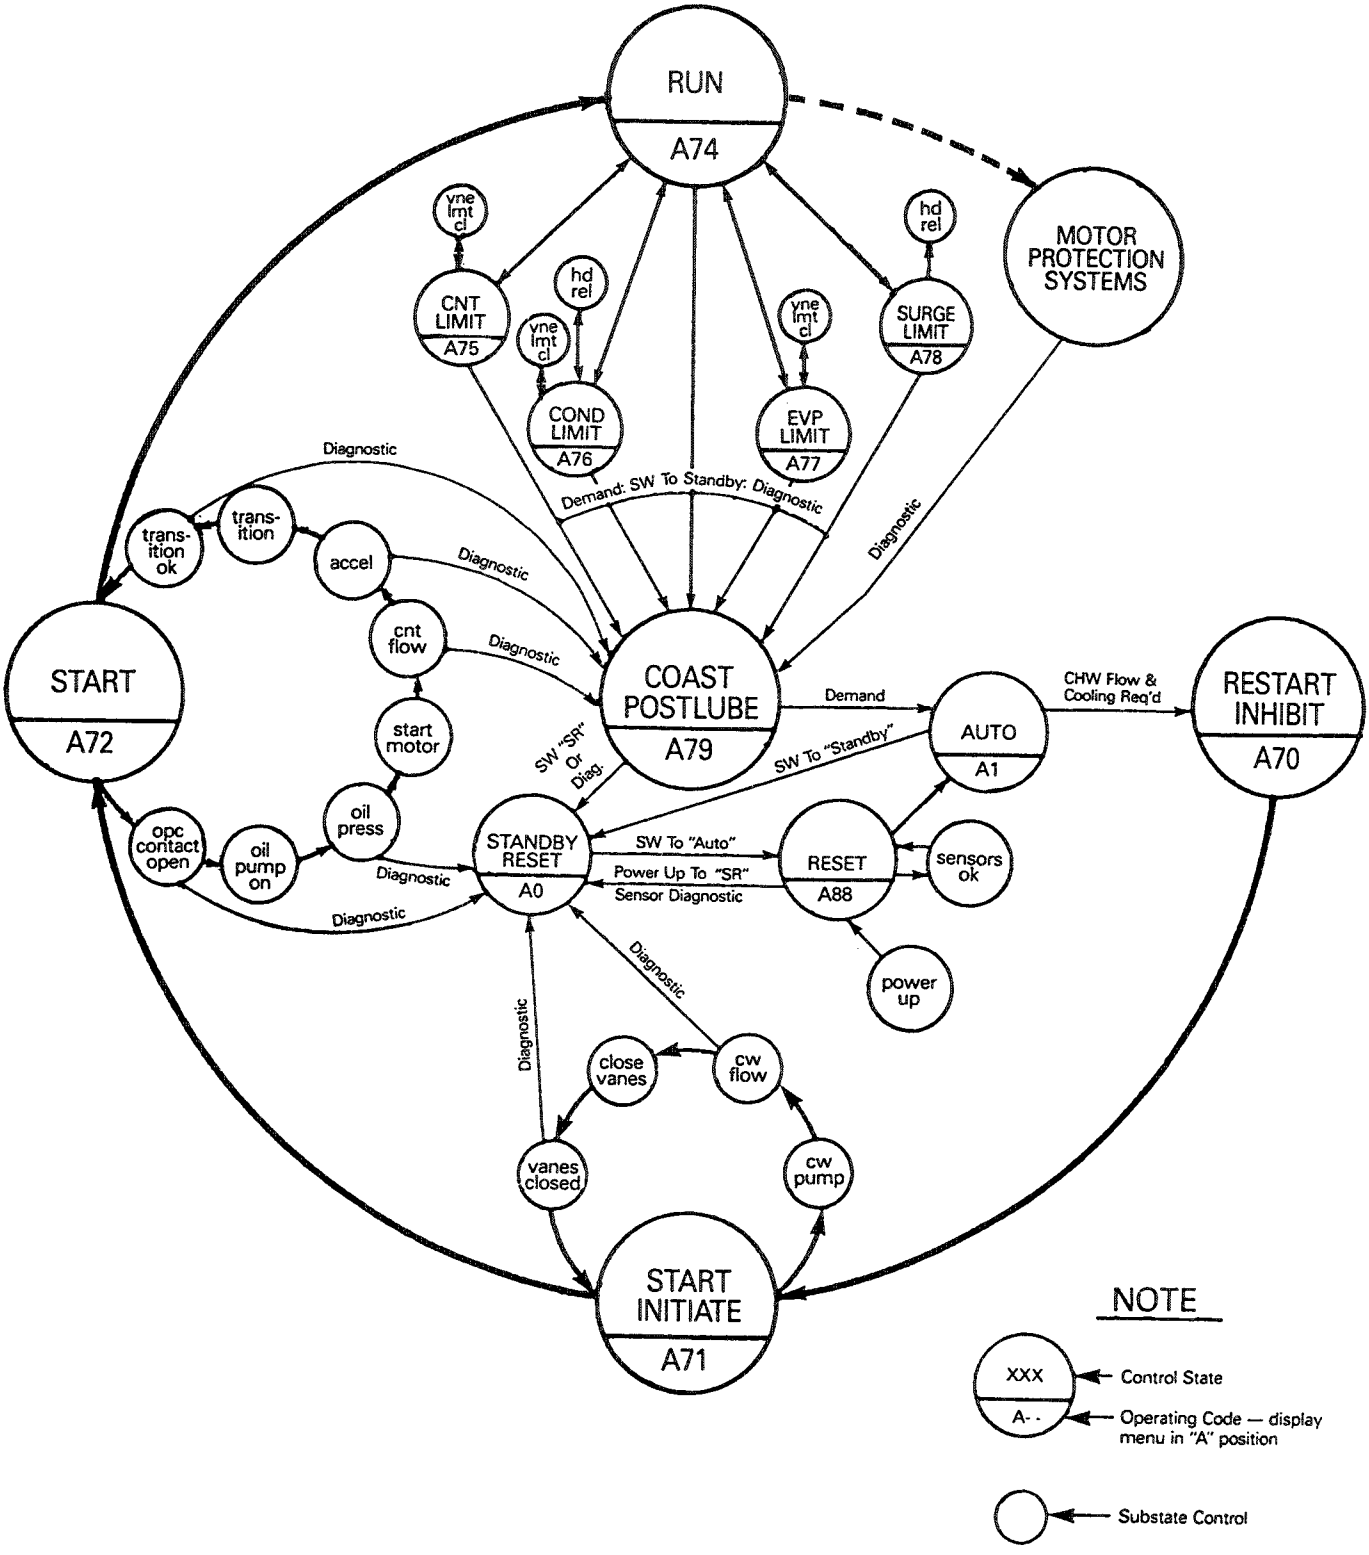
If the UCP determines that the difference between the evaporator leaving water temperature and chilled water setpoint exceeds the start differential setpoint, the unit enters the restart inhibit mode, and the "Cooling Required" status indicator light illuminates.

At the end of the restart inhibit period, the UCP issues a signal to start the condenser water pump. The operating code appearing on the display changes from A 70 to A 71 as the UCP checks for condenser water flow. If flow is not proven (i.e., flow switch 5S3 does not close) within 3 minutes, the unit is locked out; latching diagnostic b dC will flash alternately with operating code A 71 on the display.

With condenser water flow established, the UCP checks the position of the inlet guide vanes; they must be closed before a start sequence can occur. If the vanes are open, the UCP sends a "close" signal to the actuator. A latching diagnostic (i.e., b FA flashing alternately with operating code (A 71) occurs if vane closure is not established within 3 minutes.

Once the inlet guide vanes are closed, the unit enters the start mode (A 72) and the UCP sends a signal to begin oil pump operation. (In addition, an interval timer energizes at this time to close a solenoid valve in the oil sump vent line for a 2-minute period.)

Figure 23 UCP Start-Run-Shutdown Sequence



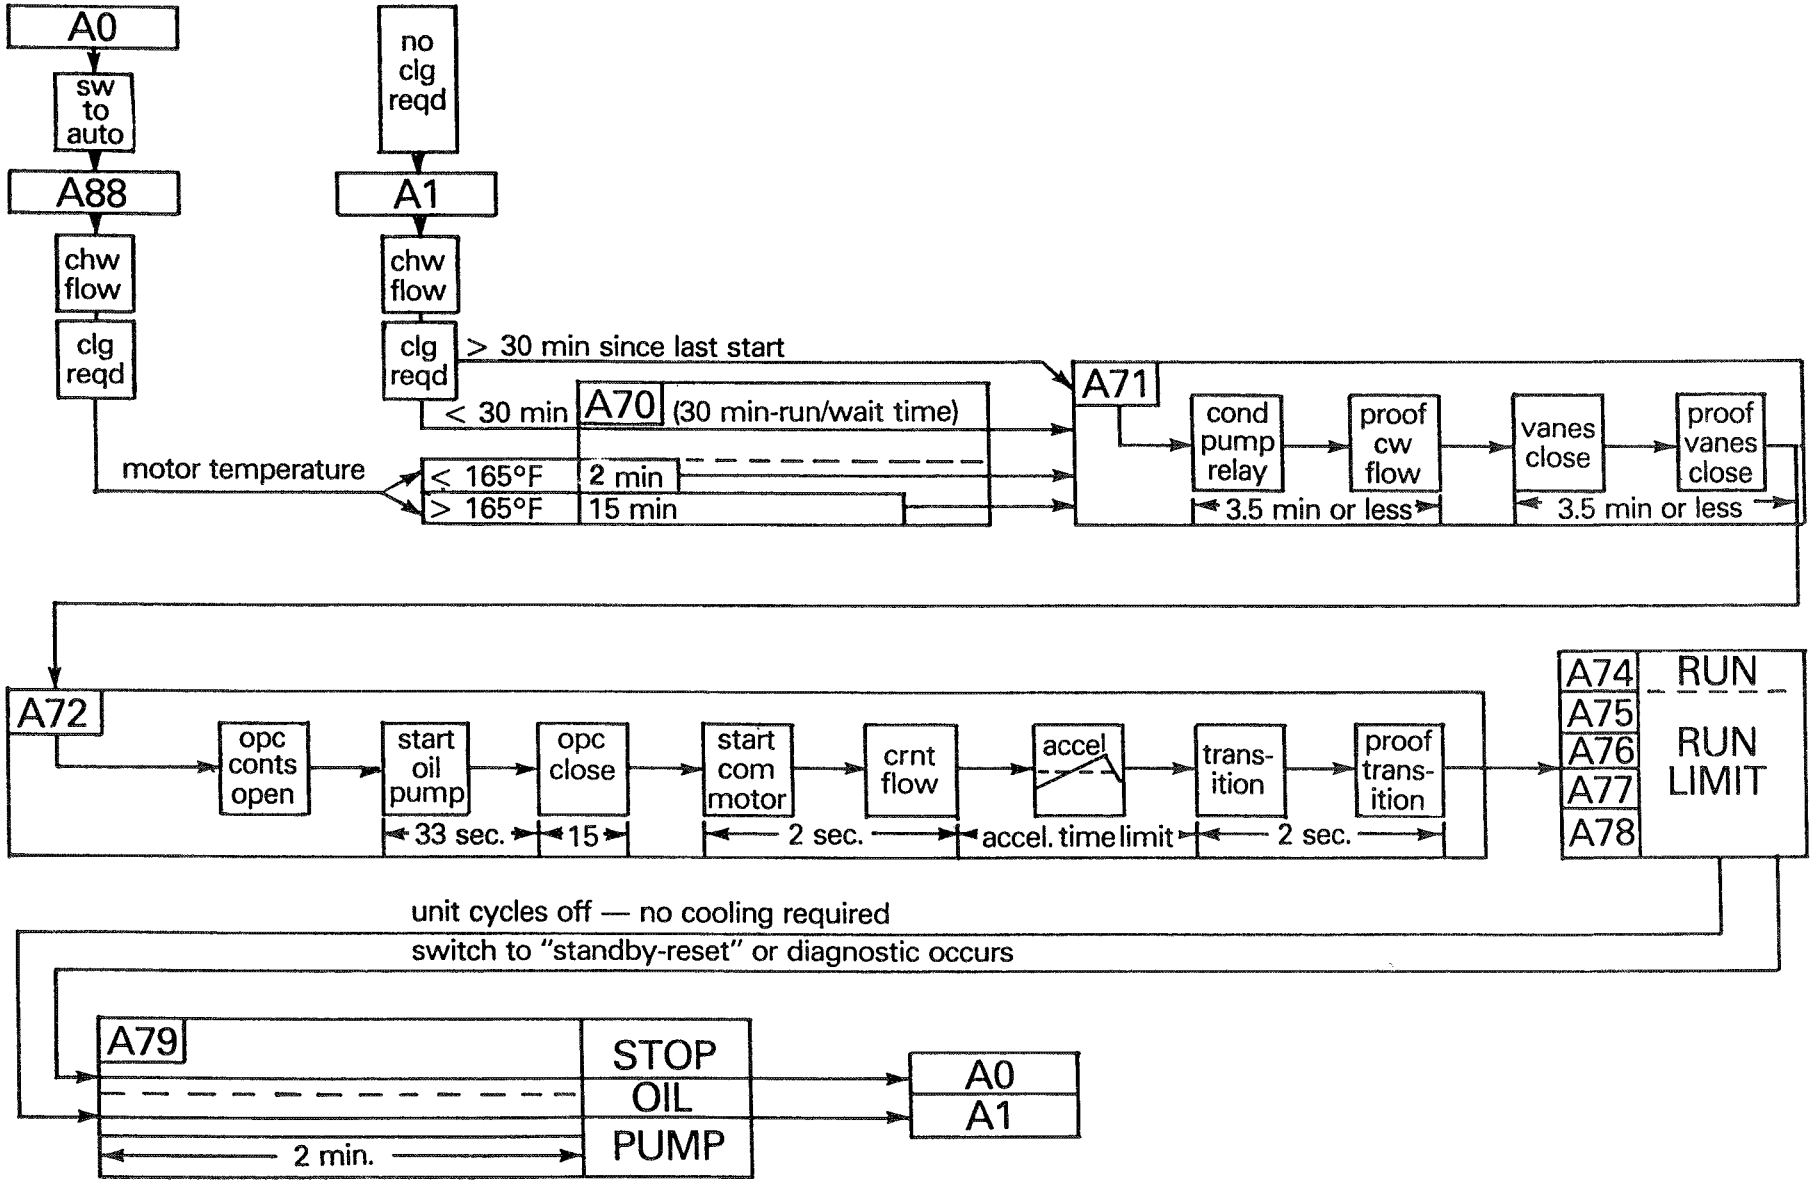


Figure 24
UCP Timing Functions

Sufficient oil pressure (i.e., 15 ± 1 psid) must be confirmed within 33 seconds, or the unit locks out on low oil pressure. (Latching diagnostic b F2 will flash alternately with operating code A 72 on the display.) A 15-second prelube cycle begins when oil pressure is successfully established.

Note: Since (a) "sufficient" oil pressure may be confirmed at any point during the 33-second "oil pressure overdue" timing interval, and (b) the 15-second "prelube" period begins only when sufficient oil pressure is sustained, the actual time required to "establish oil pressure" and "prelube" can be 15 to 48 seconds.

At the end of the prelube period, the UCP sends a start signal to the compressor motor. Within 2-seconds, 3 phases of current in the correct phase sequence must be detected if there is no current 1 or 2 phases missing, or reverse electrical sequence diagnostics will occur within the maximum acceleration time setpoint and proof of transition must occur within 2-second s of transition initiation, or unit start-up is aborted. (If this occurs, the unit goes into the post-lube mode--A 79--and coasts to a stop. Latching diagnostic b EE or b F0 will flash on the display.)

If the compressor motor starts and accelerates successfully, operating code A 74 (Run: Normal) appears on the display and the "Running" status indicator light illuminates. At this time the purge unit will start operating on "Automatic" and will continue to operate as long as chiller compressor is running.

Note: Whenever the UCP detects a latching diagnostic condition during start-up, unit operation is locked out and manual reset is required before the start-up sequence can begin again. If the fault condition has not cleared, the UCP will not permit restart. Remember that a manual reset erases the diagnostic code identifying the fault; the display will only show operating code A 0, with no indication of what the problem was.

When the cooling requirement is satisfied, the UCP originates a "stop" signal and the unit enters a 2-minute post-lube (A 79) period. the compressor motor and condenser water pump starters are de-energized immediately, but the oil pump continues to run during this 2-minute interval; the "Running" status indicator light also remains lit during this period.

Once the post-lube cycle is complete, the unit returns to the auto (A 1) mode.

Seasonal Unit Start-Up

Note: Refer to Figures 23 and 24 for UCP Start-Run-Shutdown sequence and UCP timing functions.

1. Close all drain valves, and re-install the drain plugs in the evaporator and condenser headers.

2. Service the auxiliary equipment according to the start-up/maintenance instructions provided by the respective equipment manufacturers.

3. Vent and fill the cooling tower, if used, as well as the condenser and piping. At this point, all air must be removed from the system (including each pass). Then close the vent valves in the condenser water boxes.

4. Open all of the valves in the evaporator chilled water circuit.

5. If the evaporator was previously drained, vent and fill the evaporator and chilled water circuit. When all air is removed from the system (including each pass), close the vent valves in the evaporator water boxes.

6. Lubricate the external vane control linkage.

7. Check the adjustment and operation of each safety and operating control.

8. Close all disconnect switches.

WARNING: To prevent injury or death due to electrical shock or contact with moving parts, use care when measurements, adjustments, or other service-related operations are performed with power on.

9. Start the chilled water pump. While the chiller switch is set at "Standby/Reset", the UCP checks for closure of the chilled water flow switch (5S2), illumination of the "Chilled Water Flow" status indicator light indicates that flow is established.

If flow switch 5S2 fails to close or if it reopens following a closure diagnostic bEd appears on the display.

10. Check the oil tank oil level; the level must be visible in or above the lower sight glass. Also, be sure to check the oil tank temperature; normal oil tank temperature before start-up is 140 to 145 F (60 to 63 C).

Note: Unit start-up will not occur if the oil pump switch is in the "On" position.

11. If the chiller is equipped with the free cooling option, ensure that the free cooling switch is in the "Off" position.

12. Check the chilled water setpoint and readjust it, if necessary. (Set point value can be observed by pressing the advance menu button until code prefix "C" appears on the display.

13. If necessary, readjust the current limit setpoint. (To determine the setpoint value, press the advance menu push-button until code prefix "d" appears on the display.)

14. Adjust the 3-position chiller switch from "Standby/Reset" to "Auto/Local" or "Auto/Remote".

Unit Shutdown Procedures

Daily Unit Shutdown

Note: Refer to Figures 23 and 24 for UCP Start-Run-Shutdown sequence and UCP timing functions.

1. Adjust the chiller switch to the "Standby/Reset" position.

2. If desired, turn off the chilled water pump.

Seasonal Unit Shutdown

Note: Refer to Figures 23 and 24 for UCP Start-Run-Shutdown sequence and UCP timing functions.

1. Adjust the chiller switch to the "Standby/Reset" position.

2. If desired, turn off the chilled water pump at the pump's push-button station. (Or, stop chilled water flow by the means devised for this particular application.)

3. Open all disconnect switches except the control power disconnect switch.

WARNING: To prevent injury or death due to electrical shock or contact with moving parts, use care when servicing system with power on.

Caution: Control power disconnect must remain closed during entire shutdown period to allow oil sump heater operation. This prevents refrigerant from condensing in oil sump.

4. Drain the condenser piping and cooling tower, if used.

5. Remove the drain and vent plugs from the condenser headers to drain the condenser.

6. Once the unit is secured for winter, the maintenance procedures described under "Annual Maintenance" in the Periodic Maintenance section of this manual should be performed by qualified Trane service technicians.

Note: During extended shutdown, be sure to operate the purge unit for a 2-hour period every 2 weeks. This will prevent the accumulation of air and non-condensibles in the machine. To start the purge, adjust purge switch to the "Manual" position.

CAUTION: Do not allow the chiller to increase in temperature (pressure) while the unit is off to temperature above 110°F (43C) since this will cause the rupture disk to relieve and discharge the refrigerant from the machine. Continuous running of pumps while the machine is off may cause this condition to occur. The rupture disk is designed to relieve if the pressure in the evaporator exceeds 15 psig.

Periodic Maintenance

Overview

This section describes basic chiller preventive maintenance procedures, and recommends the intervals at which these procedures should be performed. Use of a periodic maintenance program is important to ensure the best possible performance and efficiency from a CenTraVac chiller.

Recommended purge maintenance procedures for the **Purifier Purge unit** are covered by PRG-OM-4.

An important aspect of the chiller maintenance program is the regular completion of a CenTraVac "Operating Log". An example of this log is provided in this manual. When filled out accurately by the machine operator, the completed logs can be reviewed to identify any developing trends in the chiller's operating conditions.

For example, if the machine operator notices a gradual increase in condensing pressure during a month's time, he can systematically check, then correct the possible cause(s) of this condition (e.g., fouled condenser tubes, non-condensibles in the system, etc.)

Daily Maintenance and Checks

[ ] Check the chiller's evaporator, condenser and purge drum pressures, oil sump pressure, and net oil pressure. Compare the readings obtained with the values provided in Table 6.

Caution: If frequent purging is required (i.e., monitor purge timer, identify and correct source of air or water leak as soon as possible. Moisture contamination caused by leakage can shorten chiller life expectancy.

[ ] Check the oil level in the chiller oil sump using the 2 sight glasses provided in the oil sump head. When the unit operating, the oil level should be visible in the lower sight glass.

Weekly Maintenance

[ ] Complete all daily maintenance procedures and checks.

Note: If the unit is operating in the cooling mode, close the manual shutoff valves on the heating condenser and open the valves on the cooling condenser. Reverse this procedure when the unit is operating in the heat-recovery mode.

Table 6
Normal Chiller Operating Characteristics

Operating Characteristic	Normal Reading
Evaporator Pressure	12 to 18" Hg (vacuum)
Condenser Pressure (see Notes 1, 2)	2 to 12 psig (standard condensers)
Purge Drum Pressure	0 to 25 psig
Oil Sump Temperature:	
Unit Not Running	140 to 145 F (60 to 63 C)
Unit Running	115 to 150 F (47 to 66 C)
Net Oil Pressure	12 to 18 psid

Notes:
1. Condenser pressure is dependent on condenser water temperature, and should equal the saturation pressure of R-11 at a temperature 5-10 F (-15 to -12 C) above that of leaving condenser water at full load.
2. Normal pressure readings for ASME condensers exceed 12 psig.
3. Net oil pressure (i.e., usable oil pressure) is determined by subtracting the low oil pressure value from the high oil pressure gauge reading.

Example:
High oil pressure gauge = 9 psig;
Low oil pressure gauge = 18" Hg (vacuum).

First, convert 18" Hg to psig (i.e., -18/2.03 = -8.87 psig). Then, subtract -8.87 psig from 10 psig (i.e., 10 - [-8.87] = 9 + 8.87 = 17.87 psid). In this example, the net oil pressure of 17.87 psid is within the acceptable limits.

COMMENTS:

LOP/2 + HOP = Net Oil Pressure, CHW = Chilled Water, CW = Condenser Water

Every 3 Months

WARNING: To prevent injury or death due to electrical shock or contact with moving parts, lock unit disconnect switch in open position.

[ ] Complete all recommended weekly maintenance procedures. (Refer to the previous sections for details.

[ ] Clean all water strainers in the CenTraVac water piping system.

Every 6 Months

WARNING: To prevent injury or death due to electrical shock or contact with moving parts, lock unit disconnect switch in open position.

[ ] Complete all recommended quarterly maintenance procedures.

[ ] Lubricate the vane control linkage bearings, ball joints, and pivot points; a few drops of light machine oil (e.g., SAE-20) is sufficient.

[ ] Drain the contents of the rupture disc/purge discharge vent line drip leg into an evacuated waste container at a minimum and more often if the purge operated excessively.

Also, apply 1 or 2 drops of oil on the vane operator shaft and spread it into a very light film; this will protect the shaft from moisture and rust.

Off-Season Maintenance

During those periods of time when the chiller is not operated, **be sure control panel is energized.**

Annual Maintenance

Shut down the chiller once each year to check the items listed below; a more detailed inspection checklist is provided on the "Model CVHE CVHF CenTraVac Annual Inspection Checklist and Report" illustrated in this manual.

[ ] Perform the annual maintenance referred to in the Maintenance Section of the purge manual.

[ ] Use an ice water bath to verify that the accuracy of the evaporator refrigerant temperature sensor (4RT5) is still within tolerance (i.e., ± 2.0 F at 32 F).

If the evaporator refrigerant temperature displayed on the UCP's read-out is outside this 4-degree tolerance range, replace the sensor.

Note: If the sensor is exposed to temperature extremes outside its normal operating range (0 F to 90 F) (-18 C to 32 C), check its accuracy at 6-month intervals.

Compressor Oil Change on CVHE /CVHF units.

[ ] Recommendations are to subscribe to an oil analysis program to determine the necessity to change oil, rather than change it automatically every year. This will reduce the chiller's overall lifetime oil consumption and minimize refrigerant emissions. A drain fitting should be installed in the oil line after the oil filter for obtaining oil samples.

Oil Change Procedure

When oil analysis indicates the need to change compressor oil, use the following procedure for removing oil.

CAUTION: To prevent possible burnout of the oil sump heater, be sure to open control panel disconnect switch before draining the sump.

[ ] Draw the oil from the chiller through the oil charging valve on the chiller oil sump into an approved, evacuated tank, or;

[ ] Pump the oil from the chiller through the oil charging valve into an air-tight resealable container, using a magnetically-driven auxiliary pump.

Forcing the oil from the oil sump by pressurizing the chiller (i.e. by raising chiller temperature or adding nitrogen) is NOT recommended.

Refrigerant dissolved in the oil can be removed and returned to the chiller by using an appropriate deep-vacuum recovery unit and heating/agitating the oil container. Follow all Federal, state and local regulations with regard to disposal of waste oil.

Replacing Oil Filter

Replace oil filter: (1) annually, (2) at each oil change, (3) or if erratic oil pressure is experienced during chiller operation.

Replacement Procedure

[ ] Run oil pump for two to three minutes to insure that the oil filter is warmed up to oil sump temperature.

[ ] Close the shutoff valves before and after the filter and open the filter drain valve. Time required to drain oil can be momentarily opening the oil sampling drain valve.

[ ] Allow time for the filter to drain. Remove filter and place into a resealable container. Follow all

Annual Inspection Check List and Report: CVHEs/CVHFs w/UCP695 Control Panels

Review unit with operating personnel.

Compressor Motor

[ ] Motor continuity check
Good [ ] Open [ ]

[ ] Check and tighten motor terminals

[ ] Meg motor
Phase 1___ Phase 2 ___ Phase 3 ___

[ ] Check nameplate rating

Starter

[ ] Check condition of starter contacts
Good [ ] Fair [ ] Replace [ ]

Oil Sump

[ ] Change oil
If oil analysis, refer to program procedures.
___ Gallons (7) required

[ ] Check oil condition
Good [ ] Fair [ ] Poor [ ]

[ ] Oil pump continuity test
Good [ ] Open [ ]

[ ] Oil pump motor ground check
Good [ ] Bad [ ]

[ ] Check motor terminals
[ ] Change oil filter

Condenser

[ ] Visually inspect for scaling in tubes:
note findings and make recommendations.

Control Circuits

[ ] Low temperature control calibration
___ F set point ___ F trip point (ice water)

[ ] High pressure control calibration
___ psig setpoint
___ psig trip point (oil-pumped dry nitrogen)

[ ] Oil pressure control calibration
___ psid cut-in
___ psig cut-out

[ ] Check adjustment and calibration of inlet guide vane actuator motor

Leak Test Chiller

Refrigerant and oil analysis for acid content.

[ ] Sample refrigerant and oil for laboratory analysis (attach copy of analysis to next monthly inspection report)

Purge Unit

[ ] Check purge unit/controls for proper operation.
[ ] Check moisture indicator, replace filter-drier cores as necessary.
[ ] Check purge tank sump for water, remove free water as necessary.
[ ] Inspect/clean air-cooled condenser coil as necessary.

Cover Logs/Logging System with Operator

[ ] Review proper logging procedures with operator.

Comments: _____

_____

_____

Recommendations: _____

_____

Important: This check list is intended for use by qualified Trane service organizations ONLY. It is not a part of the maintenance oprations performed by the CVHE owner/operator.

federal, state and local regulations with regard to disposal of the filter.

Note: If the unit is under positive pressure, the entering and leaving lines at the oil filter must be disconnected. Be sure to plug the open end of each line with a flare fitting plug to reduce refrigerant loss during the filter change-out procedure.

Other Maintenance Requirements

[ ] Inspect the condenser tubes for fouling; clean if necessary.

[ ] Measure the compressor motor winding resistance to ground; a Qualified service technician should conduct this check to ensure that the findings are properly interpreted.

Contact a qualified service organization to leak-test the chiller; this procedure is especially important if the system requires frequent purging.

[ ] Use a nondestructive tube test to inspect the condenser and evaporator tubes at 3-year intervals.

Note: It may be desirable to perform tube tests on these components at more frequent intervals, depending upon chiller application. This is especially true of critical process equipment.

[ ] Depending on chiller duty, contact a qualified service organization to determine when to conduct a complete examination of the unit to discern the condition of the compressor and internal components.

a. chronic air leaks, which can cause acidic conditions in the compressor oil and result in premature bearing wear; and,

b. evaporator or condenser water tube leaks. Water mixed with the compressor oil can result in bearing pitting, corrosion, or excessive wear.

[ ] Submit a sample of the compressor oil to a Trane qualified laboratory for comprehensive analysis on an annual basis; this analysis determines system moisture content, acid level and wear metal content of the oil, and can be used as a diagnostic tool.

Lubrication

The only CVHE/CVHF chiller component that requires periodic lubrication is the external vane linkage assembly.

Lubricate the vane linkage shaft bearings and rod end bearings with a few drops of light-weight machine oil.

Refrigerant Charge

WARNING: To avoid injury or death due to inhalation of, or skin exposure to refrigerant, closely follow all safety procedures described in the Material Safety Data Sheet for the refrigerant containers. Certain procedures common to refrigeration system service may expose operating and/or servicing personnel to liquid and/or vaporous refrigerant.

The refrigerant charging procedure for Trane centrifugal chillers is:

1. If water is present in the tubes, break machine vacuum with refrigerant vapor, or circulate water, to avoid tube damage.

2. Always use refrigerant-compatible hoses or copper-tubing with self-sealing connections or shut-off valves.

3. Transfer the refrigerant using one of the following (listed in order of preference):

a. An approved Trane low-pressure refrigerant recovery/recycle unit.

b. The available pressure differential.

c. Gravity. (Use a return vent line to refrigerant drums to equalize pressure.)

d. A mechanical gear pump with compatible seals, or a magnetically-driven pump.

4. When charging from new drums, use fitting designed for use with 3/4-inch center drum bung of 2-inch bung.

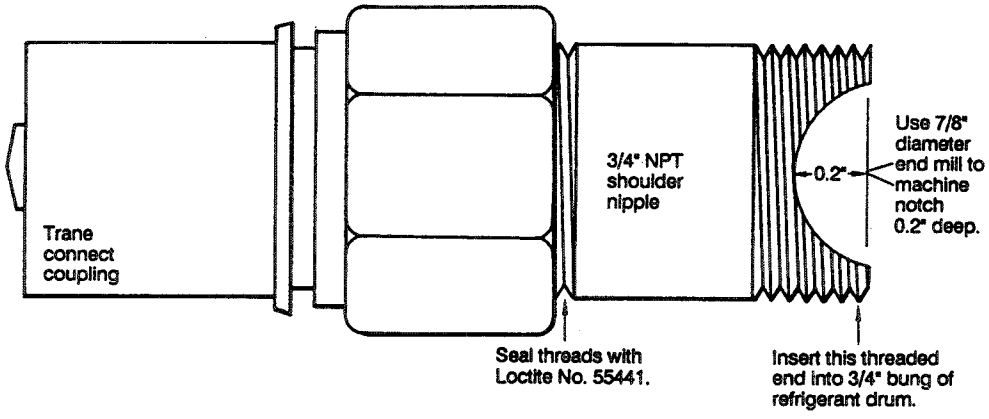
5. Do not use dry nitrogen to push refrigerant into the chiller as was common practice in the past. This will contaminate the charge require excessive purging, which will result in unnecessary release of refrigerant.

6. Weigh in the proper charge.

7. Use recovery/recycle unit or vacuum pump to evacuate hoses; discharge outdoors.

Recovery/Recycle Connections

To facilitate refrigerant removal and replacement, newer-design CVHE and CVHF units are provided with a 3/4-inch vapor fitting with shutoff valve on the chiller suction and with a 3/4-inch liquid connection with shutoff valve at the bottom of the evaporator shell.



Recovery/Recycle Connections

To facilitate refrigerant removal and replacement, newer-design CVHE and CVHF units are provided with a 3/4-inch vapor fitting with shutoff valve on the chiller suction and with a 3/4-inch liquid connection with shutoff valve at the bottom of the evaporator shell.

Leak Testing

To leak-test a chiller containing full refrigerant charge, raise chiller pressure using a controlled hot water or electric-resistance system to a maximum of 8 psig. Do not use nitrogen, which will cause excessive refrigerant discharge by the purge system.

Figure 25
Trane-Designed Drum Bung Fitting w/Quick-Connect Coupling

Periodic Maintenance

Cleaning the Condenser

CAUTION: Do not use untreated or improperly treated water, or equipment damage may occur.

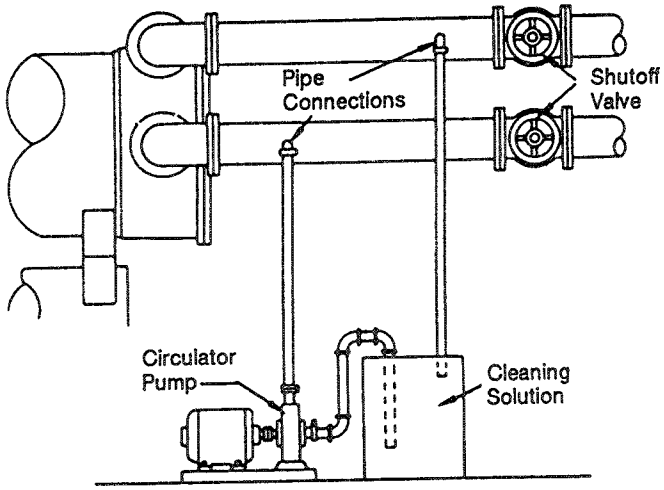
Condenser tube fouling is indicated when "the approach" temperature (i.e., the difference between the refrigerant condensing temperature and the leaving water temperature) is higher than predicted.

If the annual condenser tube inspection indicates that the tubes are fouled, 2 cleaning methods mechanical and chemical can be used to rid the tubes of contaminants.

Use the mechanical cleaning method to remove sludge and loose material from smooth- bore tubes.

(To clean other types of tubes including internally-enhanced types, consult a qualified service organization for recommendations.)

1. Remove the retaining nuts and bolts from the water box covers at each end of the condenser. Use a hoist to lift the covers off the water box (A threaded connection is provided on each water box cover to allow insertion of an eyebolt.)



2. Work a round nylon or brass bristled brush (attached to a rod) in and out of each of the condenser water tubes to loosen the sludge.

3. Thoroughly flush the condenser water tubes with clean water.

Scale deposits are best removed by chemical means. Be sure to consult any qualified chemical house in the area (i.e., one familiar with the local water supply's chemical/mineral content) for a recommended cleaning solution suitable for the job. (Remember a standard condenser water circuit is composed solely of copper, cast iron and steel.)

A typical chemical cleaning setup is illustrated in Figure 26.

Figure 26
Typical Chemical Cleaning Setup

CAUTION: Improper chemical cleaning can damage tube walls.

CAUTION: All of the materials used in the external circulation system, the quantity of the solution, the duration of the cleaning period, and any required safety precautions should be approved by the company furnishing the materials or performing the cleaning.

Remember, however, that whenever the chemical tube cleaning method is used, it must be followed up with mechanical tube cleaning, flushing and inspection.

Cleaning the Evaporator

Since the evaporator is typically part of a closed circuit, it does not accumulate appreciable amounts of scale or sludge. Normally every 3 years is sufficient. However on open CVHE/CVHF systems such as air washers periodic inspection and cleaning is recommended.

Control Settings And Adjustments

A list of CVHE/CVHF time delays and safety control cutout settings is provided in Table 1 in the Chiller Control System section of this manual. For control calibration and check-out, contact a Trane qualified service organization.

Purge System

Because some sections of the chiller's-refrigeration system operate at less-than-atmospheric pressure, the possibility exists that air and moisture may leak into the system. If allowed to accumulate, these non-condensibles become trapped in the condenser; this increases condensing pressure and compressor power requirements, and reduces the chiller's efficiency and cooling capacity.

The Trane Purifier Purge is the only purge system available for the CVHE/CVHF chiller. The purge is designed to remove non-condensible gasses and water from the refrigeration system. Purifier Purge unit operation, maintenance and troubleshooting is covered by a separate operation and maintenance manual (PRG-OM-4).

Trouble Analysis

Note: The troubleshooting charts in this manual are provided solely as a guide for determining the cause of a mechanical failure or equipment malfunction. when operational problems do occur, always contact a qualified service organization to ensure proper diagnosis and repair of the chiller.

UCP695 Control System

As described in the Chiller Control System section of this manual, the UCP-695 control panel visually indicates operating and diagnostic codes at the display window.

If the UCP detects a diagnostic condition, the display alternately flashes the unit operating mode (code prefix A) at the time the unit shut down and diagnostic code (code prefix b). Complete listings of the codes used to identify CVHE/CVHF operating modes and diagnostic conditions are provided in Tables 3 and 4. (See "Operator Interface: Display" in Chiller Control System.)

Organization of the UCP troubleshooting charts on the following pages is based on the possible 3-digit diagnostic codes that may appear on the display at one time or another.

Notice that each diagnostic code is classed by type ("latching" or "non-latching"); the condition that generated the diagnostic is then described briefly. Suggested actions for correcting the problem are provided under "Recommended Action".

Note: Remember that nonlatching diagnostics allow automatic restart as soon as the diagnostic condition clears, while latching diagnostics require a manual reset before unit operation can resume. The "Manual Reset Required" status indicator light illuminates whenever a latching diagnostic occurs.

UCP "Summary Sheet"

Immediately following the troubleshooting charts just described, is a 2-page owner/ operator guide to the UCP's micro module (1U3).

Use this summary sheet as a quick reference for identifying operating and diagnostic codes that appear on the UCP's display. Also included there are lists of the micro module's timing functions, run inhibit points, and inputs (including terminal connection designations).

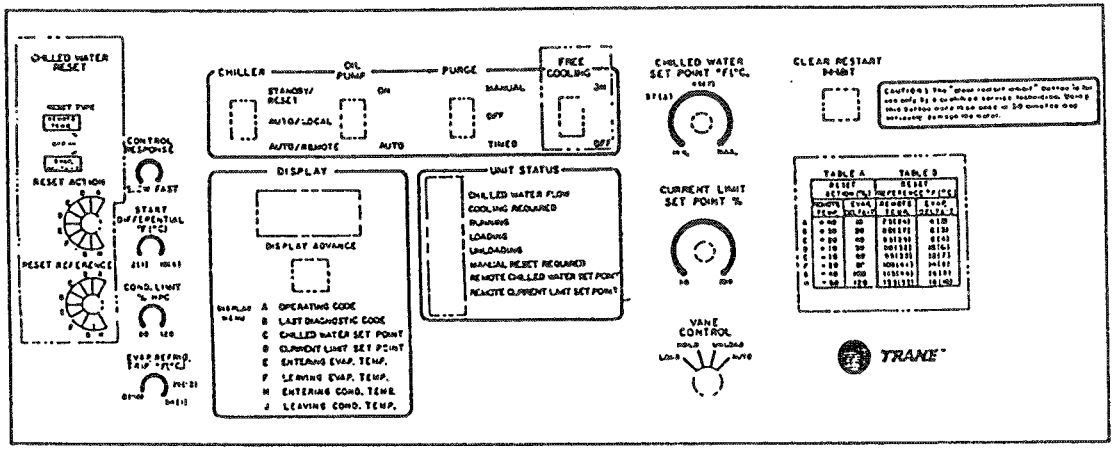
b Ab	L	Leaving Water Temperature Sensor 4RT1	Check sensor connections.
b AC	L	Condenser Refrigerant Pressure Sensor 1R1 (optional)	Check sensor connections.
b Ad	L	Evaporator Refrigerant Temperature Sensor 4RT5 (optional)	Check sensor connections.
b AE	L	Ambient Temperature Sensor 4RT6 (optional)	Check sensor connections.
b AF	L	Inboard Bearing Temperature Sensor #1 (4RT8; optional)	Check sensor connections.
b b0	L	Outboard Bearing Temperature Sensor #2 (4RT9; optional)	Check sensor connections.
b d9	NL	Extended Power Loss	None. Power lost; unit restarted normally when power was restored.
b dA	L	Surge	Check for proper operating conditions (entering condenser water temperature, flow rate, etc.). Also check for air dirty tubes and air in condenser.
b dC	L	Condenser Water Flow Overdue	Check condenser water flow switch, valves and pump contactor.
b E2	NL	Momentary Power Loss	None. Power lost briefly; unit restarted normally when power was restored.
b E3	L	Phase Imbalance	Contact a qualified service organization.
b E4	L	Phase Loss	Contact a qualified service organization.
b E5	L	Phase Reversal	Contact a qualified service organization.
b E7	L	High Motor Temperature (4B1R2, 4B1R3 or 4B1R4)	Contact a qualified service organization.
b E8	L	Differential Oil Pressure Switch 1S2	Contact a qualified service organization.
b E9	L	Stop Relay 1U2K2	Contact a qualified service organization.

Notes: See conclusion of "Troubleshooting Charts: UCP-Generated Diagnostics" on next page.

UCP-Generated Diagnostics

3-Digit Diagnostic Code	Type (1)	Diagnostic Description	Recommended Action
b EA	L	High Inboard Bearing Temperature, Sensor #1 (4RT8)	Check for proper oil sump heater (and oil cooler on CVHE 360 thru 1250) operation.
b Eb	L	High Outboard Bearing Temperature, Sensor #2 (4RT9)	Check for proper oil sump heater operation.
b EC	L	Running Overload (1U2K3)	Contact a qualified service organization.
b Ed	NL	Chilled Water Flow	Check chilled water flow switch, valves and pump interlock.
b EE	L	Exceeded Maximum Acceleration Time	Contact a qualified service organization.
b F0	L	Transition	Contact a qualified service organization.
b F1 (4)	L	Running External Interlock (optional)	Identify and correct problem that triggered interlock.
b F2	L	Low Oil Pressure (1S2)	Check oil level in oil sump.
b F3 b F4	NL L	Low Oil Temperature (4RT7) High Oil Temperature (4RT7)	Check oil heater and sensors for proper operation.
b F5	L	High Condenser Refrigerant Pressure (1R1)	Check for proper operation. Also check for dirty tubes and air in condenser.
b F7	NL	Condenser Water Flow	Check condenser water flow switch valves and pump interlock circuit.
b F8	L	Improper Unit Identification	Contact a qualified service organization.
b F9	L	Free Cooling Valves (4B12, 4B13)	Contact a qualified service organization.
b FA	L	Actuator (4B2)	Contact a qualified service organization.
b Fb	L	Low Evaporator Refrigerant Temperature (4RT5)	Contact a qualified service organization.
b Fd	L	External Interlock (optional)	Identify and correct problem that triggered interlock.
b FF	L	Unit Control Module (1U3)	Contact a qualified service organization.

Notes:



1. Latching diagnostic conditions (L) require manual reset; "Manual Reset Required" status indicator light illuminates whenever a latching diagnostic condition occurs. Nonlatching diagnostic conditions (NL) do not require a manual reset; the unit automatically restarts as soon as the diagnostic condition clears.

2. Notice that the chiller will not start if the oil temperature is too low (<140 F); contact a qualified service organization for recommendations.

3. It is not possible to clear a latching diagnostic condition from a higher-level, supervisory control device (e.g., SCP699, Trane BAS or generic BAS).

4. HGBP only - bF1 is generated when condenser discharge temperature exceeds 210 F.

UCP Summary Sheet

Terminal Block 1TB6 Input

Term. Nos.	Description of Input
1 2	Optional Bidirectional Communications Link

Unit Timers

Timer	Nom. Interval
Prelube*	15 seconds
Restart Inhibit (Standby--Auto): Winding Temp. <165 F (74 C) Winding Temp. ≥165 F (74 C) Since Last Start	 2 minutes 15 minutes 30 minutes
Post-Lube	2 minutes
Free-Cool/Vane Open Inhibit	3 minutes
Purge	5 minutes ON, 115 minutes OFF

*Since (a) "sufficient" oil pressure may be confirmed at any point during the 33-second "oil pressure overdue" timing interval, and (b) the 15-second "prelube" period begins only when sufficient oil pressure is sustained, the actual time required to "establish oil pressure" and "prelube" can be 15 to 48 seconds.

Terminal Block 1TB3 Inputs

Term. Nos.	Description of Input	Term. Nos.	Description of Input
1, 2	Leaving Evaporator Water Temperature	14, 15	Ambient Temp. (Opt.)
3, 4	Entering Evaporator Water Temperature (Opt.)	16, 17	External Interlock (Opt.)
5, 6	Leaving Condenser Water Temperature (Opt.)	18, 19	Free-Cool Valves Closed (Opt.)
7, 8	Entering Condenser Water Temperature (Opt.)	20, 21	Proof of Chilled Water Flow
9 10 11	Cond. Refrig. Pressure (POW) Cond. Refrig. Pressure (WIP) Cond. Refrig. Pressure (COM)	22, 23	Proof of Condenser Water Flow
12, 13	Evaporator Refrigerant Temperature	24, 25	Vanes Closed

Terminal Block 1TB4 Inputs

Term. Nos.	Description of Input	Term. Nos.	Description of Input
1, 2	Differential Oil Pressure	13, 14	Oil Temperature
3, 4	Running External Interlock (Opt.)	15 16 17	Winding Temperature #1 Winding Temperature #2 Common
5, 6	Transition Complete	18	Winding Temperature #3
7 8	Phase Current 3+ Phase Current 3-	19, 20	Bearing Temperature #1 (Opt.)
9 10	Phase Current 2+ Phase Current 2-	21, 22	Bearing Temperature #2 (Opt.)
11 12	Phase Current 1+ Phase Current 1-		

Nominal Fault Timeouts

Condition	Timing Interval
Oil Pressure Overdue*	33 seconds
Transition Completion Overdue	2 seconds
Condenser Water Flow Overdue	3 minutes
Vane Closure Overdue	3 minutes
Free-Cooling Valve Closure Overdue	3 minutes

*"Sufficient" oil pressure may be confirmed at any point during this 33-second period; prelube begins as soon as oil pressure is confirmed.

Predetermined Unit Cutout Points (Nominal)

Condition	Cutout Point
Winding Temperature Run Inhibit	130 C 265 F
Oil Temperature Run Inhibit	(82 C) 180 F
Bearing Temperature Run Inhibit	(82 C) 180 F
Leaving Chilled Water Temperature Low Limit	(2 C) 35.3 F, std. range only

Model Number Description

All standard Trane products are identified by a multiple-character model number that precisely identifies a particular type of unit. An explanation of the alphanumeric identification code used with CenTraVac units is provided on the next three pages. Its use will enable the owner/operator, installing contractor(s), and service engineer(s) to define the operation, components and options for a particular unit.

Be sure to refer to the model number stamped on the unit nameplate (shown below, and mounted on the left-hand side of the unit control panel enclosure) when ordering replacement parts or requesting service.

Note: Trane-built, unit-mounted starters are identified by a separate number found on the starter.

Typical CVHE Unit Nameplate

Drwg. X39470402

Trane products are identified by a multiple character model number that precisely identifies a particular type of unit. An explanation of the alphanumeric model number is shown below. It will enable the owner or Service Engineer to define operation, components and accessories.

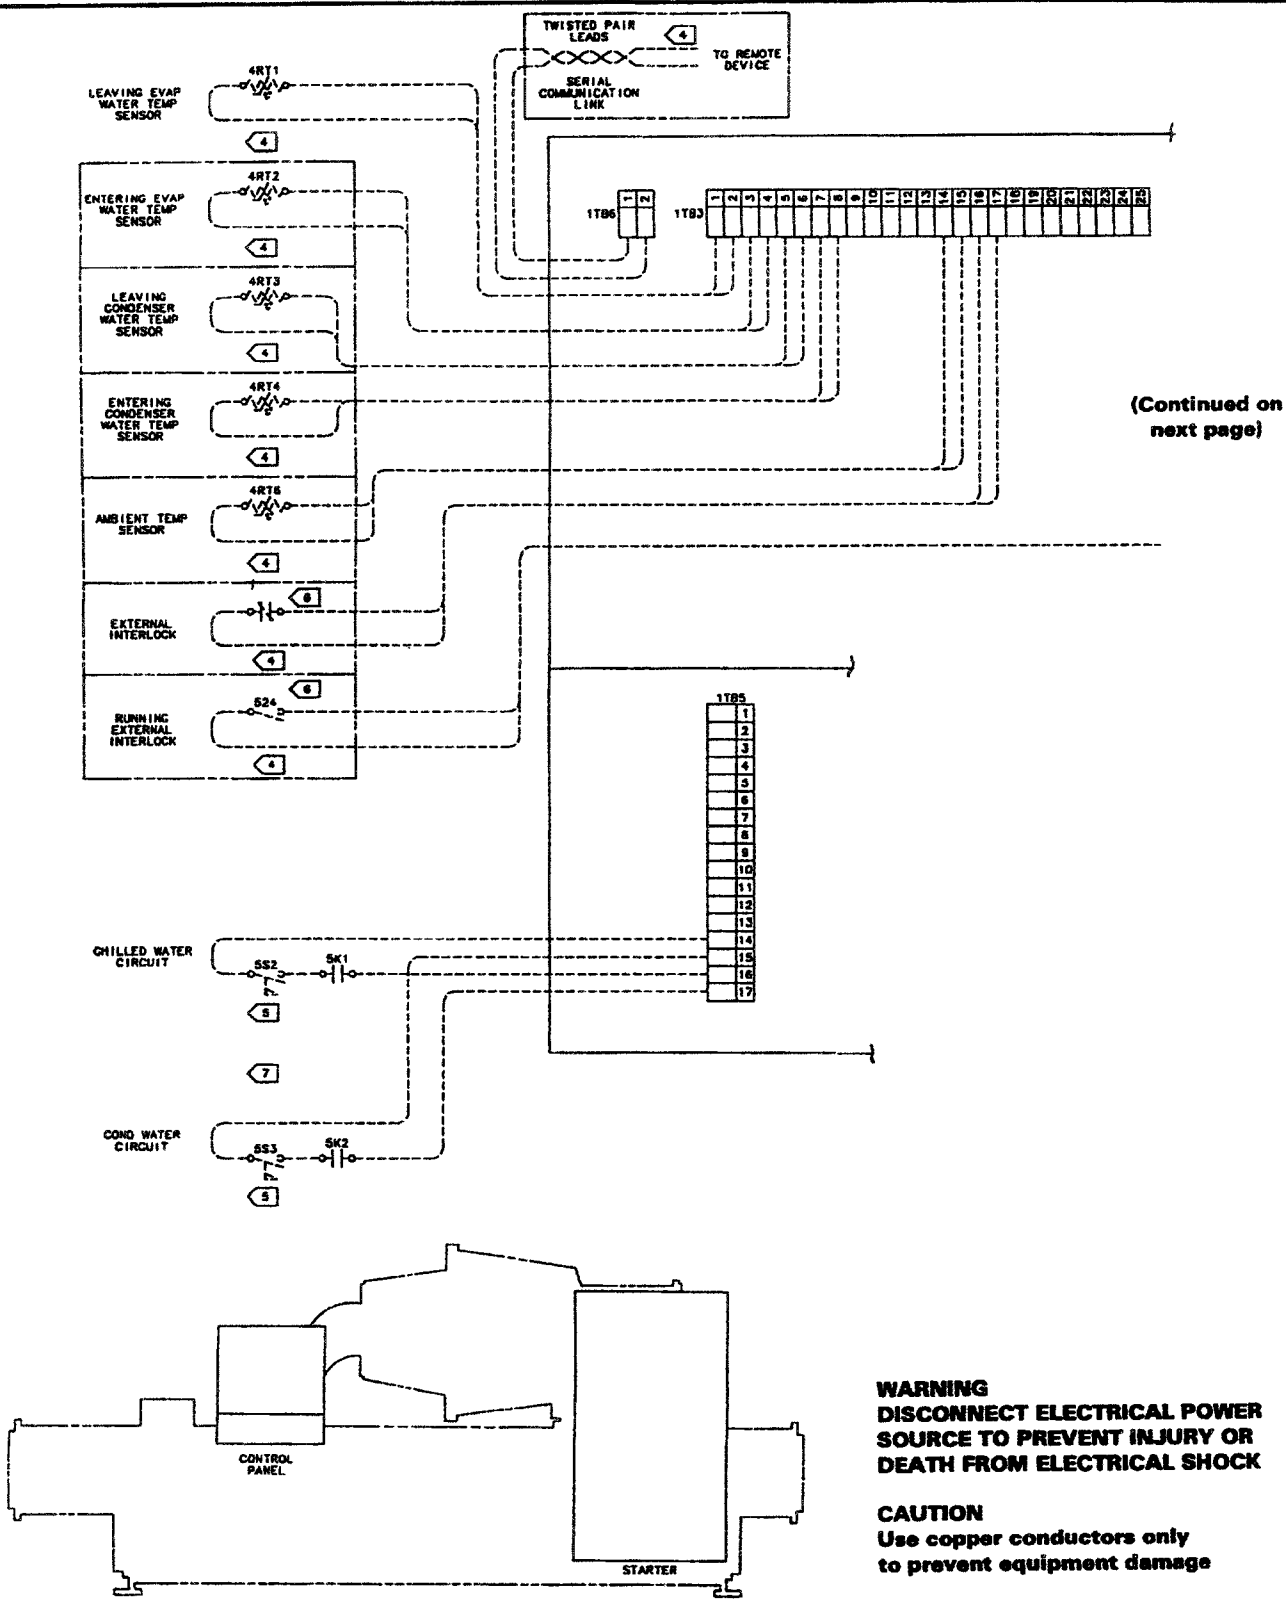
General Information

Literature Change History

CVHE-W-3 (February 1986)
Original issue of manual; provides typical field connection diagrams, electrical schematics and connection diagrams for CVHE units of "K" design with UCP695, microprocessor-based control systems.



Note: The typical wiring diagrams in this booklet are representative of "K"-design chillers, and are provided only for general reference; **it is possible that none of these diagrams exactly reflects the actual wiring of your unit.** For specific electrical connection and schematic information, always refer to the wiring diagrams that shipped with the unit.

Unit Electrical Data

To determine the specific electrical characteristics of a particular chiller, always refer to the unit nameplate (i.e., mounted on the left-hand side of the unit control panel). The nameplate (shown in "Model Number Description") provides electrical data for the compressor motor, oil pump motor, oil tank heater, and purge compressor motor.

For your reference, a summary of compressor motor electrical data is published in the installation manual that shipped with the unit.

NOTES

1. UNLESS OTHERWISE NOTED, ALL SWITCHES ARE SHOWN AT 25°C (77°F) AT ATMOSPHERIC PRESSURE, AT 60% RELATIVE HUMIDITY, WITH ALL UTILITIES TURNED OFF AND AFTER A NORMAL SHUTDOWN HAS OCCURED.
2. SOLID LINES INDICATE TRANE WIRING. DASHED LINES INDICATE FIELD WIRING. PHANTOM LINES INDICATE OPTIONAL FEATURES.
3. NUMBERS ALONG THE RIGHT SIDE OF THE SCHEMATIC DESIGNATE THE LOCATION OF THE CONTACTS BY LINE NUMBER. AN UNDERLINED NUMBER INDICATES A NORMALLY CLOSED CONTACT. AN OPEN ARROWHEAD BELOW THE LINE NUMBER POINTING UPWARD INDICATES A TIMED CONTACT WHICH BEGINS TIMING WHEN ENERGIZED.
4. SEE INSET D FOR TYPICAL INTERNAL WIRING OF ACTUATOR.
5. 575/600 VOLT PRIMARY SHOWN. SEE INSET A FOR OTHER VOLTAGES.
6. OPTIONAL AMP METERS SHOWN. IF NOT REQUIRED SEE INSET B. WIRE NO. 302A,304A, AND 306A ARE NOT REQUIRED.
7. RESISTOR SHOWN FOR 200/208V AND 200-400 RLA. FOR OTHER VOLTAGES AND RLA SEE INSET C
8. SEE SERVICE MANUAL FOR INDIVIDUAL SECONDARY VOLTAGES
9. THREE PHASE POWER SUPPLY VOLTAGE SEE UNIT NAMEPLATE.
10. 30A FOR 200/208V-10A FOR 440/460/480 OR 8A FOR 575/600V

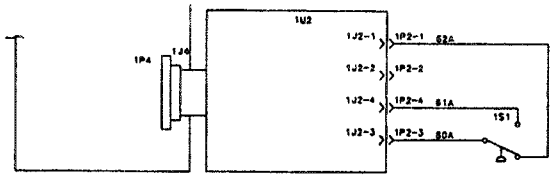

Figure 3 (concluded)

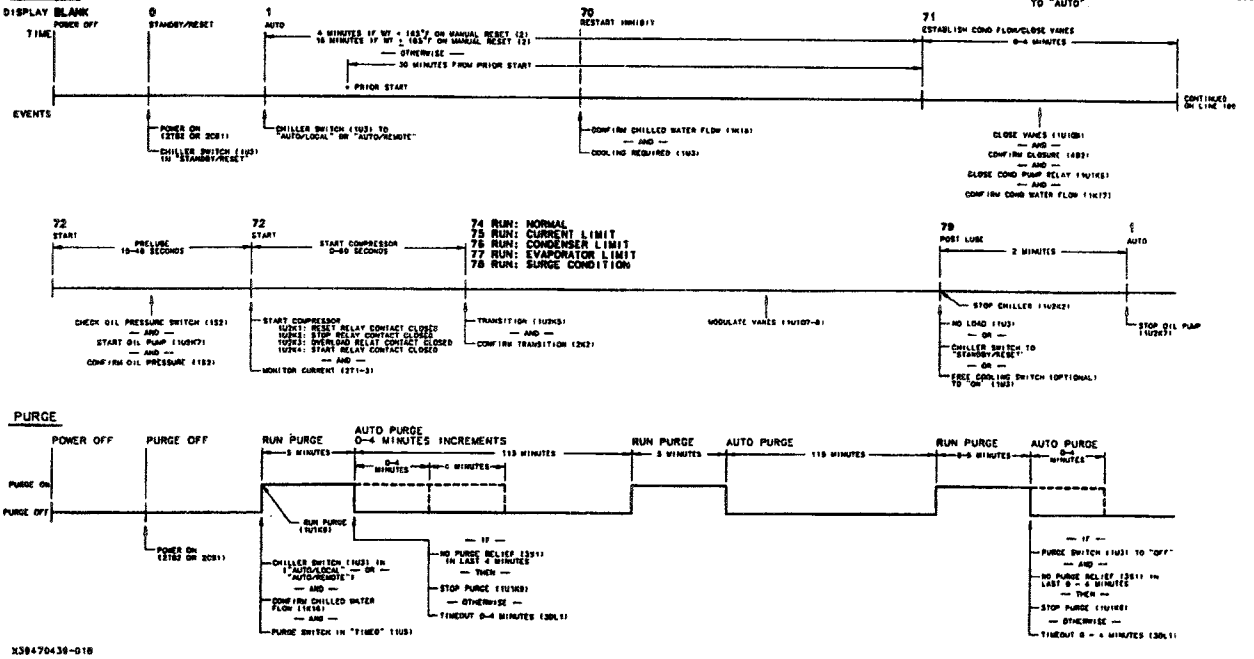
(Continued from previous page)



WARNING
DISCONNECT ELECTRICAL POWER SOURCE TO PREVENT INJURY OR DEATH FROM ELECTRICAL SHOCK

CAUTION
Use copper conductors only to prevent equipment damage

NOTES:
1. TERMINALS 1TB3-16 AND 1TB3-17 MUST BE JUMPERED IF EXTERNAL INTERLOCK IS NOT USED.
2. MANUAL RESET IS ACCOMPLISHED BY MOVING THE CHILLER SWITCH FROM "STANDBY/RESET" TO "AUTO".

Since the Trane Company has a policy of continuous product and product data improvement, it reserves the right to change design and specifications without notice. Only qualified technicians should perform the installation and servicing of the equipment referred to in this publication.

Warnings and Cautions

NOTICE

Warnings and Cautions appear at appropriate locations throughout this manual. Read these carefully.

WARNING: Indicates a potentially hazardous situation which, if not avoided, could result in death or serious injury.

CAUTION: Indicates a potentially hazardous situation which, if not avoided, may result in minor or moderate injury. It may also be used to alert against unsafe practices and where property-damage-only accidents could occur.

About this Manual

This manual discusses proper installation of Models CVHE, CVHF and CVHG 50 Hz. and 60 Hz. chillers with a refrigerant pump. See Figure 1 for an example of a chiller with a refrigerant pump. The chillers are equipped with microcomputer-based control systems whether standard cooling or heat-recovery. A careful review of this information along with the submittal package provided for the unit will assure that the chiller is correctly installed.

Extended capacity is available only on models CVHF 1470 and 1720.

CVHE, CVHF and CVHG machines, as of this Revision C manual, are built only with a refrigerant pump. 032 and 050 shell size information has also been included in this manual.

Product Description Block

Trane 50 Hz and 60 Hz hermetic CenTraVac® units are defined by the product definition and selection system (PDS). Each unit is defined by the product description block which appears on the unit nameplate. An explanation of the PDS product code is provided in the unit operation and maintenance manual.

Commonly Used Acronyms

AFD = Adjustable Frequency Drive
ASME = American Society of Mechanical Engineers
ASRAE = American Society of Heating, Refrigerating and Air Conditioning Engineers

BAS = Building Automation System
LBU = La Crosse Business Unit
CABS = Auxiliary Condenser Tube-Bundle Size
CDBS = Condenser Bundle Size
CESZ = Condenser Shell Size
CWR = Chilled Water Reset

DTFL = Delta-T at Full Load (i.e., the difference between entering and leaving chilled water temperatures at design load)
EVBS = Evaporator Size
EVSZ = Evaporator Shell Size

FC = Free Cooling
GPM = Gallons-per-Minute
HGBP = Hot Gas Bypass

HVAC = Heating, Ventilating and Air Conditioning
IE = Internally Enhanced Tubes
IPC = Interprocessor Communication
PFCC = Power Factor Correction Capacitor
PSID = Pounds-per-Square-Inch Differential
UCP2 = Chiller Control Panel

Unit Nameplate

The chiller nameplate is located on the left side of the unit control panel (UCP). The following information is provided on the unit nameplate.

1. Unit model and size descriptor
2. Unit serial number
3. Unit electrical requirements are identified
4. Correct operating charge and type of refrigerant
5. Unit test pressures and maximum operating pressures
6. Installation, operation and maintenance manuals
7. Product description block (Identifies all unit components and unit "design sequence" used to order literature and make other inquiries about the unit).
8. Lists unit wiring diagrams.

Metric Conversion

For tables and charts in this manual, the following conversions apply:

In. x 2.54 = cm
Ft. x 30.48 = cm
Lbs. x .453 = kg

Responsibilities of Installing Contractor(s)

A list of the contractor responsibilities typically associated with the unit installation process is provided below. See Table 1.

1. Locate and maintain the loose parts, i.e. isolators, bulb wells, temperature sensors, flow sensors or other factory-ordered field installed options, for installation as required. Loose parts are located in the starter panel on units with factory-installed unit-mounted starters or in the motor terminal box for units with remote-mounted starters.

2. Install the machine on a foundation with flat support surfaces level within 1/16" and of sufficient strength to support concentrated loading.

3. Place manufacturer-supplied isolation pad assemblies under unit. (Use spring isolators for upper floor installations.)

4. Install the machine per applicable Trane Installation Manual.

5. Complete all water piping and electrical connections.

Note: Field-piping must be arranged and supported to avoid stress on the equipment. It is strongly recommended that the piping contractor refrain from piping closer than 3'-0" minimum to the equipment. This will allow for proper fit-up upon arrival of the unit at the job-site. Any adjustment that is necessary can be made to the piping at that time.

6. Where specified, supply and install valves in water piping upstream and downstream of evaporator and condenser water boxes to isolate shells for maintenance and to balance and trim system.

7. Supply and install flow switches (or equivalent devices) in both chilled water and condenser water piping. Interlock each switch with proper pump starter to ensure that unit can only operate when water flow is established.

8. Supply and install taps for thermometers and pressure gauges in water piping adjacent to inlet and outlet connections of both evaporator and condenser.

9. Supply and install drain valves to each water box.

10. Supply and install vent cocks on each water box.

11. Where specified, supply and install strainers ahead of all pumps and automatic modulating valves.

12. Supply and install pressure-relief piping from pressure-relief rupture disc to atmosphere.

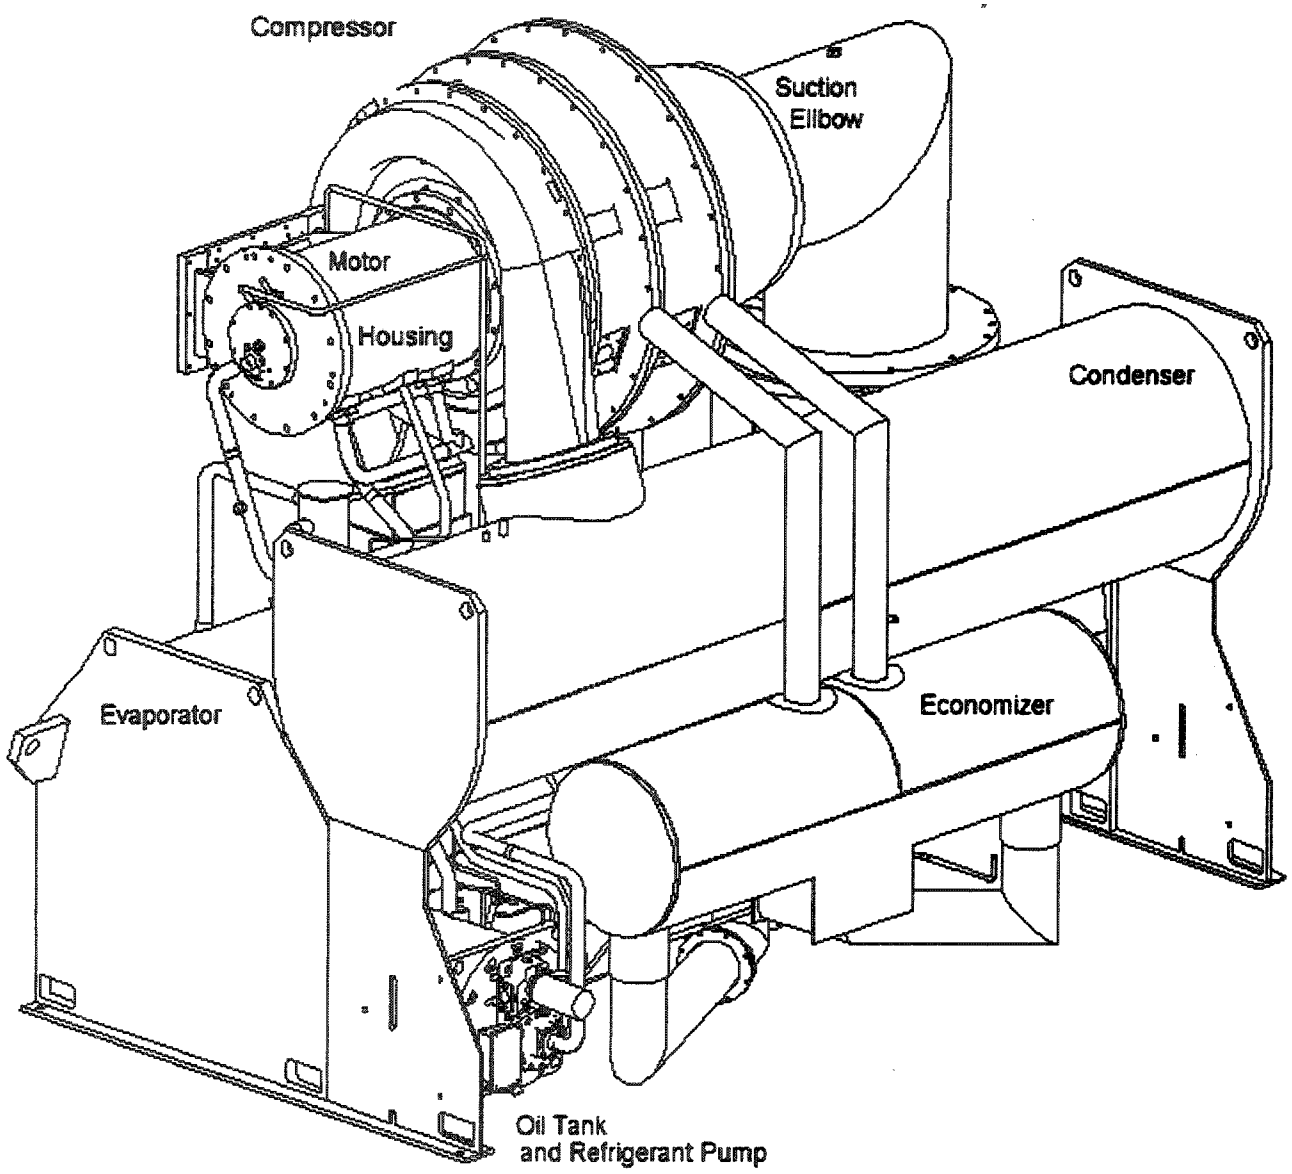
13. If necessary, supply sufficient HCFC-22 refrigerant (maximum of 1 Lb. per machine) for leak testing and dry nitrogen (8 PSIG per machine) for pressure testing under manufacturer's supervision.

14. Start unit under supervision of a qualified service technician.

15. Where specified, supply and insulate evaporator and any other portions of machine as required to prevent sweating under normal operating conditions.

16. **Unit-Mounted Starters Only** Remove top of starter panel and cut access area for line-side wiring; front left quadrant of top provides recommended access to starter lugs.

17. Supply and install wire terminal lugs to starter.



18. **Unit-Mounted Starters Only** Supply and install field wiring to line-side lugs of starter.

19. Supply and install a Refrigerant Monitor per ASHRAE 15 specifications. For additional information, refer to CenTraVac® Checksheet and Request for Serviceman form 1-27.08. Contact the nearest Trane office for the most recent up to date copy.

Table 1 - Installation Requirements

Type of Requirement	Trane-Supplied Trane-Installed	Trane-Supplied Field-Installed	Field-Supplied Field-Installed
Rigging			A. Safety chains B. Clevis connectors C. Lifting beam
Isolation		A. Isolation pads or spring isolators	A. Isolation pads or spring isolators
Electrical	A. Circuit breakers or fusible disconnects (optional) B. Unit-mounted starter (optional) C. PFCCs (optional)	A. Jumper bars B. Temperature sensor (optional outdoor air) C. Flow switches (may be field supplied)	A. Circuit breakers or fusible disconnects (optional) B. Remote-mounted starter, AFD (optional) C. PFCCs (Remote-mounted starter option only) D. Terminal lugs E. Ground connection(s) F. Jumper bars G. BAS wiring (optional) H. IPC wiring (AFD and remote-mounted starters only I. Control voltage wiring (AFD and remote-mounted starters only) J. Oil pump interlock wiring (AFD and remote-mounted starters only) K. High condenser pressure interlock wiring (AFD and remote-mounted starters only). L. Chilled water pump contactor and wiring M. Condenser water pump contactor and wiring N. Option relays and wiring (See Table 12)
Water Piping		A. Flow switches (May be field supplied)	A. Thermometers B. Water flow pressure gauges C. Isolation and balancing valves water piping D. Vents and drain valves (1 each per class) E. Pressure-relief valves (for water boxes as required)
Rupture Disc	A. Rupture disc assy		A. Vent line and flexible connector
Insulation	a. Insulation (Optional)		A. Insulation

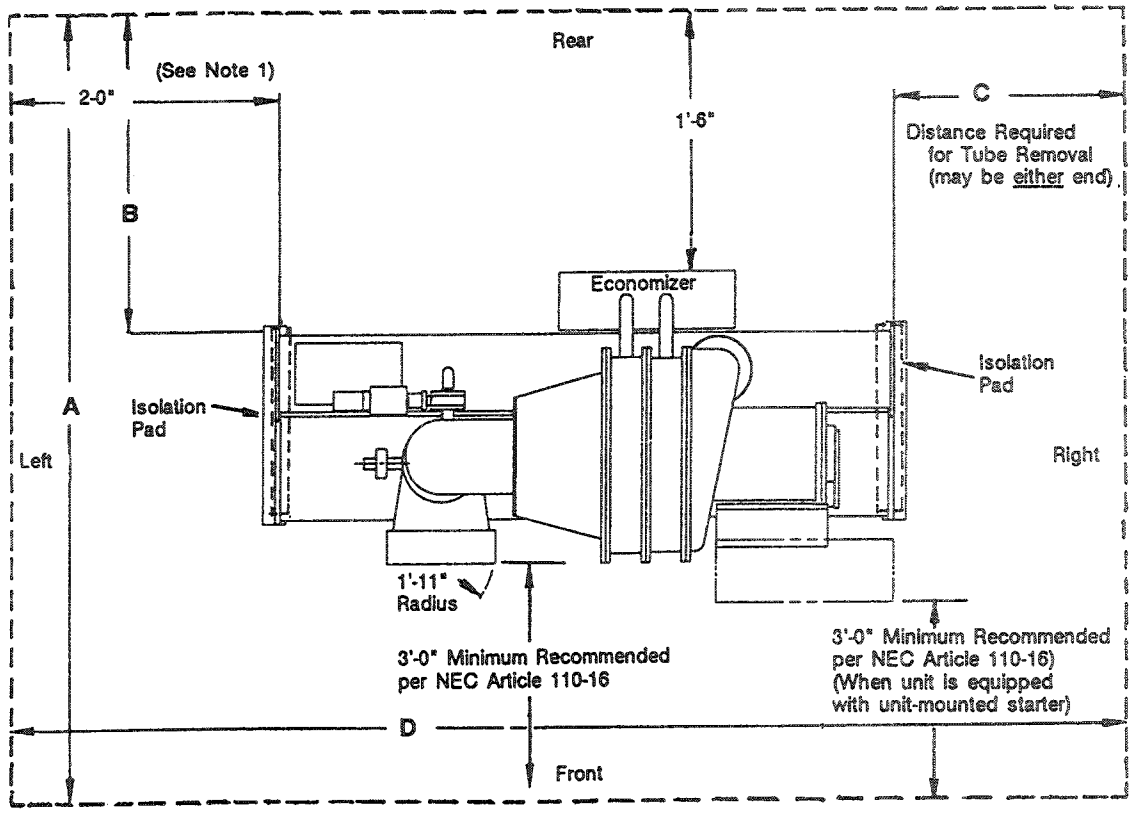
Figure 1
Typical CVHE and CVHG Chiller with Refrigerant and Oil Pump

⚠ CAUTION

CHILLER OPERATION AT AMBIENT TEMPERATURES EXCEEDING 100°F (38C) CAN FATIGUE THE UNIT'S RUPTURE DISC, CAUSING IT TO BREAK AT A REDUCED REFRIGERANT PRESSURE (I.E., <15 PSIG.) STARTER COMPONENT DAMAGE CAN ALSO OCCUR WHEN ADVERSE OPERATING CONDITIONS ARE PRESENT.THE ABOVE CAN HAPPEN, BECAUSE OF THE PANEL'S INABILITY TO DISSIPATE HEAT ADEQUATELY. Take whatever action is necessary to improve the equipment room environment if any of these adverse operating conditions are present.

Foundation Requirements

Provide rigid, non-warping mounting pads or a concrete foundation as a mounting surface for the chiller. Ensure that the base is of sufficient strength and mass to properly support the chiller at its full operating weight (i.e., including completed piping, and full operating charges of refrigerant, oil and water.



For your convenience, a summary of standard tube bundle locations are provided in Table 2 and Table 3. Table 4 indicates the weights of various chiller options. Table 5 shows typical weights for Cooling Only units.

Notice that the floor loading for all sizes of CVHE, CVHF and CVHG chillers is 62 pounds per square inch.

To assure proper unit operation, the chiller must be level within 1/16" over its length and width when set into place on the mounting surface.

The Trane Company will not assume responsibility for equipment problems resulting from an improperly designed or constructed foundation.

Figure 2
Clearance Requirements for Cooling and Auxiliary Units

Top View

Notes:
1. Does not include water box. Add water box dimension to this figure.
2. Minimum vertical clearance over chiller is 3 feet.

Do not install piping or conduit above compressor motor assembly or behind suction elbow.

Note: Immediately report any unit damage incurred during handling or installation at the job site to Trane sales office.

Rigging

Lifting is the recommended method for moving chillers. Suggested lifting arrangements for standard and heat-recovery units are illustrated in Figure 5.

Note that each of the cables used to lift the unit must be capable of supporting the entire weight of the chiller.

⚠ WARNING
LIFT THE CHILLER HORIZONTALLY. Failure to do so could result in death or serious bodily injury and equipment damage.

See shipping tables 2, 3 and 5 for shipping weights.

Refer to lifting arrangement and rigging in Figure 5. Notice that the lifting beam used to lift the unit must be at least 12 feet long.

To lift the chiller properly, insert clevis connections at the points indicated in Figure 5, a 2"- diameter lifting hole is provided at each of these points. Next attach the lifting chains or cables.

Once the lifting cables are in place, attach a safety chain or cable between the first-stage casting of the compressor and the lifting beam. To do this, remove a retaining bolt from the compress first-stage casting and replace it with an eyebolt.

Note: There should not be tension on this safety cable; it is used only to prevent the unit from rolling during the lift.

When the lift is complete, detach the clevis connections and safety chain, then remove the eyebolt that was used to secure the safety chain to the compressor, and reinstall the retaining bolt in its place.

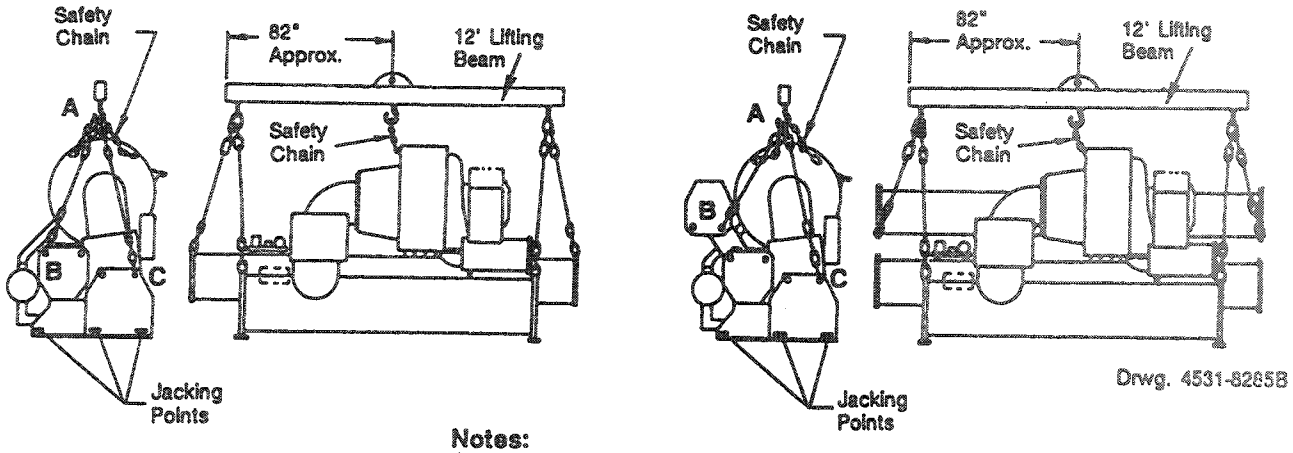
If the chiller cannot be moved using the conventional rigging method just described, consider these points.

1. If job site conditions require rigging of the chiller at an angle greater than 45° from horizontal (end-to-end), dowel-pin the compressor and remove it from the unit. Be sure to contact a qualified service organization for specific rigging instructions.

⚠ CAUTION
IF THE UNIT WILL BE LIFTED AT ANY ANGLE GREATER THAN 15° FROM END-TO-END, REMOVE THE OIL FROM THE OIL TANK. Failure to do so, will cause oil to drain out of oil tank into other areas of chiller. It will be extremely difficult to return the oil to the oil tank even during operation.

2. When lifting the chiller is either impractical or undesirable, attach cables or chains to the jacking slots shown in Figure 5; then push or pull the unit across a smooth surface.

⚠ CAUTION
CHILLER SHIPPING SKIDS ARE NOT DESIGNED TO SUPPORT THE ENTIRE WEIGHT OF THE UNIT AT ANY POINT. Improperly supporting the chiller and skid assembly may result in equipment damage.



Note: The oil tank with the refrigerant pump is mounted under the condenser and may be damaged by a fork truck.

⚠ CAUTION
DO NOT USE A FORK LIFT TO REMOVE THE CHILLER. Using a fork lift can result in damaged equipment.

⚠ CAUTION
CONSULT THE TRANE COMPANY BEFORE LIFTING THE COMPRESSOR/MOTOR ASSEMBLY FROM THE SHELLS WITHOUT FACTORY-INSTALLED DOWELING IN THE COMPRESSOR CASTING FLANGES. Failure to do so can result in misalignment of the compressor castings.

3. If removal of the compressor or economizer assembly is necessary to move the chiller into its operating location, contact the Trane Company for special instructions concerning chiller disassembly and reassembly procedures. Refer to CVHE-IN-3B or latest revision.

Figure 5
Recommended Lifting Arrangements for CVHE, CVHF and CVHG Units

Notes:
1. Lifting chains (or cables) may or may not be the same length between Points A and B, or between Points A and C. Adjust as necessary for an even lift.
2. Lifting holes provided on chiller to attach chains are 2" in diameter.
3. Attach safety chain (or cable) as shown, and without tension. The safety chain is not used for lifting, but is there to prevent the unit from rolling.
4. Do not forklift the unit!

⚠ WARNING
DO NOT USE CHAINS OR CABLES OTHER THAN AS SHOWN. Failure to heed this warning by using alternative lifting arrangements may result in death or serious injury and equipment damage.

Shipping Skid Removal

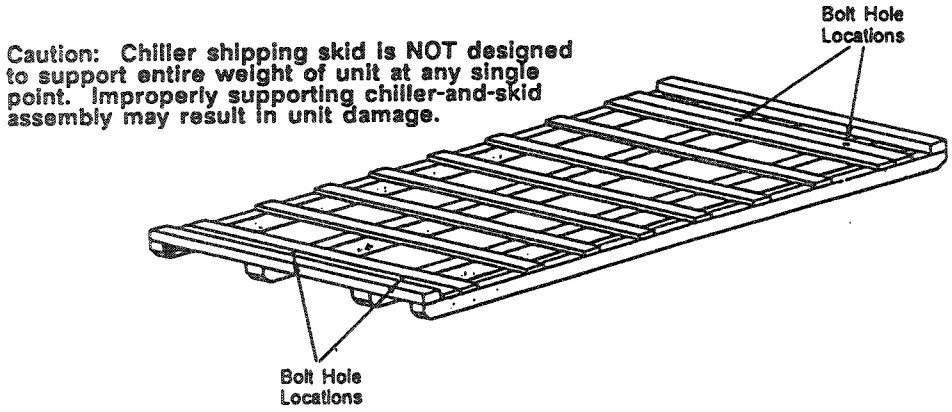
To detach the skid from the unit once the chiller is set into place:

1. Remove the carriage bolts that fasten the steel straps to the skids. Carriage bolt locations are shown in Figure 6.

2. Place jacks in the slots provided at each end of the chiller.

3. Using the jacks installed in Step 2, elevate one end of the chiller at a time; work from end to end in small increments to ensure stability. The skid will remain on the floor.

4. Once the chiller is elevated sufficiently, disassemble and remove the skid.



⚠ WARNING

SHIPPING SKIDS ARE HEAVY AND SHOULD NOT BE DROPPED. Failure to handle with care may cause death or bodily injury.

5. Position isolator pads (Spring isolators) beneath the chiller feet. (See "Unit Isolation" section for instructions.

6. Once the isolators are in place, lower the chiller. Again, work from end to end in small increments to maintain stability.

Figure 6
Typical Chiller Shipping Skid

Chiller Isolation

To minimize sound and vibration transmission through the building structure and to assure proper weight distribution over the mounting surface, install isolation pads or spring isolators under the chiller feet.

Note: Isolation pads are provided with each chiller unless spring isolators are specified on the sales order.

Specific isolator loading data is provided in the unit submittal package. Also refer to Table 6. If necessary, contact your local Trane sales office for further information.

Isolation Pads

When the unit is ready for final placement, position isolation pads end for end under the full length of the chiller leg. The pads measure 6" x 18" and on some units there may be small gaps between pads. Remember that the chiller must be level within 1/16" over its length and width after it is lowered onto the isolation pads. In addition, all piping connected to the chiller must be properly isolated and supported so that it does not place any stress on the unit.

Spring Isolators

Spring isolators should be considered whenever chiller installation is planned for an upper story location. Base isolator selection and placement on the information presented in Figures 9 and 10. (Notice that 3 types of spring isolators - each with its own maximum loading characteristics are used with the CVHE, CVHF and CVHG chillers.)

Spring isolators typically ship assembled and ready for installation. To install and adjust the isolators properly, follow the instructions given.

Note: Do not adjust the isolators until the chiller is piped and charged with refrigerant and water.

1. Position the spring isolators under the chiller as shown in Figures 8, and 9. Make sure that each isolator is centered in relation to the tube sheet.

2. Set the isolators on the sub-base; shim or grout as necessary to provide a flat, level surface at the same elevation for all mountings. Be sure to support the full underside of the isolator base plate; do not straddle gaps or small shims..

3. If required, bolt the isolators to the floor through the slots provided, or cement the pads.

Note: Fastening the isolators to the floor is not necessary unless specified.

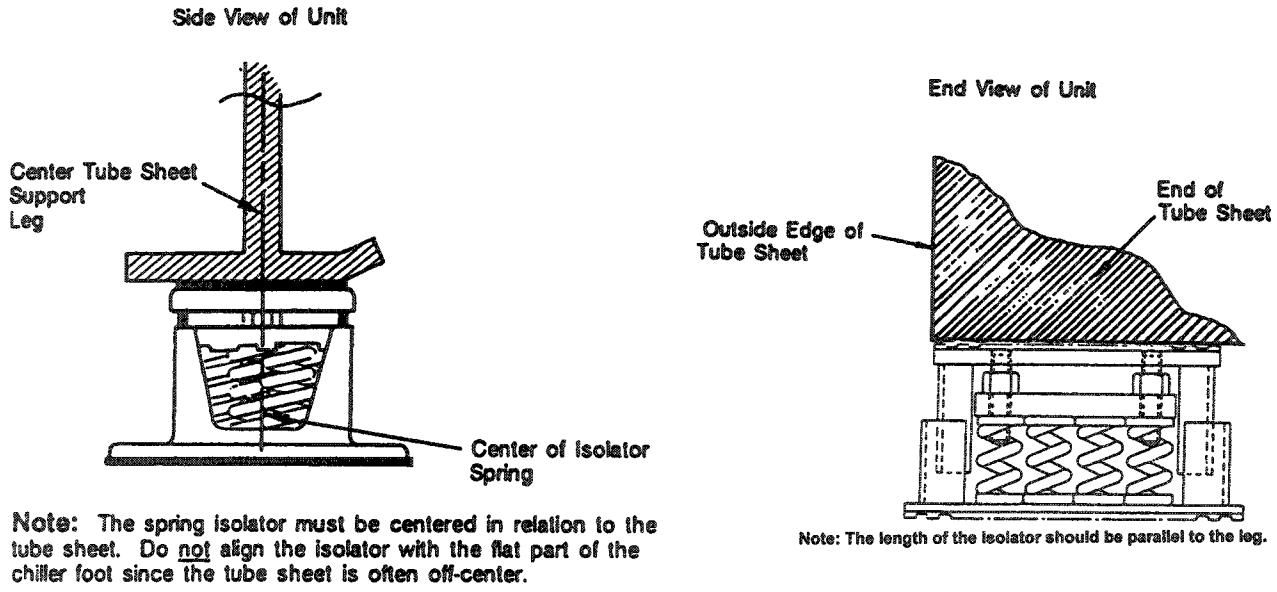
4. If the chiller must be fastened to the isolators, insert cap screws through the chiller base and into the holes tapped in the upper housing of each isolator. However, do not allow the screws to protrude below the underside of the isolator upper housing. An alternative method of fastening the chiller to the isolators is to cement the neoprene pads.

5. Set the chiller on the isolators; refer to "Rigging" for listing instructions.

The weight of the chiller will force the upper housing of each isolator down, perhaps causing it to rest on the isolators's lower housing. Figure 10 illustrates spring isolator construction.

6. Check the clearance on each isolator. If this dimension is less than 1/4-inch on any isolator, use a wrench to turn the adjusting bolt one complete revolution upward.

Repeat this operation until a 1/4-inch clearance is obtained at one or more isolators.



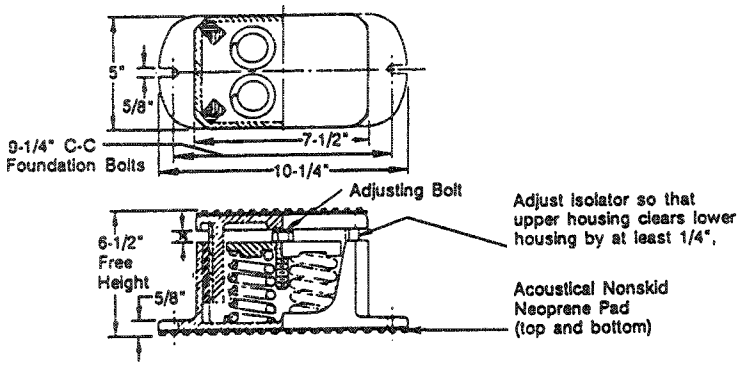
Note: When the load is applied to the isolators (Step 5), the top plate of each isolator moves down to compress the springs until either; (1) The springs support the load; or (2) The top plate rests on the bottom housing of the isolator.

a. If the springs are supporting the load, screwing down on the adjusting bolt (Step 7) will immediately begin to raise the chiller.

7. Turn the adjusting bolt on each of the remaining isolators to obtain the required minimum clearance of 1/4-inch.

8. Once the minimum required clearance is obtained on each of the isolators, level the chiller by turning the adjusting bolt on each of the isolators on the low side of the unit. Be sure to work from one isolator to the next. Remember that the chiller must be level to within 1/16: over its length and width, and that clearance of each isolator must be 1/4-inch.

Figure 9
Chiller Foot and Isolator Orientation



Note: The spring isolator must be centered in relation to the tube sheet. Do not align the isolator with the flat part of the chiller foot since the tube sheet is often off-center.

Note: The length of the isolator should be parallel to the leg.

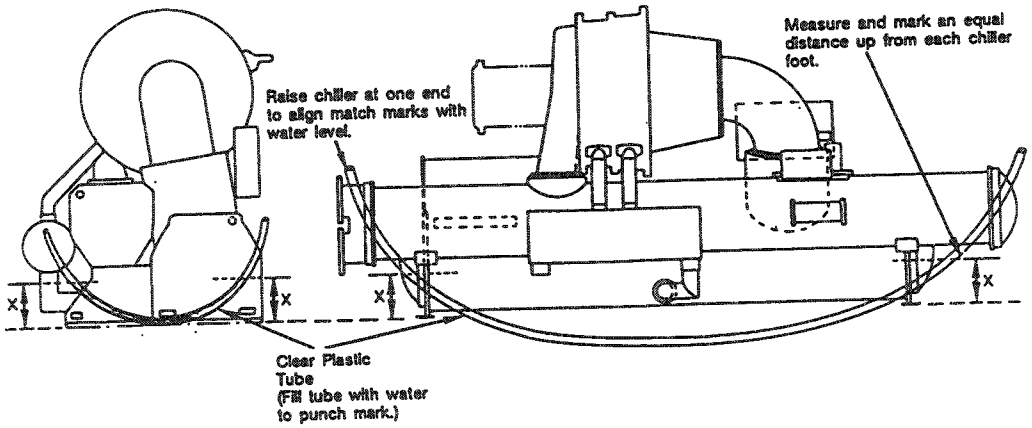
Type CT-12 Spring Isolators

Unit Leveling

Follow the instructions outlined below and illustrated in Figure 11 to determine whether or not the chiller is set level.

1. Measure an equal distance up from each foot of the chiller and make a punch mark at each measured distance.



2. Suspend a clear plastic tube along the length of the chiller as shown in Figure 11.

3. Fill the tube with water until the level aligns with the punch mark at one end of the chiller; then check the water level at the opposite mark.

If the water level does not align with the punch mark, use full-length shims to raise one end of the chiller until the water level at each end of the tube aligns with the punch marks at both ends of the chiller.

4. Once the unit is level across its length, repeat Steps 1 through 3 to see if unit is level across the the width.

Since the Trane Company has a policy of continuous product and product data improvement, it reserves the right to change design and specifications without notice. Only qualified technicians should perform the installation and servicing of equipment referred to in this publication.

Warnings and Cautions

NOTICE

Warnings and Cautions appear at appropriate locations throughout this manual. Read these carefully.

WARNING: Indicates a potentially hazardous situation which, if not avoided, could result in death or serious injury.

CAUTION: Indicates a potentially hazardous situation which, if not avoided, may result in minor or moderate injury. It may also be used to alert against unsafe practices and where property-damage-only accidents could occur.

Water Piping

Overview

Several water piping circuits must be installed and connected to the chiller.

Note: Field Piping must be arranged and supported to avoid stress on the equipment. It is strongly recommended that the piping contractor refrain from piping closer than 3'-0" minimum to the equipment. This will allow for proper fit-up upon arrival of the unit at the job site. Any adjustment that is necessary can be made to the piping at that time.

(a) Pipe the evaporator into the chilled water circuit;

(b) Pipe the condenser into the condenser water circuit;

(c) A heat-recovery condenser water circuit, (optional);

(d) An auxiliary condenser water circuit, (optional)

Piping suggestions for each of the four water circuits listed above are outlined later in this section. General recommendations for the installation of field-supplied piping components (e.g., valves, flow switches, etc.) common to most chiller water circuits are listed below.

Water Treatment

Since the use of untreated or improperly treated water in a CenTraVac® may result in inefficient operation and possible tube damage, be sure to engage the services of a qualified water treatment specialist if needed. A label with the following disclamatory note is affixed to each unit.

Customer Note: The use of improperly treated or untreated water in this equipment may result in scaling, erosion, corrosion, algae or slime. The services of a qualified water treatment specialist should be engaged to determine what treatment, if any, is advisable. The Trane Company warranty specifically excludes liability for corrosion, erosion or deterioration of Trane equipment. Trane assumes no responsibilities for the results of the use of untreated or improperly treat water, or saline or brackish water.

⚠ CAUTION
DO NOT USE UNTREATED OR IMPROPERLY TREATED WATER or equipment damage may occur.

Pressure Gauges

Locate pressure gauge taps in a straight run of pipe. Place tap a minimum of one pipe diameter downstream of any elbow, orifice etc. Example, for a 6" pipe, the tap would be at least 6" from any elbow, orifice, etc.

Valves

1. Install field-supplied air vents and drain valves on the water boxes. Each water box is provided with a 3/4" NPTF vent and drain connection.

Plastic plugs are factory-installed in both openings for shipment; remove and discard these plugs as you install the water box vents and drain valves.

2. If necessary for the application, install pressure-relief valves at the drain connections on the evaporator and condenser water boxes. To do so, add a tee with the relief valve attached to the drain valve.

To determine whether or not pressure-relief valves are needed for a specific application, keep in mind that:

(a) Vessels with close-coupled shutoff valves may cause high potentially damaging hydrostatic pressures as fluid temperature rises; and,

(b) Relief valves are required by ASME codes when the shell waterside is ASME. Follow ASME guidelines or other applicable codes to assure proper relief valve installation.

⚠ CAUTION
INSTALL PRESSURE-RELIEF VALVES IN THE CONDENSER AND EVAPORATOR WATER CIRCUITS, failure to do may result in shell damage due to hydrostatic expansion.

Strainers

Install a strainer in the entering side of each piping circuit to avoid possible tube plugging in the chiller with debris.

⚠ CAUTION
INSTALL STRAINERS IN ALL WATER PIPING ENTERING THE CHILLER, failure to do so may result in tube plugging conditions that could damage unit components.

Flow-Sensing Devices

Use either flow switches or differential pressure switches in conjunction with the pump interlocks to verify evaporator and condenser water flows.

Water Piping

To assure adequate chiller protection, wire the chilled-water and condenser-water flow switches in series with the appropriate water pump interlock. Refer to the wiring diagrams that shipped with the unit for specific electrical connections.

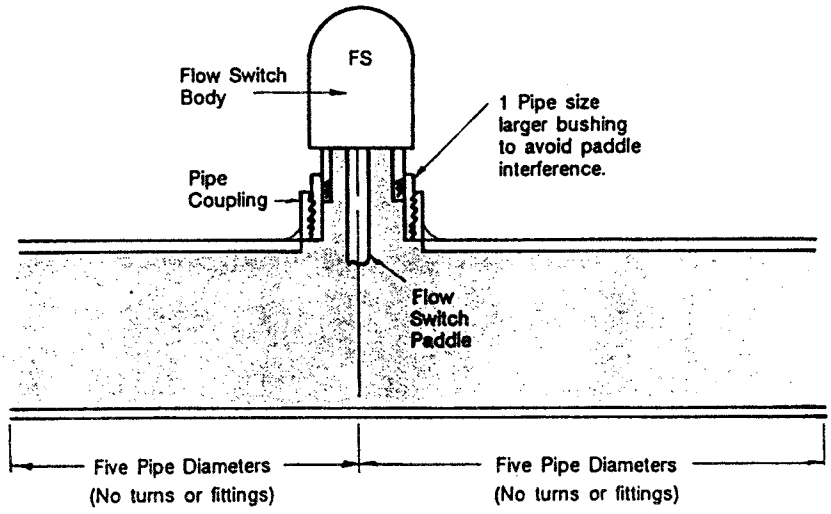
Unless stated otherwise, all flow-sensing devices must be field-supplied. Be sure to follow the manufacturer's recommendations for device selection and installation. Also, review the general flow switch installation guidelines listed below.

1. Mount the flow switch upright in a horizontal section of pipe. Allow at least 5 pipe diameters of straight, horizontal run on each side of the switch.

2. To assure that the flow switch operates as designed, adjust the length of the flow switch paddle to compensate for the pipe diameter and the height of the coupling tee used to install the switch.

3. Install the flow switch using a coupling that is large enough to allow the insertion of a bushing one pipe diameter larger than the flow switch base (Figure 1). This will prevent interference with the flow switch paddle.

4. Verify that the direction-of-flow arrow on the switch points in the same direction as actual water flow through the piping circuit.



5. Remove all air from the piping circuit to prevent possible flow switch "fluttering".

6. Adjust the flow switch to open when water flow is less than normal.

⚠ CAUTION

EVAPORATOR AND CONDENSER "PROOF OF FLOW" SWITCHES (EITHER FLOW OR DELTA-P) ARE REQUIRED IN SERIES WITH THE PUMP CONTACTOR AUXILIARY SHOWN ON WIRING DIAGRAMS. THESE SWITCHES ARE USED WITH UCP2 CONTROL LOGIC TO CONFIRM FLOW PRIOR TO STARTING A UNIT AND TO STOP A RUNNING UNIT IF FLOW IS LOST. FOR TROUBLE SHOOTING, A VIEWABLE DIAGNOSTIC IS GENERATED IF A "PROOF OF FLOW" SWITCH DOES NOT CLOSE WHEN FLOW IS REQUIRED. Failure to include the condenser "proof of flow" switch or to "jumper out" this switch could cause the unit to stop on a secondary level of protection such as high condenser pressure. Frequent cycling on these higher level diagnostic devices could cause excessive thermal and pressure cycling of unit components (O-rings, gaskets, sensors, motors, controls, etc.) resulting in premature failure.

Figure 1
Flow Switch Installation

Water Piping

Evaporator and Condenser Water Piping

Figures 2 and 3 illustrate the typical water piping arrangements recommended for the evaporator and condenser.

Note: It is strongly recommended that the piping contractor refrain from piping closer than 3'-0" mini mum to the equipment. This will allow for proper fit-up upon arrival of the unit at the job site. Any adjustment that is necessary can be made to the piping at that time.

Water piping connection sizes are identified in Tables 1, 2 and 3. Remember that entering and leaving evaporator water can be piped to either water box connection since the tube bundles are split vertically.

Note: To assure that the evaporator water piping is clear, check it after the chilled water pump is operated but before initial chiller start-up. If any partial blockages exist, they can be detected and removed to prevent possible tube damage resulting from evaporator freeze-up or erosion.

Note: Arrange the condenser water piping so that the water supply enters the shell at the lower connection, and exits from the top connection. Single-pass condenser shells may be piped as desired since both connections are at the same level.

For applications that include an "infinite source" or "multiple-use", cooling condenser water supply, install a valved bypass "leg" (optional) between the supply and return pipes; see Figure 3. This valved bypass allows the operator to short-circuit water flow through the cooling condenser when the supply water temperature is too low.

⚠ CAUTION
SYSTEM PRESSURE DIFFERENTIAL MUST BE MAINTAINED ABOVE 5 PSID AT ALL TIMES. Failure to do so could result in operating problems.

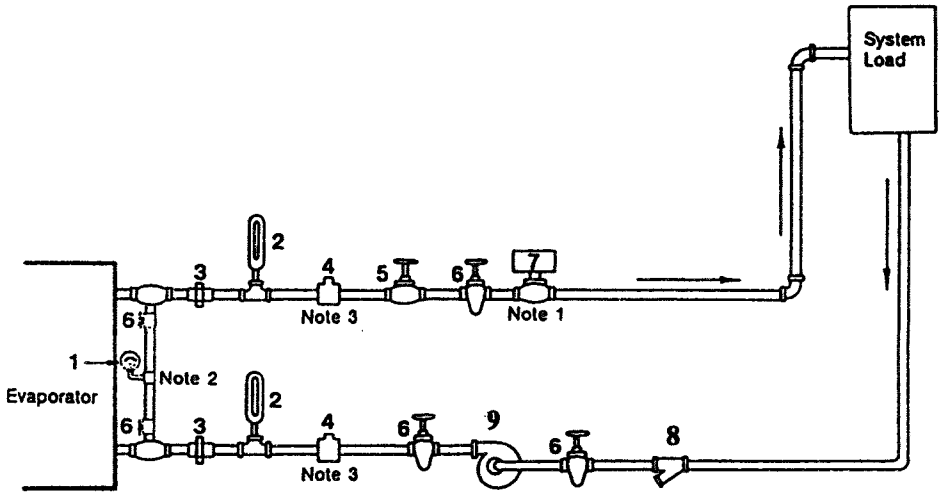
Note: Whenever a CVHE, CVHF, CVHG chiller is equipped with an auxiliary condenser, use a bypass valve system to avoid circulating water through the auxiliary shell during unit shutdown.

Water Box Locations

If necessary, the non-marine water boxes on each shell whether evaporator or condenser can be switched end-for-end to obtain the desired piping arrangement. Contact Trane LBU Marketing for switching of marine-style boxes.

⚠ CAUTION
DO NOT EXCHANGE POSITIONS OF MARINE WATER BOXES. This could alter designed water flow piping configuration and prevent proper unit operation.

To accommodate lifting apparatus, a nut is welded to each evaporator water box to enable attachment of a 3/4" eyebolt (field-supplied). Condenser water boxes are provided with 1/2" tapped holes that allow installation of the eyebolt included in the unit's loose parts-box.



If the water boxes on any of the shells are exchanged end-for-end, be sure to reinstall them right side up to maintain the correct baffle arrangements. Use a new gasket with each water box cover.

Water Piping Connections

For CVHEs beginning with design sequence "1D', all units (except those with 032 through 050 condenser shells with 150 psig non-marine water boxes) use cut-groove end NSP Victaulic®-style pipe connections. All CVHGs beginning with "1A" and later design sequences. All CVHF units, "A" and later design sequences, use grooved-pipe connections. See Figure 4.

Piping joined using grooved type couplings, like all types of piping systems, requires proper support to carry the weight of pipes and equipment. The support methods used must eliminate undue stresses on joints, piping and other components; allow movement where required, and provide for any other special requirements (i.e., drainage, etc.)

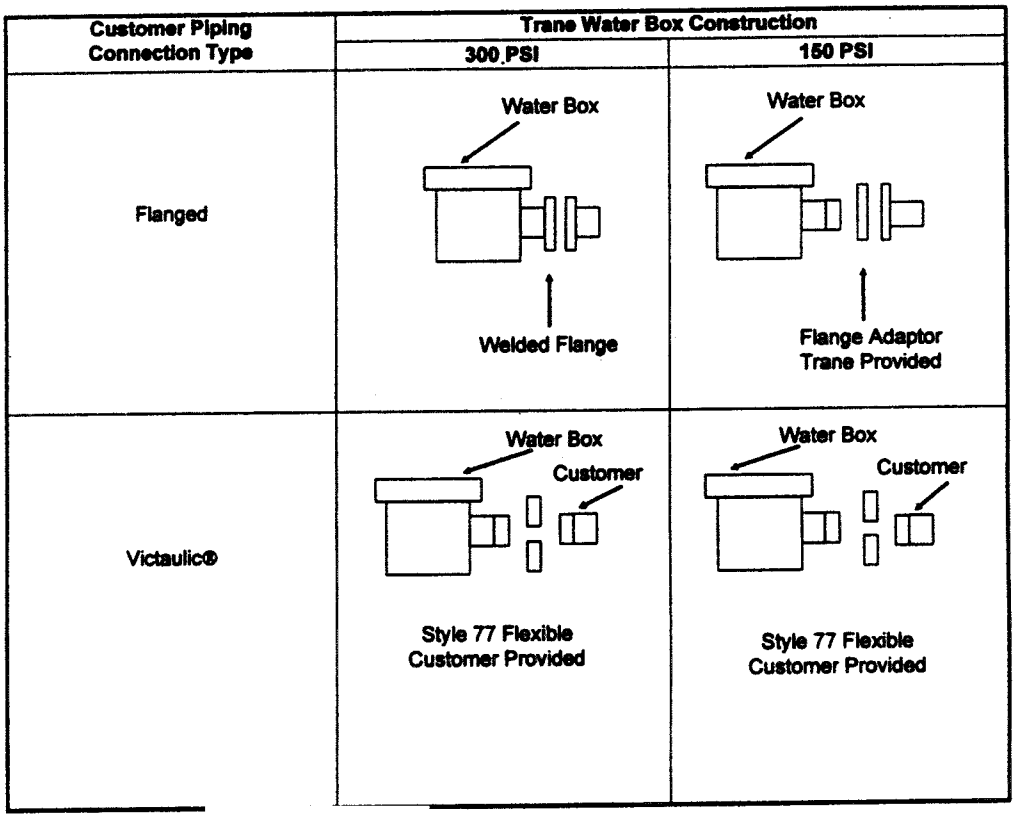
Table 3
Water Piping Connection Components

		Customer Piping Connection	
Unit Model	**Unit Connection Type**	**Victualic®**	**Flanged**
CVHE/CVHG	Flanged (Condenser 032-050 150 psig non-marine only)	Trane provided Victaulic-to-Flange Adapter	No Adapter Required
CVHE/F/G	Victaulic (All others)	Customer provided Victaulic Coupling	Trane provided Victaulic-to-Flange Adapter



Grooved Pipe Coupling

A customer-supplied, standard flexible grooved pipe coupling (Victaulic Style 77 or equivalent) should be used to complete the Victaulic connection for both 150 and 300 psig water boxes. See Table 3.

When a flexible coupling such as this is installed at the water box connections (Figure 5), other flexible piping connectors (i.e., braided-steel, elastomeric arch, etc.) are usually not required to attenuate vibration and/or prevent stress on the connections.

Note: Flexible coupling gaskets require proper lubrication before installation to provide a good seal. Refer to the coupling manufacturer's guidelines for proper lubricant type and application.

Figure 5
Customer Piping Alternatives for Water Connections

Flange-Connection Adapters

When flat-face flange connections are specified, flange-to-groove adapters are provided (Victaulic® Style 741 for 150 psig systems; Style 743 for 300 psig systems). Welded flanged connections are available only as a design special unless ordered as such, flange to groove adapters are provided if flat faced flange connections are specified. The adapters are shipped bolted to one of the chiller end-supports (Figure 6). Adapter weights are given in Tables 1 and 2. The flange adapters provide a direct, rigid connection of flanged components to the grooved-pipe chiller water box connections.

In this case, the use of flexible type connectors (i.e., braided steel, elastomeric arch, etc.) is recommended to attenuate vibration and/or prevent stress at the water box connections. Flange adapters are not provided for CVHE, CVHF, and CVHG units with 300 psig water boxes that have 14-inch or 16-inch piping connections.

All flange-to-flange assembly bolts must be provided by the installer. Bolt sizes and number required are given in Tables 1 and 2.

The four draw-bolts needed for the 14-inch and 16-inch Style 741 (150 psig) adapters are provided. The Style 741, 150 psig flange adapter requires a smooth, hard surface for a good seal.

Connection to other type flange faces (i.e., raised, serrated, rubber, etc.) will require the use of a flange washer between the faces. Refer to the flange adapter manufacturer's guidelines for specific information.

The Style 743, 300-psig flange adapters are designed to mate with raised-face flanges. They can be used with flat-faced flanges, however, if the raised projections on the outside face of the adapter are removed (Figure 8.)

Note: The flange-adapter gasket must be placed with the color-coded lip on the pipe and the other lip facing the mating flange.

⚠ **CAUTION**
GASKET-CONTACT SURFACES OF ADAPTER MUST BE FREE OF GOUGES, UNDULATIONS, OR DEFORMITIES. Failure to do so will not provide an effective seal.

Victaulic Gasket Installation

1. Check gasket and lubricate: Check gasket supplied to be certain it is suited for intended service. Code identifies gasket grade. Apply a thin coat of silicone lubricant to gasket tips and outside of gasket.

2. Install Gasket: Place gasket over pipe end, being sure gasket lip does not overhang pipe end. See Figure 7 for gasket configuration.

3. Join pipe ends: Align and bring two pipe ends together and slide gasket into position centered between the grooves on each pipe. No portion of the gasket should extend into the groove on either pipe.

4. **Apply Vic-Flange®**: Open fully and place hinged flange around the grooved pipe end with the circular key section locating into the groove.

5. Insert bolt: Insert a standard bolt through the mating holes of the Vic-Flange to secure the flange firmly in the groove.

6. Tighten nuts: Tighten nuts alternately and equally until housing bolt pads are firmly together (metal to metal). Excessive nut tightening is not necessary. **Note:** Uneven tightening may cause gasket to pinch.

Bolt-Tightening Sequence for Water Piping Connections

A bolt-tightening sequence for flanges with flat gaskets or o-rings is described below and shown in Figure 9. Remember that improperly tightened flanges may leak.

Note: Before tightening any of the bolts, align the flanges. Flange bolt torque requirements are given in Table 6.

Flanges with 4, 8 or 12 Bolts

See Figure 9. Tighten all bolts to a snug tightness, following the appropriate numerical sequence for the flange. Repeat this sequence to apply the final torque to each bolt.

Flanges with 16, 20 or 24 Bolts

See Figure 9. Following the appropriate numbered sequence, tighten only the first half of the total number of bolts to a snug tightness. Next, sequentially tighten the remaining half of the bolts in the proper order.

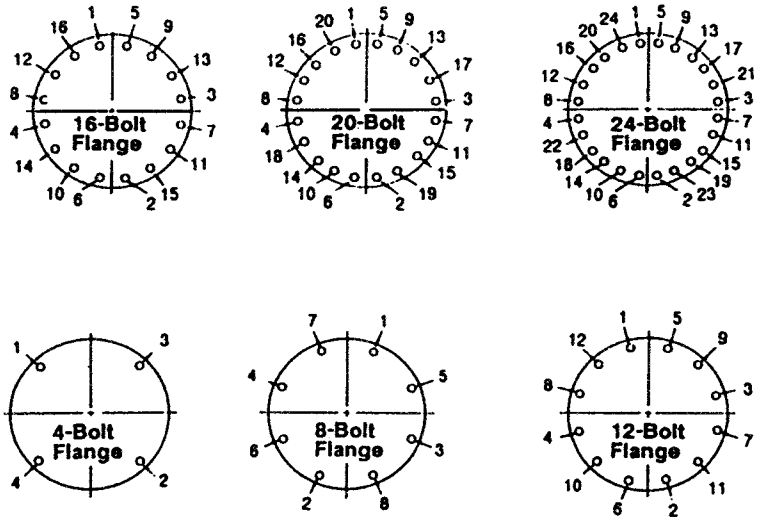
Flanges with More than 24 Bolts

Refer to Figure 9 and sequentially tighten the first 12 bolts to a snug tightness. Tighten the next 12 consecutively numbered bolts in sequence, to the final torque.

Then, apply final torque to the first 12 bolts and the bolts not yet tightened (i.e., unnumbered bolts in Figure 9). Be sure to start with bolt "1" and move progressively around the flange in a clockwise direction.

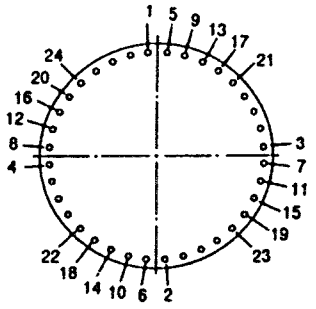
Evaporator Water Box Covers

See Figure 9. Ensure that the water box head rests tightly against the tube sheet; then snugly tighten the 26 bolts in sequential order.



If excessive tube sheet crown prevents the head from contacting the tube sheet, tighten the bolts located where the greatest gaps occur. Be sure to use an equal number of bolt turns from side to side.

Table 6
Flange Bolt Torque Recommendations for O-Ring and Flat-Gasket Piping Connections



Bolt Size (Inch)	Gasket Type	
	O-Ring	Flat
3/8	25 (34)	12-18 (16-24)
1/2	70 (95)	33-50 (45-68)
5/8	150 (203)	70-90 (95-122)
3/4	250 (339)	105-155 (142-210)

Note: Torques provided in Ft/Lbs. (Newton/metres)

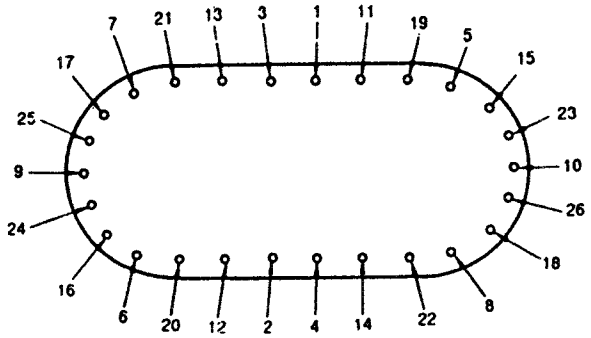


Figure 9
Bolt Tightening Sequences for Water Piping Flanges and Water Boxes

Flanges with more than 24 bolts

Evaporator Water Box Covers

Purifier Purge Requirements

Purge Installation

For certain CenTraVacs, the purge system is not mounted on the chiller when it ships. For 800-ton heat recovery chillers and 1250 and 1400 ton chillers with auxiliary condensers, the Purifier Purge is shipped in a separate container that is secured to the chiller shipping skid.

Install the purge system in accordance with the following instructions.

1. Remove Purifier Purge from its shipping brackets or container.

2. Disconnect purge gas and liquid lines and conduit from shipping bracket that spans purge supports on top of the heating or auxiliary condenser.

3. Remove shipping bracket and screws from purge supports and discard.

4. Locate purge on top of supports (purge base goes outside supports).

5. Secure purge to supports with four 1/4-20 x 1/2 long hex head thread rolling screws provided with unit.

6. Remove purge control panel access cover.

7. Connect 90° conduit connector to open 7/8 diameter hole on side of control panel.

8. Connect conduit wires to terminal block in control panel as shown in wiring connection detail.

9. Replace access cover on control panel.

10. Braze 1/4" FL and 5/8 ODS copper lines to purge per A.W.S. B CUP-3, 1/4: ODSW copper coupling provided with unit.

11. Open gas and liquid line ball valves before operating unit.

Refrigerant Vent-Line

General Recommendations

Both the purge and rupture disc vent lines must be routed to outside atmosphere. Use only material compatible with the refrigerant in use. The use of PVC (not CPVC) piping is acceptable if the pipe joint is properly primed and if the adhesive used has been tested for refrigerant compatibility. Testing conducted in Trane laboratories has approved the use of the following materials for PVC pipe construction.

Primer - Hercules, PVC Primer #60-465, RectorSeal PVC Cleaner -Smiling Sam CL-3 Adhesive-Hercules, Clear PVC, Medium Body, Medium Set, #60-020 RectorSeal PVC Cement -Green Gene 104.

Consult with the manufacturers of any field-provided components or materials added to the refrigerant-side of the machine for acceptable material compatibility.

During vent line construction, provide a drip leg on the line that is of sufficient length to accommodate a minimum of one gallon of liquid. Provide a standard 1/4" FL x 1/4" NPT, capped refrigerant service valve to facilitate liquid removal. Accumulated liquid must be drained from the drip leg into an evacuated waste container once every six months, at a minimum, and more often if the purge operates excessively.

Purge Discharge Vent Line

On CVHE, CVHF, CVHG units, the purge discharge is factory-piped downstream of the rupture disc on the unit.

Rupture Disc Vent Installation

All CenTraVac® chillers are equipped with carbon rupture discs. A cross-section of the rupture disc assembly appears in Figure 10 along with an illustration indicating the location of the rupture disc on the suction elbow.

If refrigerant pressure within the evaporator exceeds 15 psig, the rupture disc breaks, shell pressure is relieved as refrigerant escapes from the chiller.

When constructing the rupture disc vent line, be sure to consult local codes for applicable guidelines and constraints.

Several general recommendations for rupture disc vent line installation are outlined below.

1. Verify that the vacuum support side of the rupture disc is positioned as shown in the cross-section view that appears in Figure 10.

Note: If the rupture disc was removed for any reason, it must be reinstalled as shown.

2. Do not apply threading torque to the outside pipe assembly when installing the connecting pipe.

⚠ CAUTION

Applying threading torque to the outside pipe may damage the rupture disc assembly.

3. Support the vent piping, use a flexible connection to avoid placing stress on the rupture disc. (Stress can alter rupture pressure and cause the disc to break prematurely.)

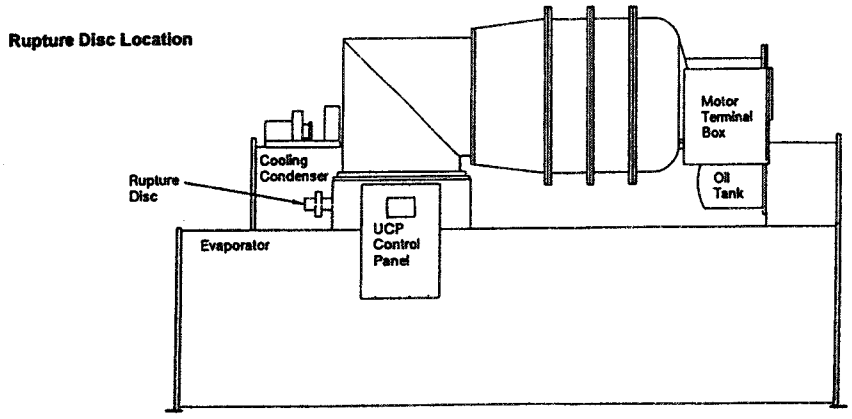
The flexible connector used to isolate the rupture disc from excessive vent line vibration must be compatible with the refrigerant in use. Use a flexible, steel connector such as the stainless-steel type MFP, style HNE, flexible pump connector (from Vibration Mounting and Control, Inc.) or equivalent.

See Figure 11 for a recommended relief piping arrangement.

Important: Vent pipe size must conform to ANSI/ASHRAE Standard Standard 15, which discusses vent pipe sizing.

Use Table 7 and then Figure 12 to determine proper vent pipe size.

Note: To determine the total "C" value for a specific unit, add the appropriate "C" values for the evaporator, standard condenser and economizer. If the unit is equipped with any options (e.g., heat recovery, free cooling, or an auxiliary condenser), add the applicable "C" value(s) to this total.



With this new sum, refer to Figure 12 to determine the vent line pipe diameter needed to handle flow.

4. Normally, where multiple chillers are used, install a separate rupture disc vent line for each unit.

5. Consult local regulations for any special relief line requirements and refer to CFC-Guide-2.

6. The discharge of the vent line outside should not be in the general vicinity of any fresh air intakes to the building. Any gas venting from the vent line should not be allowed to re-enter the building.

Figure 10
Illustrates Rupture Disc Location, Cross Section of Rupture Disc and Recommended Rupture Disc Relief Piping

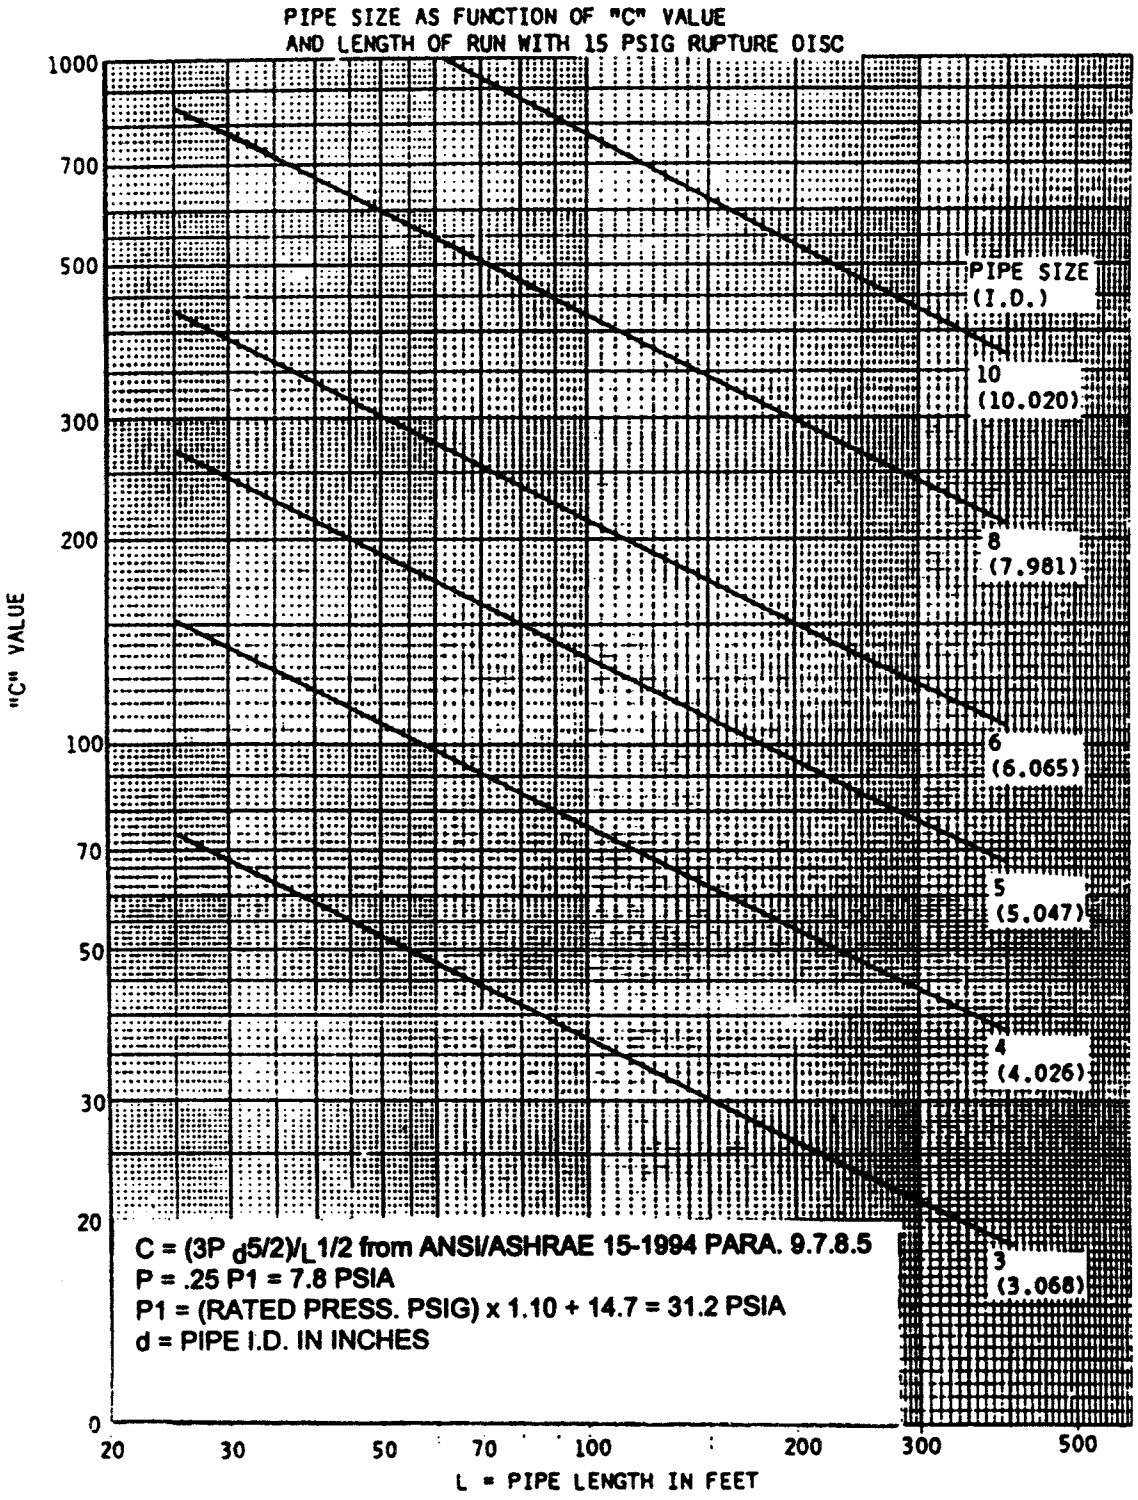
250E	250L		93.81	62.12			56.72		

Notes:



1. To determine the total "C" value for a specific unit, add the appropriate ""C" values for the evaporator, standard condenser and economizer. If the unit is equipped with any options (e.g., heat recovery, free cooling or an auxiliary condenser, add the applicable "C" values to this total. With this new sum, refer to Figure 12 to determine the vent line pipe diameter.

2. If piping multiple rupture discs (multiple units) to a common vent line, first determine the total"C" value for each unit, and then; add all "C" values together and apply the result to the "vent pipe sizing chart" in Figure 12.

3. EVSZ = Evaporator Shell Size;
   S = Short Shell
   L = Long Shell
   E = Extended Shell
   M = Medium

4. CDSZ = Condenser Shell Size;
   S = Short Shell
   L = Long Shell
   E = Extended Shell

Figure 12
Rupture Disc Vent Pipe Sizing

Unit Insulation Requirements

Factory-installed insulation is available as an option for all CVHE, CVHF and CVHG units.

Important: Refer to notes included with Table 8 because units with refrigerant pumps are insulated differently than units without refrigerant pumps.

In those instances where the chiller is not factory-insulated, install insulation over the areas shaded in Figure 13. It may also be necessary to insulate the compressor suction cover if the unit is installed in an area subjected to high humidities.

Insulate both 1/4" eductor lines, one from the suction cover and one from the evaporator to prevent sweating.

The quantities of installation required based on unit size and insulation thickness are listed in Table 8. Insulation thickness is determined at normal design conditions which are:

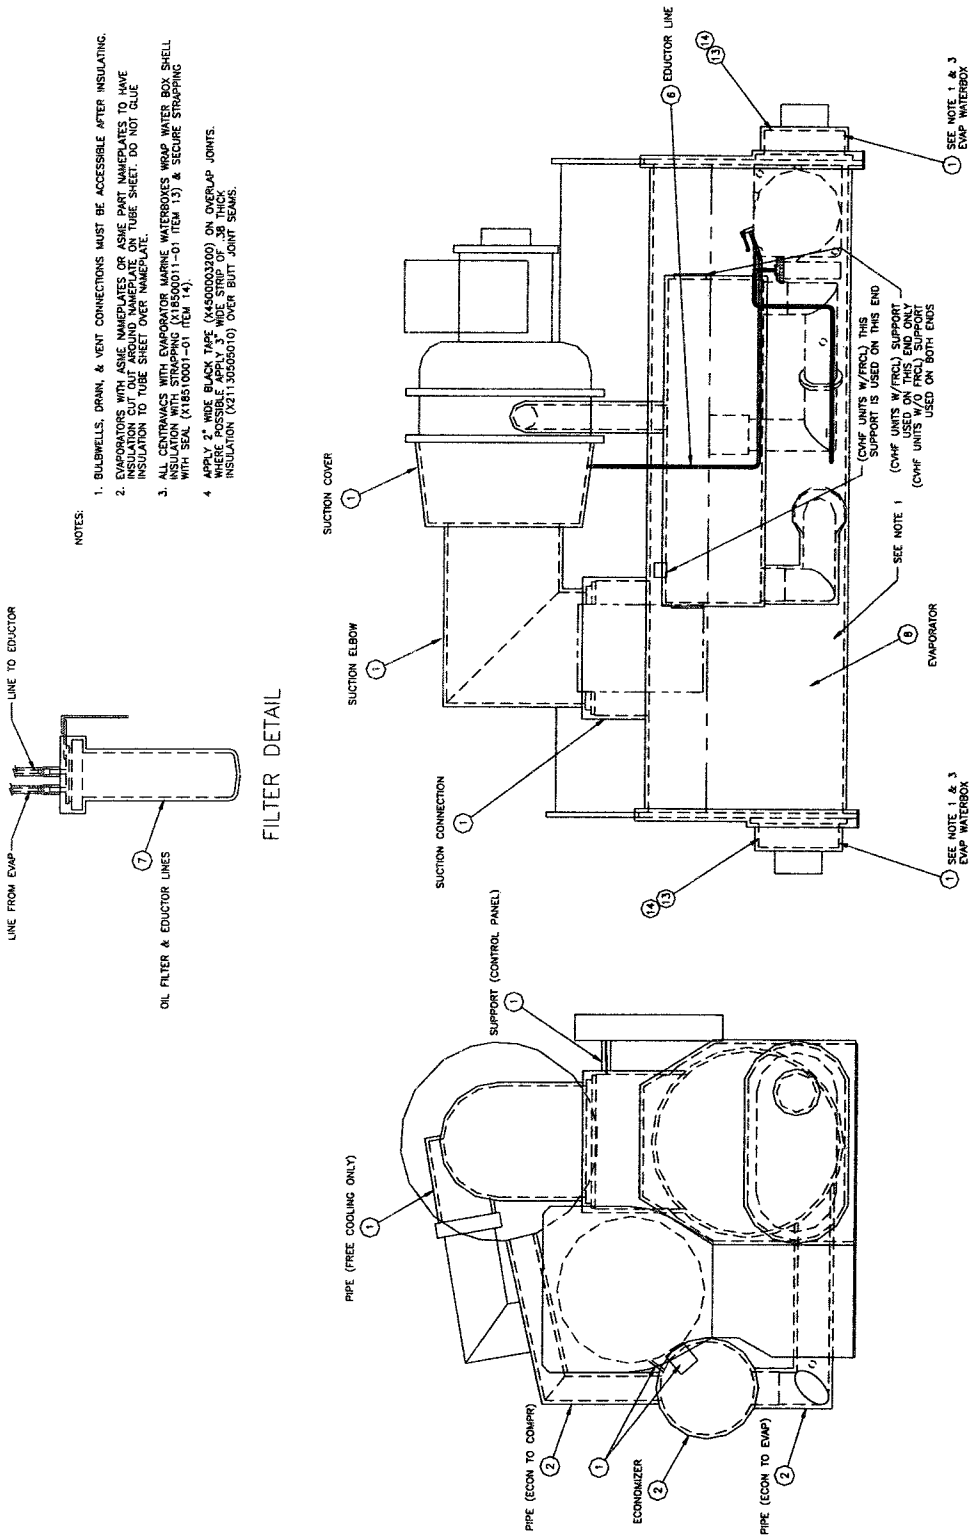
- 85°
- 75% Relative Humidity

Note: If the unit is not factory-insulated: Install insulation around the evaporator bulbwells; and, ensure that the bulbwells and connections for the water box drains and vents are still accessible after insulation is applied.

⚠ CAUTION
IN ORDER TO PREVENT DAMAGE TO FACTORY-INSTALLED INSULATION, do not allow the insulation to be exposed to excessive sunlight.

Table 8
Evaporator Insulation Requirements

EVSZ (Note 1)	Standard Unit		Free Cooling	
	3/4" Insulation (Note 3)	3/8" Insulation (Note 4)	3/4" Insulation (Note 3)	3/8" Insulation (Note 4)
032S	337 Sq. Ft.	52 Sq. Ft.	347 Sq. Ft.	74 Sq. Ft.
032L	365 Sq. Ft.	52 Sq. Ft.	377 Sq. Ft.	74 Sq. Ft.
050S	385 Sq. Ft.	63 Sq. Ft.	398 Sq. Ft.	72 Sq. Ft.
050L	420 Sq. Ft.	63 Sq. Ft.	436 Sq. Ft.	72 Sq. Ft.
080S	505 Sq. Ft.	84 Sq. Ft.	515 Sq. Ft.	97 Sq. Ft.
080L	553 Sq. Ft.	84 Sq. Ft.	566 Sq. Ft.	97 Sq. Ft.
142M	555 Sq. Ft.	98 Sq. Ft.	555 Sq. Ft.	133 Sq. Ft.
142L	578 Sq. Ft.	98 Sq. Ft.	578 Sq. Ft.	133 Sq. Ft.
142E	603 Sq. Ft.	104 Sq. Ft.	629 Sq. Ft.	133 Sq. Ft.
210L	700 Sq. Ft.	98 Sq. Ft.	710 Sq. Ft.	133 Sq. Ft.
210D	1220 Sq. Ft.	193 Sq. Ft.	N/A	N/A
250 D	1308 Sq. Ft.	193 Sq. Ft.	N/A	N/A
250 E	770 Sq. Ft.	97 Sq. Ft.	N/A	N/A



Notes:
1. EVSZ = Evaporator Shell Size, L = Long Shell, S = Short Shell
2. D = Duplex, M = Medium, E = Extended
3. 3/4" sheet insulation is installed on the evaporator, evaporator water boxes, suction elbow and suction cover as indicated in Figure 13.
4. 3/8" sheet insulation is installed on all economizers. All liquid lines and other pipes require the use of 1/2" pipe insulation or 3/8" sheet insulation. Copper oil eductor tube lines require pipe insulation.

CAUTION
⚠ IF THE INSULATION WILL BE PAINTED IN THE FIELD, USE ONLY WATER-BASED LATEX PAINTS. Thinners and solvents used or other types of paints may cause seams in the insulation to open as a result of shrinkage.

High Humidity Option

Note: The High Humidity Option is not used on units with the Refrigerant Pump.

Since the Trane Company has a policy of continuous product and product data improvement, it reserves the right to change design and specifications and without notice. Only qualified technicians should perform the installation and servicing of equipment referred to in this publication.

Warnings and Cautions

NOTICE

Warnings and Cautions appear at appropriate locations throughout this manual. Read these carefully.

WARNING: Indicates a potentially hazardous situation which, if not avoided, could result in death or serious injury.

CAUTION: Indicates a potentially hazardous situation which, if not avoided, may result in minor or moderate injury. It may also be used to alert against unsafe practices and where property-damage-only accidents could occur.

©American Standard Inc 2001

Note: Unit-mounted starters are available as an option on CVHE, CVHF, CVHG units with RLAs of 1315 amps or less, and with a nominal voltage of no more than 600 volts.

While this option eliminates most field-installed wiring requirements, the electrical contractor must still complete the electrical connection for: (1) Power supply wiring to the starter, (2) Other unit control options present, and (3) Any field-supplied control devices

General Requirements

⚠ WARNING
LOCK SUPPLY POWER AND CHILLER DISCONNECT SWITCHES OPEN. Failure to do so could result in injury or death due to electrical shock or contact with moving parts.

As you review this manual, along with the wiring instructions presented in this section, keep in mind that:

Typical field connection requirements for remote-mounted starters are shown in fold-out drawings at the end of the manual, respectively, and summarized in Table 1.

All field-installed wiring must conform to NEC guidelines, as well as to any applicable state and local codes. Be sure to satisfy proper equipment grounding requirements per NEC.

Compressor motor electrical data including motor kw, voltage utilization range, rated load amps and locked rotor amps is listed in Tables 2 through 13 for your reference.

All field-installed wiring should be checked for proper terminations, and for possible shorts or grounds.

Note: The typical customer connection diagrams shown in this manual are representative of standard CVHE, CVHF CVHG units, and are provided only for general reference. Always refer to the actual wiring diagrams that shipped with the chiller for specific as built electrical schematic and connection information.

Adaptive Frequency Drive Option

The following information is recommended when installing a drive.

Do not cut Adaptive Frequency Drive enclosure to provide electrical access. Removable panels have been provided for this purpose. Modify these panels only; away from enclosure. Refer to installation information shipped with the adjustable frequency drive or submittal drawings.

⚠ WARNING
DO NOT CUT ADAPTIVE FREQUENCY DRIVE ENCLOSURE, debris falling inside drive may cause failure of electronic components.

Table 1
Field Wiring Requirements

Description of Wiring Power Supply Wiring	Starter Panel Terminals	UCP Terminations
Standard Wiring: (To Terminal Block)

Tracer Controlled Relay	n/a	1U5-J18-1, 2, 3

Power Supply Wiring

To assure that power supply wiring to the starter panel is properly installed and connected, review and follow the guidelines outlined below.

3-Phase Power Source

1. Verify that the starter nameplate ratings are compatible with the power supply characteristics and with the electrical data on the unit nameplate.

2. If the starter enclosure must be cut to provide electrical access, exercise care to prevent debris from falling inside the enclosure. If the starter cabinet has a removable panel, be sure to remove the panel from the unit before drilling holes.

⚠ CAUTION
TO AVOID DAMAGE TO STARTER COMPONENTS, remove debris inside the starter panel which may cause an electrical short that seriously damages the starter components.

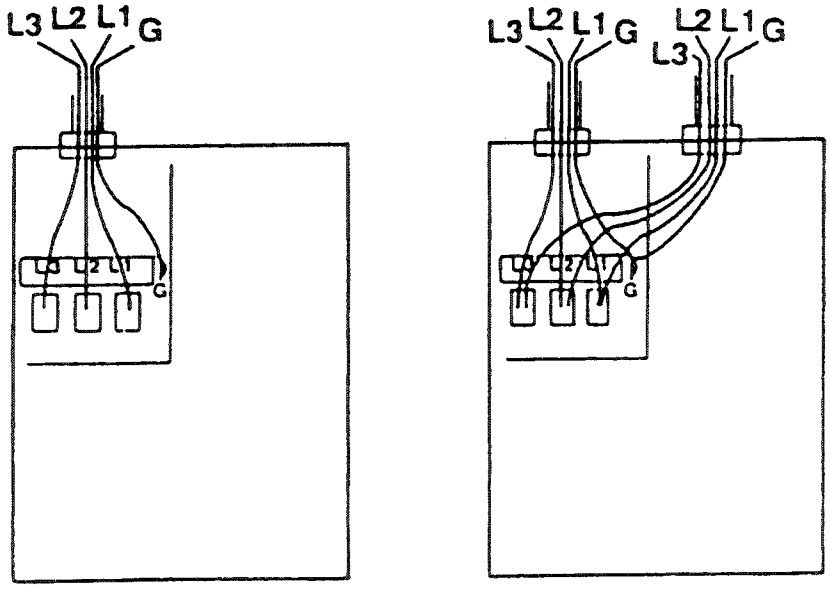
3. Use copper conductors to connect the 3-phase power supply to the remote or unit-mounted starter panel.

⚠ CAUTION
TO AVOID CORROSION OR OVERHEATING, use only copper conductors for terminal connections.

4. Size the power supply wiring in accordance with NEC, using the RLA value stamped on the chiller nameplate and control power load on L1 and L2.

5. Make sure that the incoming power wiring is properly phased; each power supply conduit run to the starter must carry the correct number of conductors to ensure equal phase representation. See Figure 1.

6. As you install the power supply conduit, make sure that this position does not interfere with the serviceability of any of the unit components, nor with structural members and equipment.



Also, assure that the conduit is long enough to simplify any servicing that may be necessary in the future (e.g., starter removal).

Note: Use flexible conduit to enhance serviceability and minimize vibration transmission.

Circuit Breakers and Fusible Disconnects

Size the circuit breaker or fuse disconnect in compliance with NEC or local guidelines.

Figure 1
Proper Phasing for Starter Power Supply Wiring

Optional PFCCs

Power factor correction capacitors (PFCCs) are designed to provide power factor correction for the compressor motor. They are available as an option.

Note: Remember that the PFCC nameplate voltage rating must be greater than or equal to the compressor voltage rating stamped on the unit nameplate. See Table 16 to determine what PFCC voltage rating is appropriate for each compressor voltage application.

⚠ CAUTION

PFCCS MUST BE WIRED INTO THE STARTER CORRECTLY! Misapplication of these capacitors could result in a loss of motor overload protection subsequently cause motor damage.

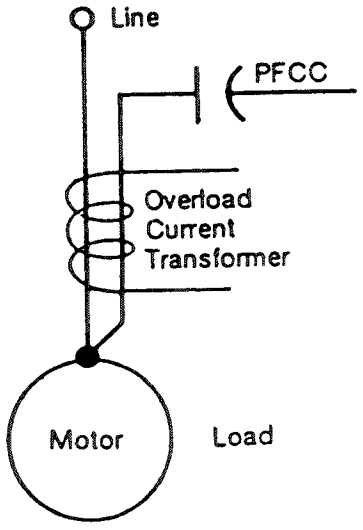


Table 2
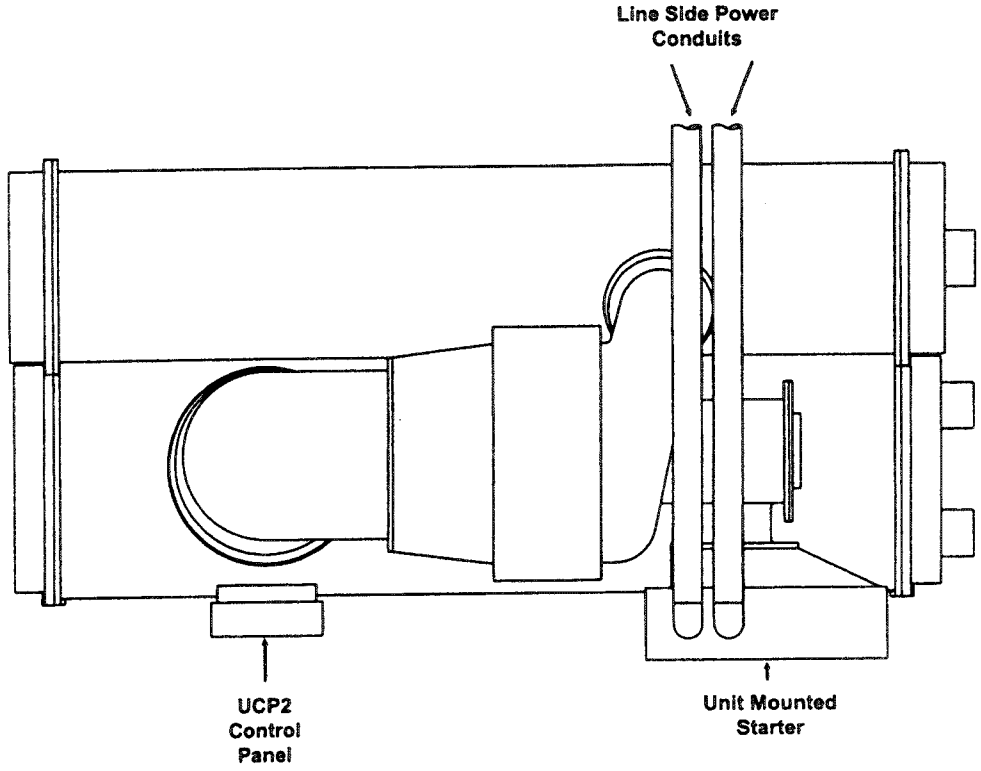
PFCC Sizing per Compressor Voltage Application

PFCC Design Voltage	Compressor Motor Rating (See Unit Nameplate)
240/60Hz	208V/60Hz
480V/60Hz	380V/60Hz 440V/60Hz 460V/60Hz 480V/60Hz
600V/60Hz	575V/60Hz 600V/60Hz
2400V/60Hz	2300V/60Hz 2400V/60Hz

Table 2 Continued

PFCC Rating	Compressor Motor Rating (See Unit Nameplate)
480V/50 Hz	346V/50 HZ 380V/50 HZ 400V/50 Hz 415V/50 Hz
4160V/50Hz	3300V/50 Hz

Figure 2
PFCC Leads Routed through Overload Current Transformer



Note: See CTV-EB-44 for more details.

Interconnecting Wiring

Typical equipment room conduit layouts with and without unit-mounted starters are shown in Figures 3 and 4, respectively.

Keep in mind that the interconnecting wiring between the starter panel, compressor and UCP2 control panel is factory-installed with unit-mounted starters but must be field-installed when a remote-mounted starter is used.

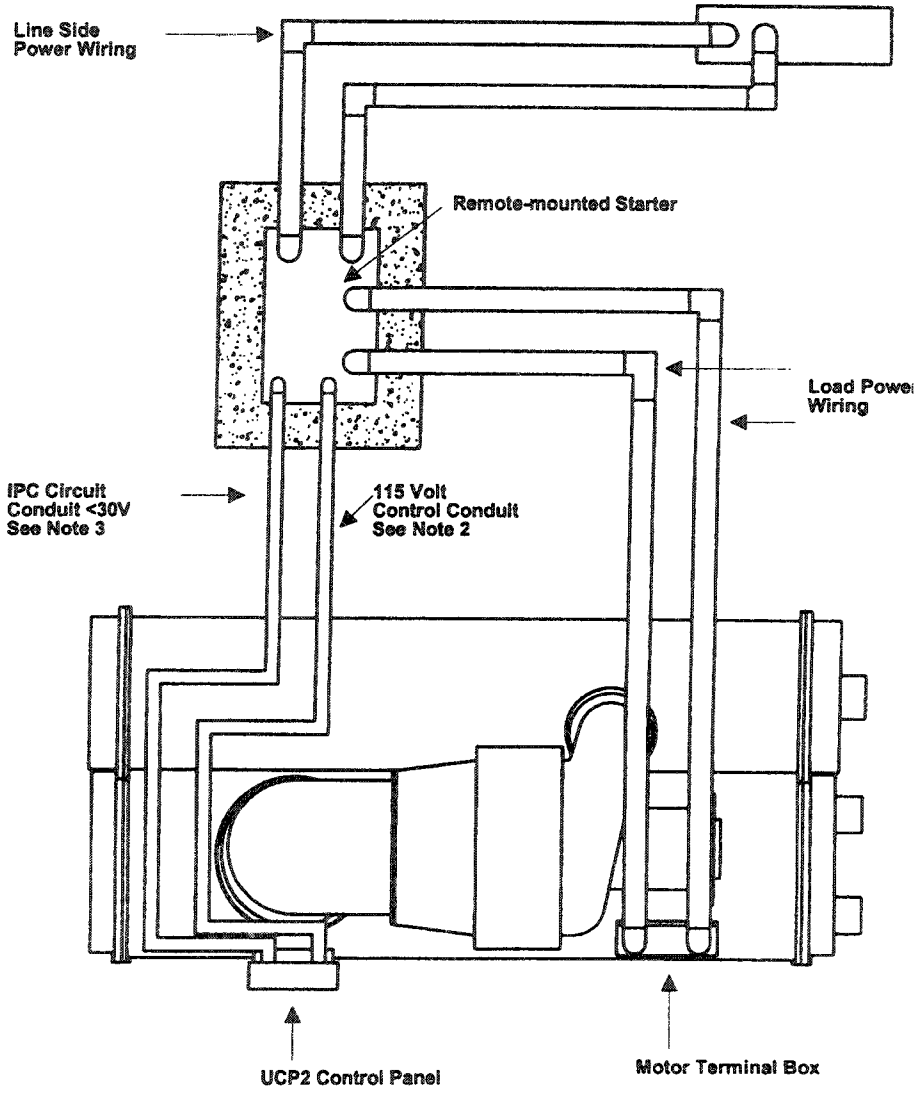


Figure 3
Typical Equipment Room Layout w/Unit-Mounted, Wye-Delta

Note:
See Starter submittal drawing for location of incoming wiring to the starter.

⚠ CAUTION
TO PREVENT DAMAGE TO THE UCP'S COMPONENTS, do not route control circuit conduit into the top of the UCP enclosure.

Figure 4
Typical Equipment Room
Layout w/Remote-Mounted Wye-Delta Starter

⚠ CAUTION
DO NOT ROUTE CONTROL CIRCUIT CONDUIT INTO THE TOP OF THE UCP ENCLOSURE. Failure to follow the above caution, could result in damage to the UCP components.

Notes:
1. Refer to the unit field connection diagram for approximate UCP knockout locations.
2. 115-Volt conduit must enter the right back portion of the unit control panel.
3. IPC circuit conduit must enter the left back portion of the UCP.
4. See starter submittal drawing for location of incoming wiring to the starter.

Starter to Motor (Remote-Mounted Starters Only)

Ground Wire Terminal Lugs. Ground wire lugs are provided in the motor terminal box and in the starter panel.

Terminal Clamps. Terminal clamps are supplied with the motor terminals to accommodate either bus bars or standard motor terminal wire lugs. Terminal clamps provide additional surface area to minimize the possibility of improper electrical connections.

Wire Terminal Lugs. Wire terminal lugs must be field-supplied.

1. Use field-provided crimp-type wire terminal lugs properly sized for the application.

Note: Wire size ranges for the starter line and load-side lugs are listed on the starter submittal drawings supplied by the starter manufacturer and/or Trane. Carefully review the submitted wire lug sizes for compatibility with the conductor sizes specified by the electrical engineer or contractor.

2. A terminal clamp with a 3/8" bolt is provided on each motor terminal stud; use the factory-supplied Belleville washers on the wire lug connections.

Figure 5 illustrates the juncture between a motor connection pad and the wire terminal lug.

3. Tighten each bolt to 24 foot-pounds.

4. Install but do not connect the power leads between the starter and compressor motor. (These connections will be completed under supervision of a qualified Trane service engineer after the prestart inspection).

Bus Bars. Install the bus bars between the motor terminals when a low-voltage "across-the-line", "primary reactor/resistor" or "auto transformer" is used.

Be sure to bus motor terminal T1 to T6, T2 to T4, and T3 to T5.

Note: Bus bars are not needed in high-voltage applications since only 3 terminals are used in the motor and starter.

Starter to UCP (Remote-Mounted Starters)

Electrical connections required between the remote-mounted starter and the chiller control panel are shown in drawing (end of manual). An example of a point-to-point starter-to-UCP connection schematic is shown at the end of the manual.

Note: Install 10 guage conduit between the right back portion when facing the front of the UCP and the starter for the 115-volt circuits; and between the left back portion of the UCP and the starter for the IPC circuit.

When sizing and installing the electrical conductors for these circuits, follow the guidelines listed.

⚠ CAUTION

KEEP INSIDE OF THE STARTER PANEL FREE FROM DEBRIS, failure to do so may cause an electrical short that seriously damages the starter components.

1. If the starter enclosure must be cut to provide electrical access, exercise care to prevent debris from falling inside the enclosure.

2. Use only shielded twisted pair for the IPC circuit between the starter and the UCP on remote mounted starters. Recommended wire is Beldon Type 8760, 18 AWG for runs up to 1000 feet.

Note: The polarity of the IPC wire pair is critical for proper operation.

3. Separate low-voltage (less than 30V) wiring from the 115V wiring by running each in its own conduit.

4. As you route the IPC circuit out of the starter enclosure, make sure that it is at least 6" from all wires carrying a higher voltage.

5. For UCP2 IPC shielded twisted pair wiring, the shield should be grounded on one end only at UCP2. The other end should be unterminated and taped back on the cable sheath to prevent any contact between shield and ground.

Refer to Figure 6 for wiring information on UCP2 Control Panel connections.

⚠ CAUTION

MAINTAIN AT LEAST 6 INCHES BETWEEN LOW-VOLTAGE (<30V) AND 115V CIRCUITS. Failure to do so could result in electrical noise that may distort the signals carried by the low-voltage wiring, including the IPC.

Purge Control Panel to UCP (Field installed purge only)

Install wiring between the purge control panel and the UCP for 115/volt circuits and the IPC circuits. See Figure 7 for wiring field installed purge.

UCP Electrical Specifications

Following is a list of constraints for the UCP2 in the control panel:

Note that the control panel is designed to receive input from the secondary of a power transformer in the starter panel.

1. **Nominal Voltage:** 115 VAC, with operating range of 98 to 132 VAC, inclusive.

2. **Maximum VA:** 4K VA (20-amp fuse) for units with the refrigerant pump

3. Power input wiring must be at least 6" from low-voltage, less than 30V wiring.

4. All signal inputs are low-voltage, less than 30V.

5. **UCP Storage Range:** -40 to 158F (-40C to 70C) i.e. not applicable for chiller.

Control Circuit Wiring

Interlock Circuits

Chilled Water Flow. Wire the evaporator water pump contactor (5K1) to a separate 120 volt single phase power supply with 14 AWG, 600 volt copper wire, then connect this circuit to 1U1-J12-1 and 2. This will allow the UCP to control the evaporator water pump, or wire the 5K1 contactor to operate remotely and independently of the UCP.

Wire the auxiliary contacts of the evaporator water pump contactor (5K1) in series with the flow switch (5S1) installed in the evaporator supply pipe. Use 14 AWG, 600-volt copper wire.

Connect this circuit to UCP terminals 1TB1-10 and 12.

When installed properly, the chilled water interlock circuit will only allow compressor operation if the evaporator pump is running and providing at least the minimum water flow required.

Condenser Water Flow. Wire the condenser water pump contactor (5K2) to a separate 120-volt, single-phase power supply with 14 AWG, 600-volt copper wire; then connect this circuit to UCP terminals 1U1-J14-1 and 2.

Next, use 14 AWG, 600-volt copper wire to connect the auxiliary contacts of the condenser water pump contactor (5K2) in series with the flow switch (5S2) installed in the condenser supply pipe.

Connect this circuit to UCP terminals 1TB-11 and -13.

When installed properly, the condenser water lock circuit will only allow the compressor to operate if the condenser pump is running and providing at least the minimum water flow required.

Temperature Sensor Circuits

1. All temperature sensors are factory installed except the optional outdoor air temperature sensor. Mount this sensor in the fresh air intake, or on a wall of the building out of direct sunlight.

2. If the leads on the sensor do not reach all the way back to the UCP:

   a. Route the sensor leads to a junction box mounted in a convenient location.

   b. Splice the leads to 14-18 AWG, 600 V wire of sufficient length inside the junction box.

   c. Route the added length of wire to the UCP in conduit (unless it is shielded).

3. Attach the outdoor air temperature sensor wires at 1U1-J5-5 and -6.

Note: If shielded cable is used to extend the sensor leads, be sure to tape off the shield wire at the junction box and ground it at the UCP. If the added length is run in conduit, do not run them in the same conduit with other circuits carrying 30 or more volts.

⚠ CAUTION
DO NOT ROUTE LOW-VOLTAGE SENSOR LEADS WITH OTHER CONDUCTORS CARRYING 30 OR MORE VOLTS. Failure to do so can result in sensor malfunction due to electrical noise.

4. All of the water temperature sensors used in the UCP control system are accurate to within ± 1.0°F, and are "matched" pairs.

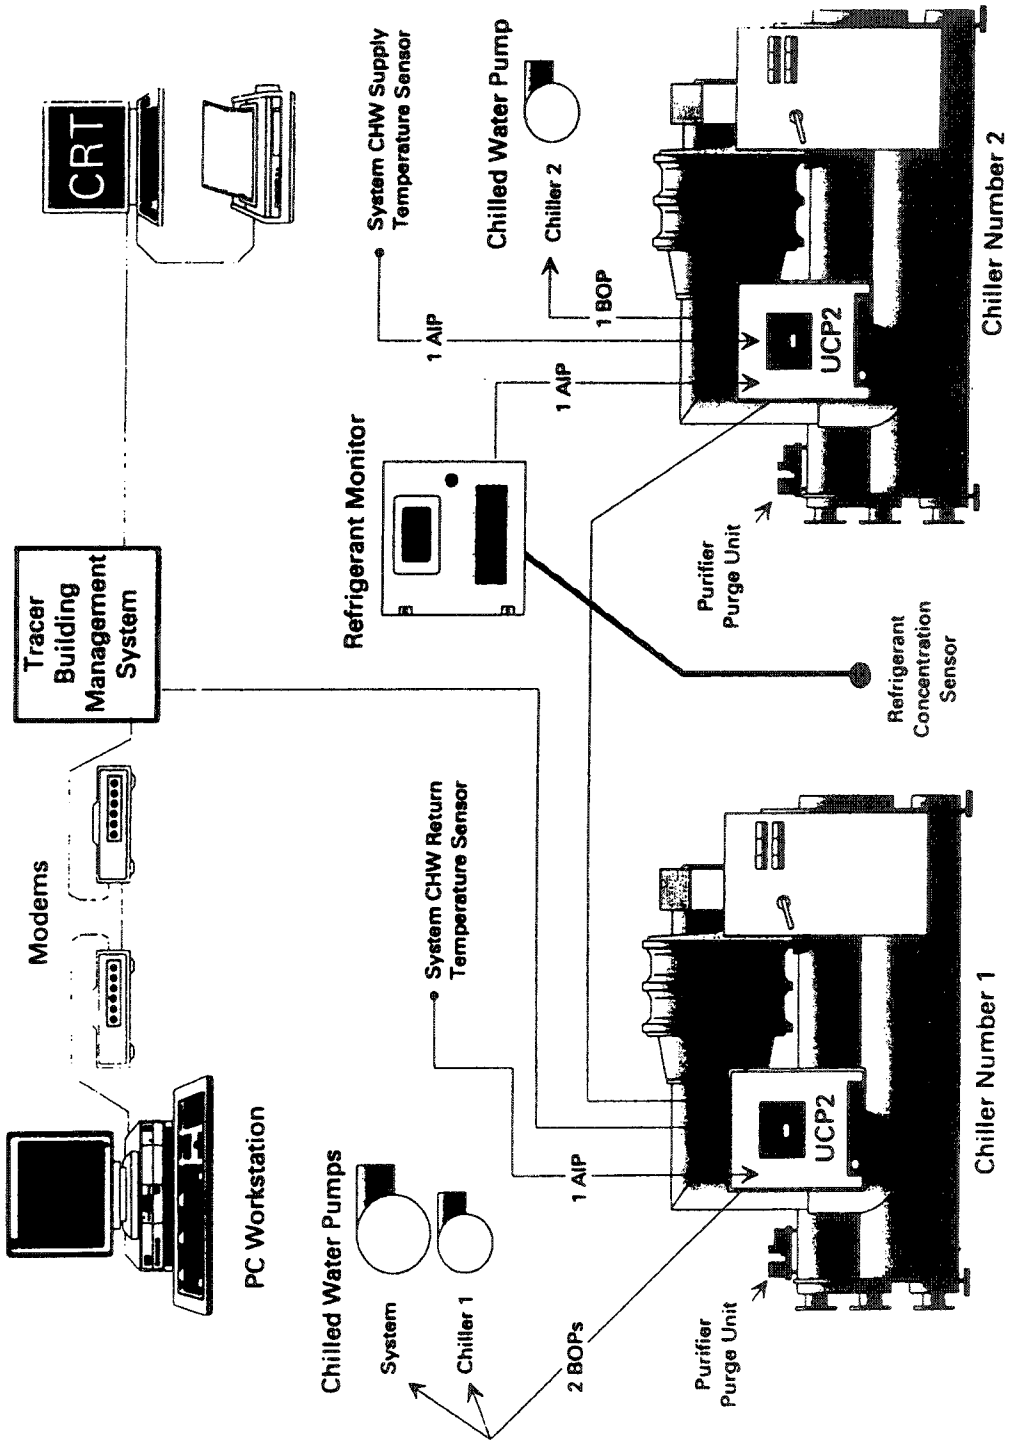
The term "matched sensor pair" indicates that both sensors in a given pair, have the same accuracy. For example, a sensor that registers a temperature that is 0.5°F higher than the "actual" value is paired with another sensor that also registers 0.5 high.

If entering and leaving water temperature sensors are not "matched", the accuracy of the temperature readings displayed on the face of the UCP is reduced.

Optional Relay Circuits

Optional Control/Output Circuits: Install various optional wiring as required by the owner's specifications.

Optional Tracer Communication Interface



This control options allows the UCP to exchange information such as chiller status and operating set points with a Tracer system.

Figure 8 illustrates how such a communication/control network might appear.

Note: The circuit must be run in separate conduit to prevent electrical noise interference.

Additional information about the TCI option is published in the installation manual and operator's guide that ships with the Tracer.

Figure 8
Illustrates Communication/Control Network to Chiller Units with UCP2

Unit Start-Up

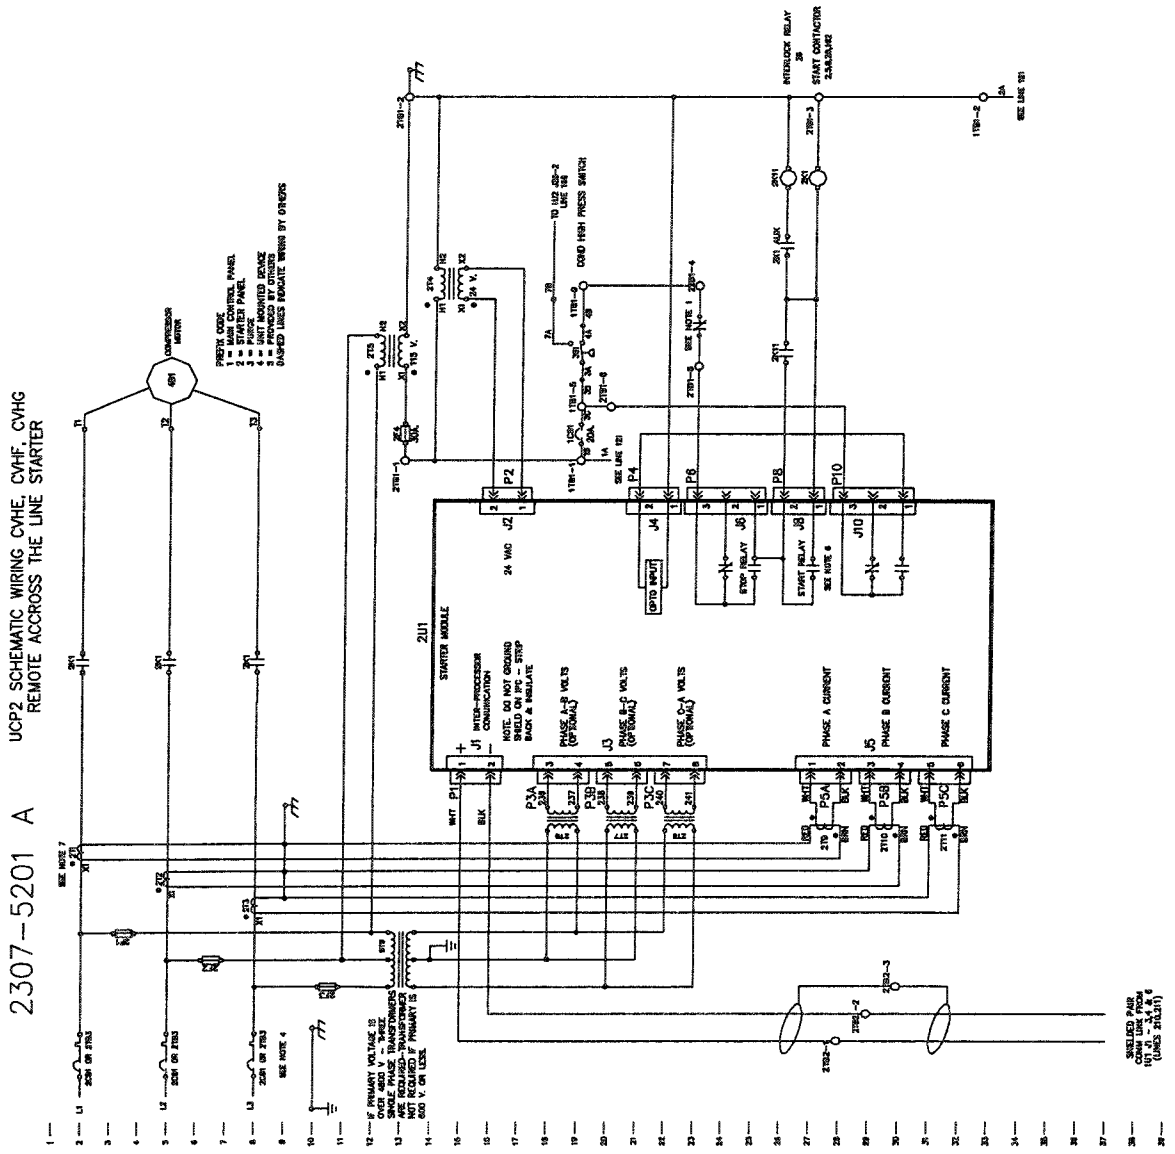
All phases of initial unit start-up must be conducted under the supervision of a qualified local service engineer. This includes pressure testing, evacuation, electrical checks, refrigerant charging, actual start-up and operator instruction.

Advance notification is required to assure that initial start-up is scheduled as close to the requested date as possible.

Forms Information

Samples of start-up and operating forms such as 1-27.08-6 and 1-27.90-5 along with other helpful forms are found in the CVHE-OM-8C or latest revision which can be obtained from the nearest Trane office.

It is recommended that the serviceman contact the local Trane office to obtain the most recent revision of a form. The forms in the operation and maintenance manual are only current at the date of printing of the manual.



After obtaining the most recent form, complete all the information and forward it to your local Trane Company.

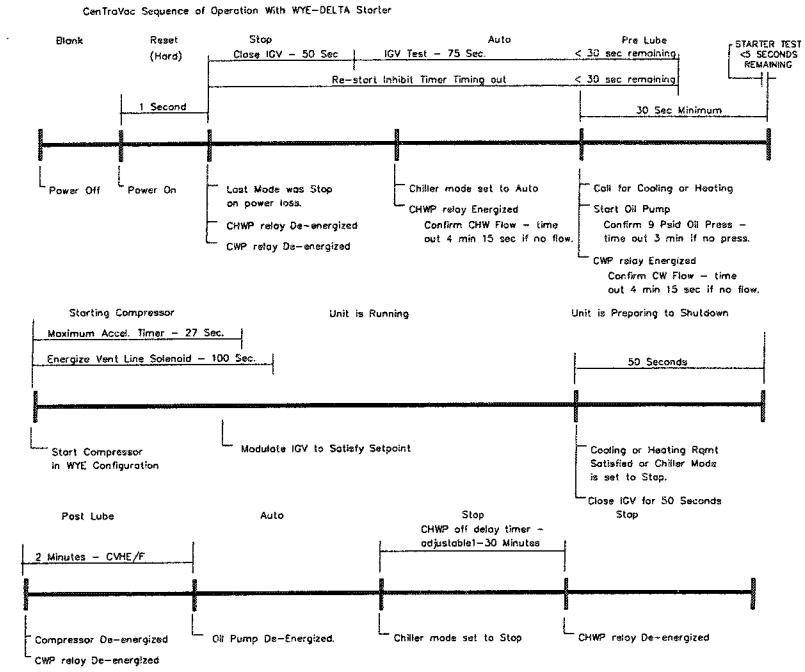
2307-5211B for UCP2 Customer Supplied Remote Mounted , Wye-Delta, Primary Reactor or Auto Transformer Starter



Wiring Drawing

Refer to Figure 9 below which shows an example of a typical sequence of operation for a Unit Mounted Wye-Delta Starter.

In the starter drawings, shown in this manual, all starter variables are the same in the Sequence of Operation except the *Maximum Acceleration Time*.

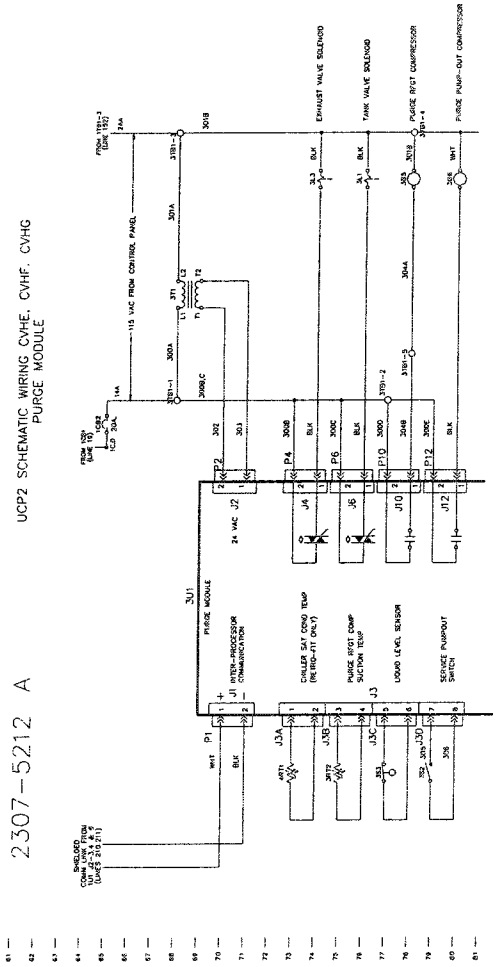
Below is a table which shows variables of the *Maximum Acceleration Time* for all starter drawings in this manual.

Figure 9 - Example of a Typical Sequence of Operation for a Unit-Mounted Wye-Delta Starter

NOTES:
1. OPTIONAL STARTER INTERLOCK. SEE STARTER MANUFACTURES WIRING DIAGRAM FOR SPECIFIC APPLICATION.
2. UNLESS OTHERWISE NOTED,ALL SWITCHES ARE SHOWN AT 25 C (77 F), AT ATMOSPHERIC PRESSURE, AT 50% RELITIVE HUMIDTY, WITH ALL UTILITIES TURNED OFF AND AFTER A NORMAL SHUTDOWN HAS OCCURED.
3. NUMBERS ALONG THE RIGHT SIDE OF THE SCHEMATIC DESIGNATE THE LOCATION OF THE CONTACTS BY LINE NUMBER. AN UNDERLINED NUMBER INDICATES A NORMALLY CLOSED CONTACT.
4. THREE PHASE POWER SUPPLY VOLTAGE-SEE UNIT NAMEPLATE
5. UNIT MOUNTED WYE-DELTA STARTER WIRING BETWEEN STARTER AND CONTROL MODULE ARE SHOWN. SEE STARTER MANUFACTURES WIRING DIAGRAM FOR SPECIFIC STARTER WIRING.
6. RELAY COILS ARE NOT SHOWN. CONTACTS ARE CONTROLLED BY THE LOGIC OF THE MICRO-CONTROLLER. SEE SEQUENCE OF OPERATION.
7. POLARITY MARKING ON THE CURRENT TRANSFORMER , (H1 MARKING ON CT) MUST BE FACING TOWARDS THE INCOMING CURRENT.

⚠ WARNING
HAZARDOUS VOLTAGE!
DISCONNECT ALL ELECTRIC POWER INCLUDING REMOTE DISCONNECTS BEFORE SERVICING.
FAILURE TO DISCONNECT POWER BEFORE SERVICING CAN CAUSE SEVERE PERSONAL INJURY OR DEATH.

⚠ AVERTISSEMENT
VOLTAGE HASARDEUX!
DECONNECTEZ TOUTES LES SOURCES ELECTRIQUES INCLUANT LES DISJONCTEURS SITUES A DISTANCE AVANT D'EFFECTUER L'ENTRETIEN.
FAUTE DE DECONNECTER LA SOURCE ELECTRIQUE AVANT D'EFFECTUER L'ENTRETIEN PEUT ENTRAINER DES BLESSURES CORPORELLES SEVERES OU LA MORT.



⚠ CAUTION
USE COPPER CONDUCTORS ONLY!
UNIT TERMINALS ARE NOT DESIGNED TO ACCEPT OTHER TYPES OF CONDUCTORS.
FAILURE TO DO SO MAY CAUSE DAMAGE TO THE EQUIPMENT.

Table 3 - Maximum Accel. Time

Sequence of Operation for UCP2 CVHE, CVHF, CVHG Starters Maximum Accel. Time		
Starter Drawing Number	**Type of Starter**	Maximum Accel Time

Warnings and Cautions

Notice:

Warnings and Cautions appear at appropriate locations throughout this manual. Read these carefully.

⚠ WARNING

Indicates a potentially hazardous situation which, if not avoided, could result in death or serious injury.

⚠ CAUTION

Indicates a potentially hazardous situation which, if not avoided, may result in minor or moderate injury. It may also be used to alert against unsafe practices and where property-damage-only accidents could occur.

CVHE-SVN01A-EN–General Information

CVHE-SVN02A-EN–Water Piping Information

CVHE-SVN03A-EN–Electrical Information

Required for chiller installation.

About this Manual

This manual describes proper installation of Model CVHE, CVHF, and CVHG 50 Hz and 60 Hz chillers with the Tracer CH530 Controls platform. See Figure 1 for an illustration of a Centrifugal Chiller with the Tracer CH530 Unit Control Panel.

These chillers are equipped with microcomputer-based control systems whether standard cooling or heat-recovery. A careful review of this information along with the submittal package provided for the unit will assure that the chiller is correctly installed.

Product Description Block

Trane 50 Hz and 60 Hz hermetic CenTraVac units are defined by the product definition and selection system (PDS). Each unit is defined by the product description block which appears on the unit nameplate. A service model number which represents the unit as-built is provided on the unit nameplate, along with a specific unit service number. Both these are utilized whenever parts or service are required. An example is provided in the unit operation and maintenance manual (CVHE-SVU01A-EN).

Commonly Used Acronyms

AFD = Adjustable Frequency Drive

ASME = American Society of Mechanical Engineers

ASHRAE = American Society of Heating, Refrigerating and Air Conditioning Engineers

BAS = Building Automation System

LBU = La Crosse Business Unit

CABS = Auxiliary Condenser Tube-Bundle Size

CDBS = Condenser Bundle Size

CESZ = Condenser Shell Size

CWR = Chilled Water Reset

DTFL = Delta-T at Full Load (i.e., the difference between entering and leaving chilled water temperatures at design load)

EVBS = Evaporator Size

EVSZ = Evaporator Shell Size

FC = Free Cooling

GPM = Gallons-per-Minute

HGBP = Hot Gas Bypass

HVAC = Heating, Ventilating and Air Conditioning

IE = Internally Enhanced Tubes

IPC = Interprocessor Communication

PFCC = Power Factor Correction Capacitor

PSID = Pounds-per-Square-Inch Differential

UCP = Chiller Control Panel

CH530 = Tracer CH530 Platform Unit Control Panel

Unit Nameplate

The unit nameplate is located on the left side of the unit control panel (UCP). The following information is provided on the unit nameplate.

1. Unit model and size descriptor
2. Unit serial number
3. Identifies unit electrical requirements
4. Lists correct operating charge and type of refrigerant
5. Lists unit test pressures and maximum operating pressures
6. Identifies unit installation, operation and maintenance manuals
7. Product description block

Metric Conversion

For tables and charts in this manual, the following conversions apply:

In. × 2.54 = cm

Ft. × 30.48 = cm

Lbs. × .453 = kg

General Information

Responsibilities of Installing Contractor(s)

A list of the contractor responsibilities typically associated with the unit installation Process is provided below. Also see Table 1.

1. Locate and maintain the loose parts, i.e. isolators, bulb wells, temperature sensors, flow sensors or other factory-ordered field installed options, for installation as required. **Loose parts are located in the starter panel on units with factory-installed unit-mounted starters or in the motor terminal box for units with remote-mounted starters.**
2. Install unit on a foundation with flat support surfaces level within 1/16" and of sufficient strength to support concentrated loading.
3. Place manufacturer-supplied isolation pad assemblies under unit. (Use spring isolators for upper floor installations.)
4. Install unit per applicable Trane Installation Manual.
5. Complete all water piping and electrical connections

   Note: Field-piping must be arranged and supported to avoid stress on the equipment. It is strongly recommended that the piping contractor refrain from piping closer than 3'-0" [914 mm] minimum to the equipment. This will allow for proper fit-upon arrival of the unit at the job-site. Any adjustment that is necessary can be made to the piping at that time.
6. Where specified, supply and install valves in water piping upstream and downstream of evaporator and condenser water boxes to isolate shells for maintenance and to balance and trim system.
7. Supply and install flow switches (or equivalent devices) in both chilled water and condenser water piping. Interlock each switch with proper pump starter to ensure that unit can operate only when water flow is established.
8. Supply and install taps for thermometer and pressure gauges in water piping adjacent to inlet and outlet connections of both evaporator and condenser.
9. Supply and install drain valves to each water box.
10. Supply and install vent cocks on each water box.
11. Where specified, supply and install strainers ahead of all pumps and automatic modulating valves.
12. Supply and install pressure-relief piping from pressure-relief rupture disc to atmosphere.
13. If necessary, supply sufficient HCFC-22 refrigerant (maximum of 1 Lb. Per machine) for leak testing and dry nitrogen (8 psig [55 kPa] per machine) for pressure testing under manufacturer's supervision.
14. Start unit under supervision of a qualified service technician.
15. Where specified, supply and insulate evaporator and any other portions of machine as required to prevent sweating under normal operating conditions.
16. **Unit-Mounted Starters Only** Remove top of starter panel and cut access area for line-side wiring; front left quadrant of top provides recommended access to starter lugs.
17. Supply and install wire terminal lugs to starter.
18. **Unit-Mounted Starters Only** Supply and install field wiring to line-side lugs of starter.
19. Supply and install a Refrigerant Monitor per ASHRAE 15 specifications. For additional information, refer to CenTraVac™ Checksheet and Request for Serviceman form 1-27.08. Contact the nearest Trane Office for the most recent up-to-date copy.

General Information

Table 1 – Installation Requirements

Type of Requirement	Trane-Supplied Trane-Installed	Trane-Supplied Field-Installed	Field-Supplied Field-Installed
Rigging			A. Safety chains B. Clevis connectors C. Lifting beam
Isolation		A. Isolation pads or spring isolators	A. Isolation pads or spring isolators
Electrical	A. Circuit breakers or fusible disconnects (optional) B. Unit-mounted starter (optional) C. PFCCs (optional)	A. Jumper bars B. Temperature sensor (optional outdoor air) C. Flow switches (may be field supplied)	A. Circuit breakers or fusible disconnects (optional) B. Remote-mounted starter, AFD (optional) C. PFCCs (Remote-mounted starter option only) D. Terminal lugs E. Ground connection(s) F. Jumper bars G. BAS wiring (optional) H. IPC wiring (AFD and remote-mounted starters only I. Control voltage wiring (AFD and remote-mounted starters only) J. Oil pump interlock wiring (AFD and remote-mounted starters only) K. High condenser pressure interlock wiring (AFD and remote-mounted starters only). L. Chilled water pump contactor and wiring M. Condenser water pump contactor and wiring N. Option relays and wiring (See Table 12)
Water Piping		A. Flow switches (May be field supplied)	A. Thermometers B. Water flow pressure gauges C. Isolation and balancing valves water piping D. Vents and drain valves (1 each per class) E. Pressure-relief valves (for water boxes as required)
Rupture Disc	A. Rupture disc assy		A. Vent line and flexible connector
Insulation	A. Insulation (Optional)		A. Insulation

General Information

Unit Shipment

Each chiller ships from the factory as a hermetically-assembled package; it is factory-piped, wired and tested. All openings are covered or plugged to prevent contamination during shipment and handling.

See Figure 1 for an illustration of a typical chiller and its components. When the unit arrives at the job site, inspect it thoroughly for damage and material shortages. Suggested inspection steps below:

1. To prevent damaging moisture from entering the unit and causing corrosion, each chiller is pressurized with dry nitrogen before shipment.
2. Verify that the chiller is dehydrated by checking the evaporator press for an indication of holding charge pressure. Temporarily attach service gauge to refrigerant charging valves.

   Note: The holding charge should register approximately 5 psig [34.5 kPa) on the gauge at 72°F [22.2°C]. If the charge has escaped, contact your local Trane sales office for instructions.
3. The loose parts box and isolator pads ship in the motor terminal box or unit mounted starter enclosure if so equipped. Remove the sheet metal shipping bracket from the motor terminal box and discard.
4. Check the oil sump sight glasses to verify that the sump was factory-charged with 9 gallons [34 l] of oil on units with a Refrigerant Pump.

   Beginning with design sequence 2K for the CVHE, L0 for the CVHG and U0 for the CVHF a new redesigned lubrication system has been incorporated. Aluminum balls, which are incorporated into the sight glass, float when oil is present, showing a better visible display of the oil level indication.
5. If no oil level indication is visible, contact your local Trane sales office.
6. Compare the unit nameplate data (including electrical characteristics) with the corresponding ordering and shipping information to verify that the correct unit was shipped to the job site.
7. If a thorough inspection of the chiller reveals damage or material shortages, be sure to file these claims with the carrier immediately. Specify the extent and type of damage found, and notify the appropriate Trane sales representative. Do not install a damaged unit without the sales representative's approval.

Storage

If the chiller will be stored at the job site for an extended period of time before it is installed, exercise these precautionary measures to protect the unit from damage.

1. Do not remove the protective coverings factory-installed on the control panel and compressor inlet vane actuator for shipment.
2. Store the chiller in a dry, vibration free and secure area. If factory insulated, protect chiller from prolonged exposure to sunlight.

⚠ CAUTION

TO PREVENT DAMAGE TO THE FACTORY-INSTALLED INSULATION, do not allow excessive exposure to sunlight.

3. Periodically check evaporator pressure to verify that 3 to 5 psig [21 to 34.5kPa] dry nitrogen @ 72°F [22.2°C] ambient holding charge is still in the chiller. If this charge escapes, contact a qualified service organization and the Trane sales engineer that handled the order.

Note: The storage for the microcomputer-based devices in the unit control panel is -40°F [-40°C] to 158°F [70°C].

Recommended Unit Clearances

Adequate clearances around and above the chiller is required to allow sufficient access for service and maintenance operations.

Figures 2, 3, 4, 5 and 6 illustrate the recommended clearances for units with and without options.

Note: In each instance, the minimum vertical clearance above the chiller is three feet.

In addition, be sure to provide working space clearance in front of the unit control panel to satisfy national and local electric codes.

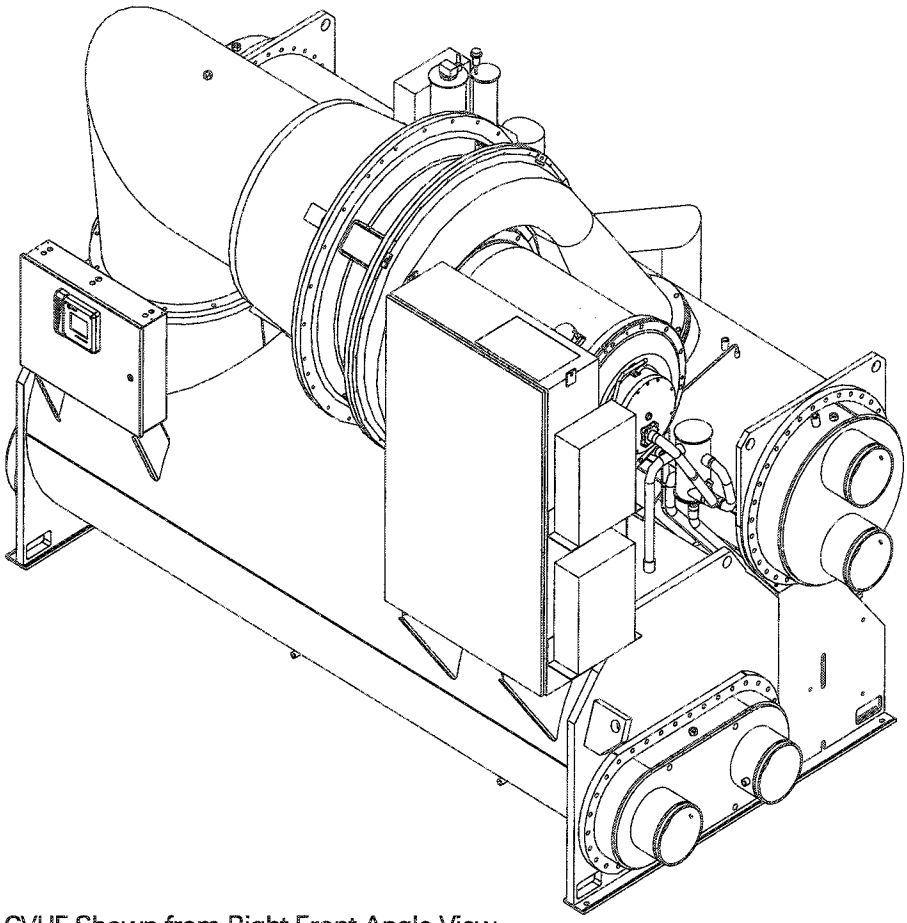
Important: Do NOT install piping or conduit above the compressor motor assembly or behind the suction elbow.

(Specific unit clearance requirements are also indicated in the submittal package provided for your unit.)

General Information

Operating Environment

Besides assuring that the site selected for chiller installation provides the necessary clearances, consider the equipment's operating environment.



To assure that electrical components operate properly, do not locate the chiller in an area exposed to dust, dirt, corrosive fumes, or excessive hear and humidity. Note that the maximum ambient temperature range for chiller operation to 100°F [38°C].

Storage Requirements if Chiller is not installed

1. Store the chiller in a dry, vibration free and secure area on a solid foundation. If the chiller has factory installed insulation, protect the chiller from direct sunlight. Do not remove any of the factory installed protective coverings.
2. Do not charge the chiller with refrigerant. If the refrigerant is at the site, follow the refrigerant manufacture's instructions for refrigerant charge.
3. A dry nitrogen holding charge of 3 to 5 psig [21 to 34.5kPa] was installed at the factory. This positive pressure must be checked monthly to insure that moisture and non- condensibles do not get into the chiller. Check the pressure gauge on the evaporator shell to verify that the dry nitrogen holding charge is still in the chiller. If this charge had escaped, contact a qualified service organization to leak test and repair as necessary and also notify the Trane sales engineer that handled the order.
4. Do not operate the purge unit on the chiller.
5. The oil can be left in the chiller if an oil analysis is initially obtained after six months, and once each succeeding year. If no oil breakdown is evident you do not have to change oil. If breakdown is evident, the oil will need to be replaced. If an oil analysis program is not followed, discarded, and new oil installed just prior to start-up by a qualified service organization.
6. The water side of the chiller requires no special attention but there may be slight scale build-up inside the tubes. Tubes should be inspected and cleaned before the unit is placed into service.
7. If the motor sits for a long time, the bearings could take a set and cause bearing problems/ replacement later. Once every six months the chiller oil pump must be started and the compressor shaft rotated 450 degrees. Contact a qualified service organization to perform this task.
8. If the chiller is stored for more than five years, and the storage is expected to be indefinite, the chiller should be examined for leaks every five years from the initial storage date. Contact a qualified service organization to perform this task.
9. When the unit is to be installed, follow instruction manuals that were shipped with the chiller. The services of a qualified service organization should be obtained to conduct all activities associated with the start-up of a new chiller.

General Information

Figure 1 – Typical Chiller and its Components

CVHF Shown from Right Front Angle View

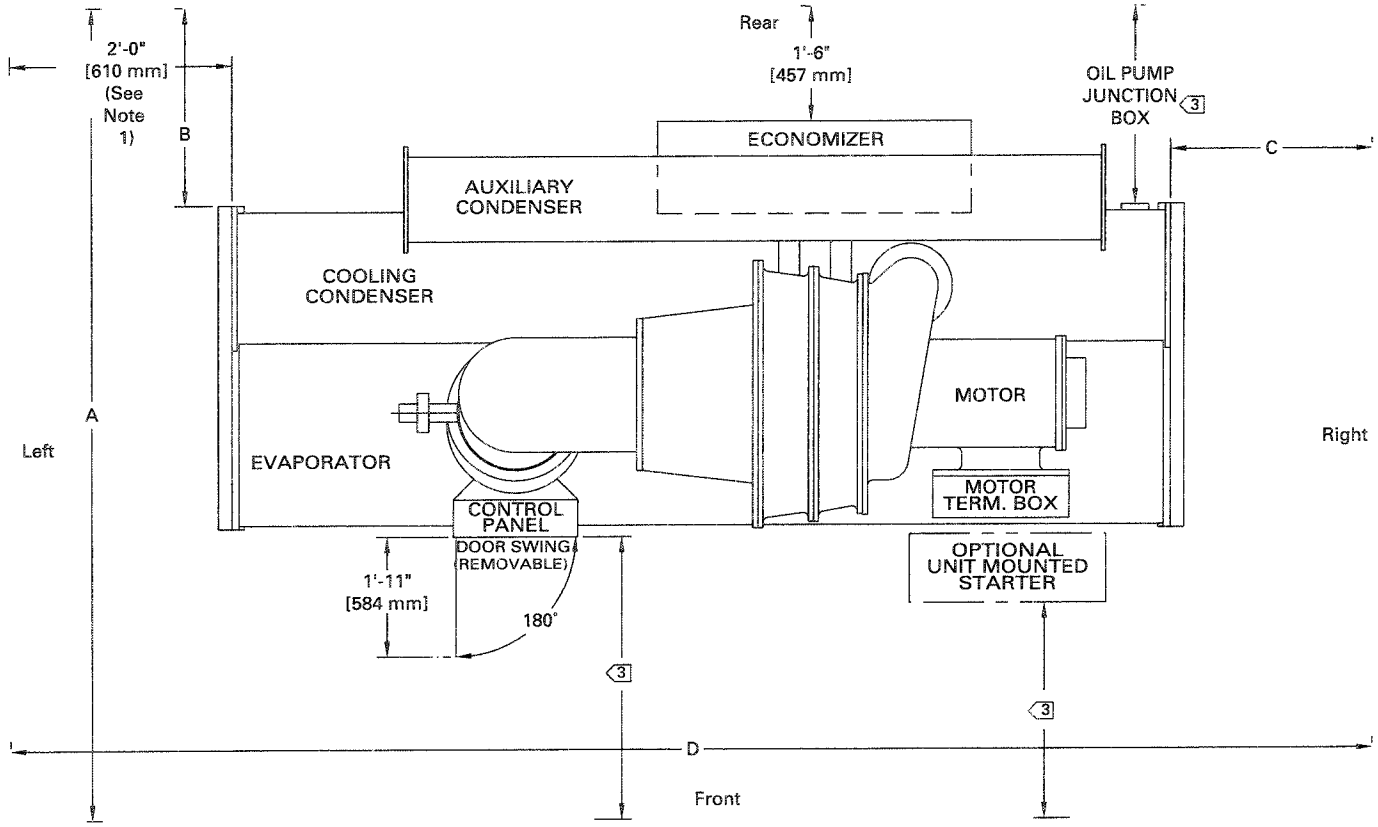
Foundation Requirements

Provide rigid, non-warping mounting pads or a concrete foundation as a mounting surface for the chiller. Ensure that the bade is of sufficient strength and mass to properly support the chiller at its full operating weight (i.e., including completed piping, and full operating charges of refrigerant, oil and water.)

Table 2 and Table 3 give a summary of standard tube bundle locations. Table 4 indicates the weights of various chiller options. Table 5 shows typical weights for Cooling Only units.

Notice that the floor loading for all sizes of CVHE, CVHF and CVHG chillers is 62 pounds per square inch [427 kPa].

To assure proper unit operation, the chiller must be level within 1/16" [1.6 mm] over its length and width when set into place on the mounting surface.



The Trane Company will not assume responsibility for equipment problems resulting from an improperly designed or constructed foundation.

⚠ CAUTION

CHILLER OPERATION AT AMBIENT TEMPERATURES EXCEEDING 100°F [38°C] CAN FATIGUE THE UNIT'S RUPTURE DISC, CAUSING IT TO BREAK AT A REDUCED REFRIGERANT PRESSURE (I.E., <15 PSIG [<103 KPA]) STARTER COMPONENT DAMAGE CAN ALSO OCCUR WHEN ADVERSE OPERATING CONDITIONS ARE PRESENT. THE ABOVE CAN HAPPEN, BECAUSE OF THE PANEL'S INABILITY TO DISSIPATE HEAT ADEQUATELY. Take whatever action is necessary to improve the equipment room environment if any of these adverse operating conditions are present.

General Information

Note: Immediately report any unit damage incurred during handling or installation at the job site to Trane sales office.

Rigging

Lifting is the recommended method for moving chillers. Suggested lifting arrangements for standard and heat-recovery units are illustrated in Figure 5.

Note that each of the cables used to lift the unit must be capable of supporting the entire weight of the chiller.

⚠ WARNING

LIFT THE CHILLER HORIZONTALLY. Failure to do so could result in death or serious injury and equipment damage.

See Tables 2, 3 and 5 for shipping weights.

Refer to lifting arrangement and rigging in Figure 5. Notice that the lifting beam used to lift the unit must be at least 12 feet [3.7 m] long.

To lift the chiller properly, insert clevis connections at the points indicated in Figure 5, a 2" [51 mm] diameter lifting hole is provided at each of these points. Next attach the lifting chains or cables.

Once the lifting cables are in place, attach a safety chain or cable between the first-stage casting of the compressor and the lifting beam. To do this, remove a restraining bolt from the compress first-stage casting and replace it with an eyebolt.

Note: There should not be tension on this safety cable; it is used only to prevent the unit from rolling during the lift.

When the lift is complete, detach the clevis connections and safety chain. Then, remove the eyebolt that was used to secure the safety chain to the compressor, and reinstall the retaining colt in its place.

If the chiller cannot be moved using the conventional rigging method just described, consider these points.

1. If job site conditions require rigging of the chiller at an angle greater than 45° from horizontal (end-to-end) dowel-pin the compressor and remove it from the unit. Be sure to contact a qualified service organization for specific rigging instructions.

⚠ CAUTION

IF THE UNIT WILL BE LIFTED AT AN ANGLE GREATER THAN 15° FROM END-TO-END, REMOVE THE OIL FROM THE OIL TANK. Failure to do so, will cause oil to drain out of oil tank into other areas of chiller. It will be extremely difficult to return the oil to the oil tank even during operation.

2. When lifting the chiller is either impractical or undesirable, attach cables or chains to the jacking slots shown in Figure 5; then push or pull the unit across a smooth surface.

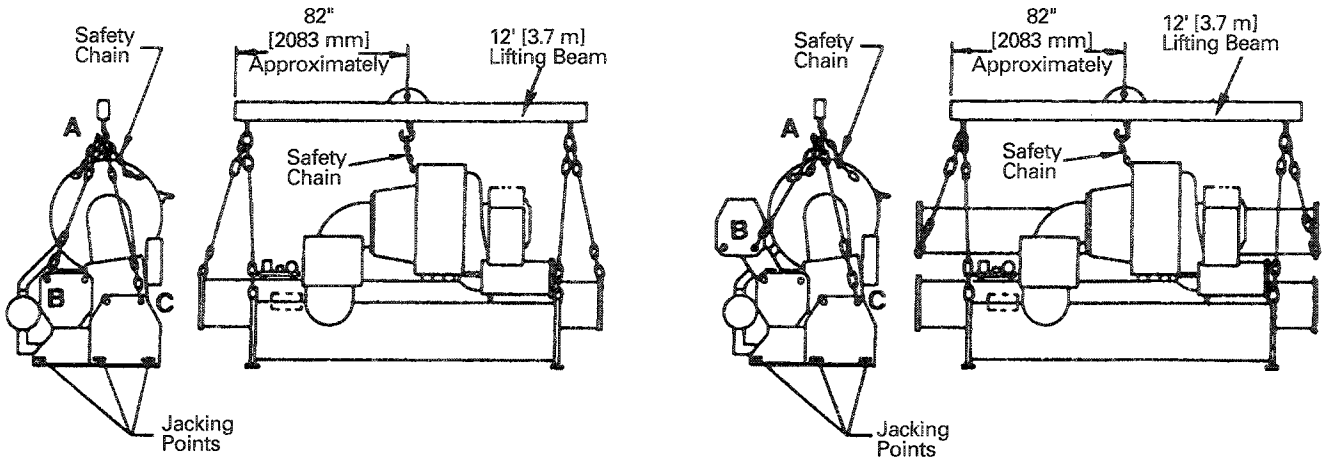
Note: The oil tank with the refrigerant pump is mounted under the condenser and may be damaged by a fork truck.

⚠ CAUTION

DO NOT USE A FORKLIFT TO REMOVE THE CHILLER. Using a forklift can result in damaged equipment.

⚠ CAUTION

CONSULT THE TRANE COMPANY BEFORE LIFTING THE COMPRESSOR/MOTOR ASSEMBLY FROM THE SHELLS WITHOUT FACTORY-INSTALLED DOWELING IN THE COMPRESSOR CASTING FLANGES. Failure to do so can result in misalignment of the compressor castings.



3. If removal of the compressor or economizer assembly is necessary to move the chiller into its operating location, contact The Trane Company for special instructions concerning chiller disassembly and reassembly procedures.

⚠ WARNING

BE CAREFUL TO AVOID DAMAGING UNIT WIRING DURING RIGGING, ASSEMBLY AND DISASSEMBLY.

General Information

Figure 5 – Recommended Lifting Arrangements for CVHE, CVHF, and CVHG Units

⚠ WARNING

DO NOT USE CHAINS OR CABLES OTHER THAN AS SHOWN. Failure to heed this warning by using alternative lifting arrangements may result in death or serious injury and equipment damage.

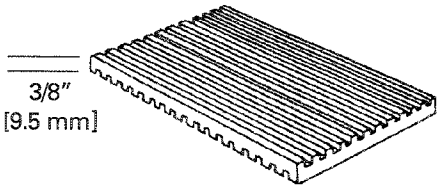
Notes:
1. Lifting chains (or cables) may or may not be the same length between Points A and B, or between Points A and C. Adjust as necessary for an even lift.
2. Lifting holes provided on chiller to attach chains are 2" [51 mm] in diameter.
3. Attach safety chain (or cable) as shown, and **without tension**. The safety chain is **not** used for lifting, but is there to prevent the unit from rolling.
4. Do **not** forklift the unit!

General Information

Chiller Isolation

To minimize sound and vibration transmission through the building structure and to assure proper weight distribution over the mounting surface, install isolation pads or spring isolators under the chiller feet.

Note: Isolation pads are provided with each chiller unless spring isolators are specified on the sales order.



Specific isolator loading data is provided in the unit submittal package. Also refer to Table 6. If necessary, contact your local Trane sales office for further information.

Isolation Pads

When the unit is ready for final placement, position isolation pads end for end under the full length of the chiller leg. The pads measure 6"x18" [152.4x457 mm] and on some units there may be small gaps between pads.

Remember that the chiller must be level within 1/16" [1.6 mm] over its length and width after it is lowered onto the isolation pads. In addition, all piping connected to the chiller must be properly isolated and supported so that it does not place any stress on the unit.

General Information

Figure 7 – Isolation Spring Placement

General Information

Spring Isolators

Spring isolators should be considered whenever chiller installation is planned for an upper story location. Base isolator selection and placement on the information presented in Figures 8 and 9. (Notice that three types of spring isolators, each with their own maximum loading characteristics, are used with the CVHE/F/G chillers.)

Spring isolators typically ship assembled and ready for installation. To install and adjust the isolators properly, follow the instructions given.

Note: Do not adjust the isolators until the chiller is piped and charged with refrigerant and water.

1. Position the spring isolators under the chiller as shown in Figures 7 and 8. Make sure that each isolator is centered in relation to the tube sheet.
2. Set the isolators on the sub-base; shim or grout as necessary to provide a flat, level surface at the same elevation for all mountings. Be sure to support the full underside of the isolator bade plate; do not straddle gaps or small shim.
3. If required, bolt the isolators to the floor through the slots provided or cement the pads.

   Note: Fastening the isolators to the floor is not necessary unless specified.
4. If the chiller must be fastened to the isolators, insert cap screws through the chiller base and into the holes tapped in the upper housing of each isolator. However, do not allow the screws to protrude below the underside of the isolator upper housing. An alternative method of fastening the chiller to the isolators is to cement the neoprene pads.
5. Set the chiller on the isolators; refer to "Rigging" for listing instructions.

   The weight of the chiller will force the upper housing of each isolator down, perhaps causing it to rest on the isolator's lower housing. Figure 9 illustrates spring isolator construction.
6. Check the clearance on each isolator. If this dimension is less than ¼ inch on any isolator, use a wrench to turn the adjusting bolt one complete revolution upward.

   Repeat this operation until a ¼ inch clearance is obtained at one or more isolators.

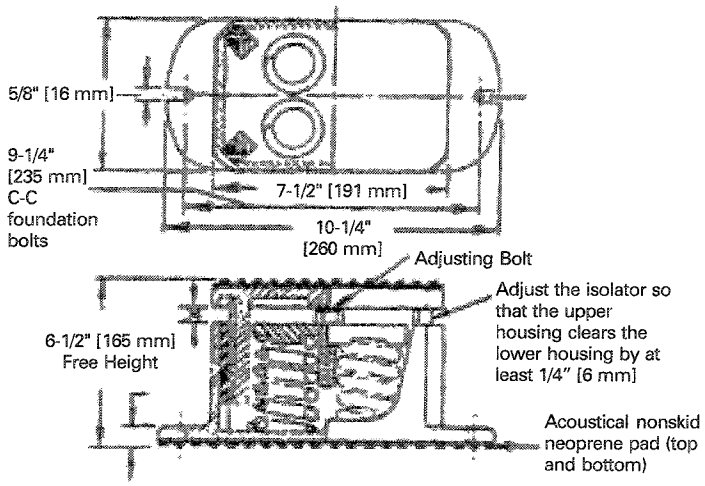
   Note: When the load is applied to the isolators (Step 5), the top plate of each isolator moves down to compress the springs until either:

   (1) The springs support the load, or

   (2) The top plate rests on the bottom housing of the isolator.

   a. If the springs are supporting the load, screwing down on the adjusting bolt (Step 7) will immediately begin to raise the chiller.
7. Turn the adjusting bolt on each of the remaining isolators to obtain the required minimum clearance of ¼" [6.9 mm].
8. Once the minimum required clearance is obtained on each of the isolators, level the chiller by turning the adjusting bolt on each of the isolators on the low side of the unit. Be sure to work from one isolator to the next. Remember that the chiller must be level to within 1/16" [1.6 mm] over its length and width, and that clearance of each isolator must be ¼" [6.9 mm].

Figure 8 – Chiller Foot/Isolator Orientation



Note: The spring isolator must be centered in relation to the tube sheet. Do **not** align the isolator with the flat part of the chiller foot since the tube sheet is often off-center.

Note: The length of the isolator should be parallel to the leg.

General Information

General Information

Unit Leveling

Follow the instructions outlined below and illustrated in Figure 10 to determined whether or not the chiller is set level.

1. Measure an equal distance up from each foot of the chiller and make a punch mark at each measured distance.
2. Suspend a clear plastic tube along the length of the chiller as shown in Figure 10.
3. Fill the tube with water until the level aligns with the punch mark at one end of the chiller; then check the water level at the opposite mark.

   If the water level does not align with the punch mark, use full-length shims to raise one end of the chiller until the water level at each end of the tube aligns with the punch marks at both ends of the chiller
4. Once the unit is level across its length, repeat Steps 1 through 3 to see if unit is level across the width.

Warnings and Cautions

Notice

Warnings and Cautions appear at appropriate locations throughout this manual.

Read these carefully.

Warning: Indicates a potentially hazardous situation which, if not avoided, could result in death or serious injury.

Caution: Indicates a potentially hazardous situation which, if not avoided, may result in minor or moderate injury. It may also be used to alert against unsafe practices and where property-damage-only accidents could occur.

Water Piping

Overview

Several water piping circuits must be installed and connected to the chiller.

Note: Field Piping must be arranged and supported to avoid stress on the equipment. It is strongly recommended that the piping contractor refrain from piping closer than 3' [.91 m] minimum to the equipment. This will allow for proper fit-up upon arrival of the unit at the job site. Any adjustment that is necessary can be made to the piping at that time.

(a) Pipe the evaporator into the chilled water circuit;

(b) Pipe the condenser into the condenser water circuit;

(c) A heat-recovery condenser water circuit, (optional);

(d) An auxiliary condenser water circuit, (optional)

Piping suggestions for each of the four water circuits listed above are outlined later in this section. General recommendations for the installation of field supplied piping components (e.g., valves, flow switches, etc.) common to most chiller water circuits are listed below.

Water Treatment

Since the use of untreated or improperly treated water in a CenTraVac™ may result in inefficient operation and possible tube damage, be sure to engage the services of a qualified water treatment specialist if needed. A label with the following disclaimer note is affixed to each unit.

Customer Note
The use of improperly treated or untreated water in this equipment may result in scaling, erosion, corrosion, algae or slime. The services of a qualified water treatment specialist should be engaged to determine what treatment, if any, is advisable. The Trane Company warranty specifically excludes liability for corrosion, erosion or deterioration of Trane equipment. Trane assumes no responsibilities for the results of the use of untreated or improperly treat water, or saline or brackish water.

DO NOT USE UNTREATED OR IMPROPERLY TREATED WATER. Failure to do so could result in equipment damage.

Pressure Gauges

Locate pressure gauge taps in a straight run of pipe. Place tap a minimum of one pipe diameter downstream of any elbow, orifice etc. Example, for a 6" [152 mm] pipe, the tap would be at least 6" [152 mm] from any elbow, orifice, etc.

Valves

1. Install field-supplied air vents and drain valves on the water boxes. Each water box is provided with a 3/4" [19 mm] National Pipe Thread Female (NPTF) vent and drain connection.

   Plastic plugs are factory-installed in both openings for shipment; remove and discard these plugs as you install the water box vents and drain valves.

2. If necessary for the application, install pressure-relief valves at the drain connections on the evaporator and condenser water boxes. To do so, add a tee with the relief valve attached to the drain valve.

   To determine whether or not pressure relief valves are needed for a specific application, keep in mind that:

   (a) Vessels with close-coupled shutoff valves may cause high potentially damaging hydrostatic pressures as fluid temperature rises; and,

   (b) Relief valves are required by American Society of Mechanical Engineers (ASME) codes when the shell waterside is ASME. Follow ASME guidelines or other applicable codes to assure proper relief valve installation.

INSTALL PRESSURE-RELIEF VALVES IN THE CONDENSER AND EVAPORATOR WATER CIRCUITS, failure to do may result in shell damage due to hydrostatic expansion.

Strainers

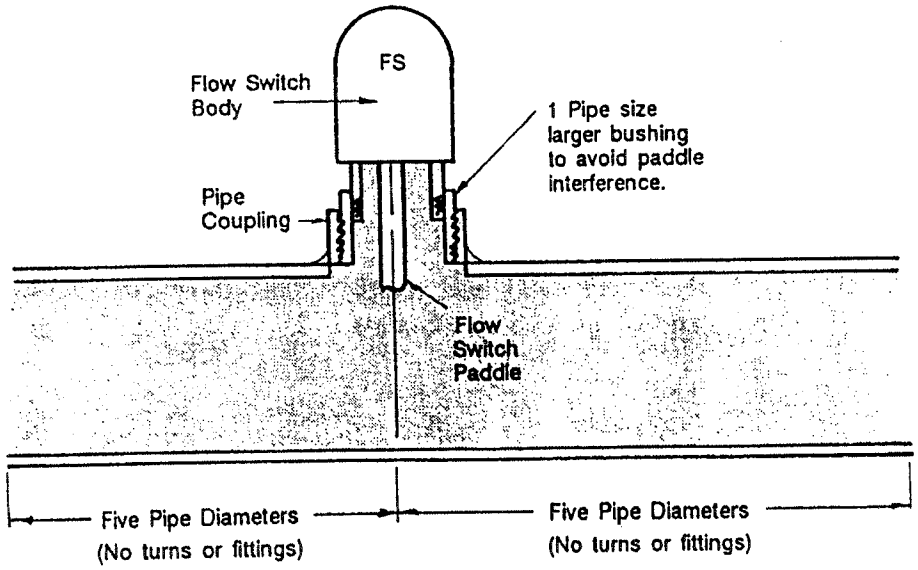
Install a strainer in the entering side of each piping circuit to avoid possible tube plugging in the chiller with debris.

INSTALL STRAINERS IN ALL WATER PIPING ENTERING THE CHILLER, failure to do so may result in tube plugging conditions that could damage unit components.

Water Piping

Required Flow-Sensing Devices

Use either flow switches or differential pressure switches in conjunction with the pump interlocks to verify evaporator and condenser water flows.



To assure adequate chiller protection, wire the chilled-water and condenser-water flow switches in series with the appropriate water pump interlock. Refer to the wiring diagrams that shipped with the unit for specific electrical connections.

Unless stated otherwise, all flow sensing devices must be field supplied. Be sure to follow the manufacturer's recommendations for device selection and installation.

Also, review the general flow switch installation guidelines listed below.

1. Mount the flow switch upright in horizontal section of pipe. Allow at least five pipe diameters of straight, horizontal run on each side of the switch.
2. To assure that the flow switch operates as designed, adjust the length of the flow switch paddle to compensate for the pipe diameter and the height of the coupling tee used to install the switch.
3. Install the flow switch using a coupling that is large enough to allow the insertion of a bushing one pipe diameter larger than the flow switch base (Figure 1). This will prevent interference with the flow switch paddle.
4. Verify that the direction-of-flow arrow on the switch points in the same direction as actual water flow through the piping circuit.
5. Remove all air from the piping circuit to prevent possible flow switch "fluttering."
6. Adjust the flow switch to open when water flow is less than normal.

Figure 1 – Flow Switch Installation

EVAPORATOR AND CONDENSER "PROOF OF FLOW" SWITCHES (EITHER FLOW OR DELTA-P) ARE REQUIRED IN SERIES WITH THE PUMP CONTACTOR AUXILIARY SHOWN ON WIRING DIAGRAMS.

THESE SWITCHES ARE USED WITH CONTROL LOGIC TO CONFIRM FLOW PRIOR TO STARTING A UNIT AND TO STOP A RUNNING UNIT IF FLOW IS LOST. FOR TROUBLE SHOOTING, A VIEWABLE DIAGNOSTIC IS GENERATED IF A "PROOF OF FLOW" SWITCH DOES NOT CLOSE WHEN FLOW IS REQUIRED. Failure to include the condenser "proof of flow" switch and "jumping out" this switch could cause the unit to stop on a secondary level of protection such as high condenser pressure. Frequent cycling on these higher level diagnostic devices could cause excessive thermal and pressure cycling of unit components (O-rings, gaskets, sensors, motors, controls, etc.) resulting in premature failure.

Water Piping

Evaporator and Condenser Water Piping

Figures 2 and 3 illustrate the typical water piping arrangements recommended for the evaporator and condenser.

Note: It is strongly recommended that the piping contractor refrain from piping closer than 3' [.91 m] minimum to the equipment. This will allow for proper fit-up upon arrival of the unit at the job site. Any adjustment that is necessary can be made to the piping at that time.

Water piping connection sizes are identified in Tables 1, 2 and 3. Remember that entering and leaving evaporator water can be piped to either water box connection since the tube bundles are split vertically.

Note: To assure that the evaporator water piping is clear, check it after the chilled water pump is operated but before initial chiller start-up. If any partial blockages exist, they can be detected and removed to prevent possible tube damage resulting from evaporator freeze-up or erosion.

Note: Arrange the condenser water piping so that the water supply enters the shell at the lower connection, and exits from the top connection. Single-pass condenser shells may be piped as desired since both connections are at the same level.

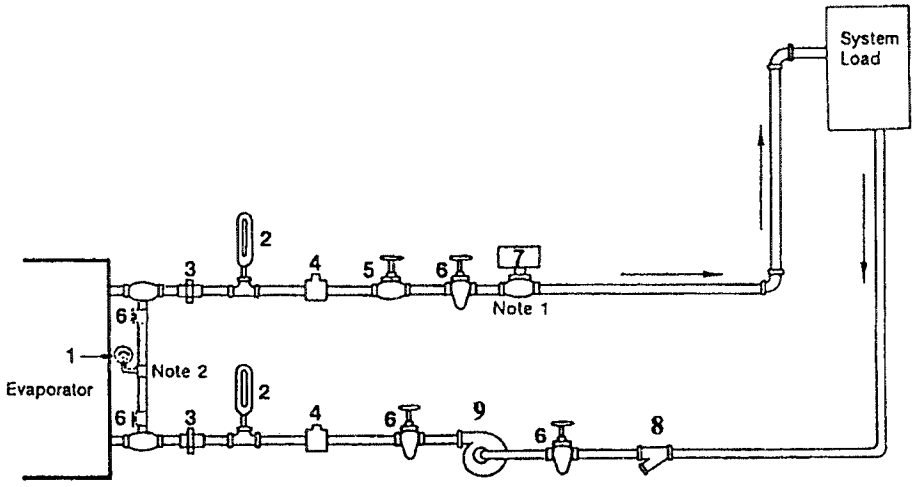
For applications that include an "infinite source" or "multiple-use", cooling condenser water supply, install a valved bypass "leg" (optional) between the supply and return pipes; see Figure 3. This valved bypass allows the operator to short-circuit water flow through the cooling condenser when the supply water temperature is too low.

SYSTEM PRESSURE DIFFERENTIAL MUST BE MAINTAINED ABOVE 5 PSID [34 kPa] AT ALL TIMES. Failure to do so could result in operating problems.

Note: Whenever a CVHE, CVHF and CVHG unit is equipped with an auxiliary condenser, use a bypass valve system to avoid circulating water through the auxiliary shell during unit shutdown.

Water Box Locations

If necessary, the non-marine-style water boxes on each shell whether evaporator or condenser can be switched end-for-end to obtain the desired piping arrangement. Contact Trane LBU Marketing for switching of marine-style boxes.



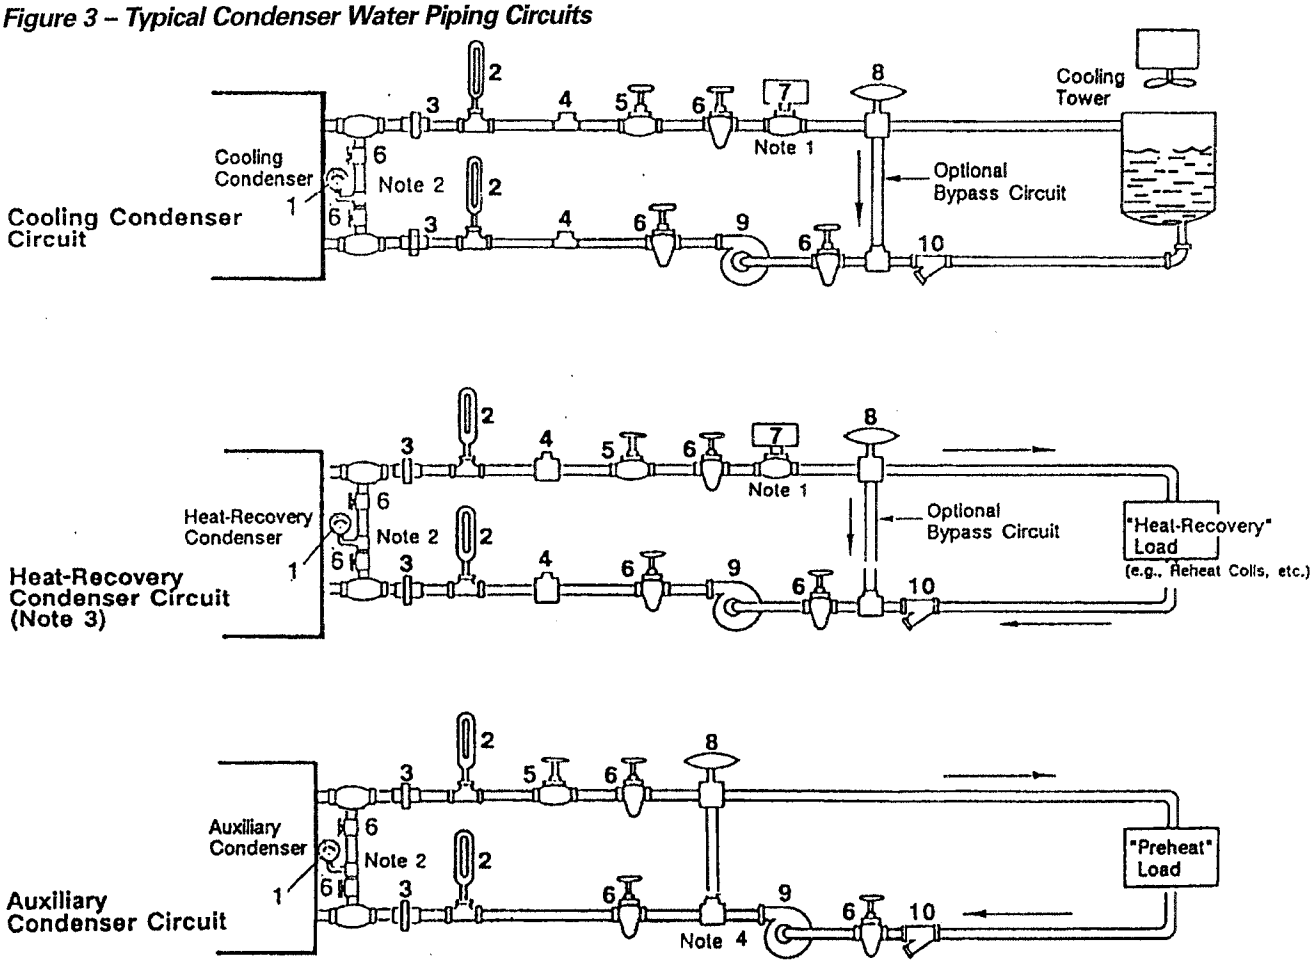
DO NOT EXCHANGE POSITIONS OF MARINE-STYLE WATER BOXES. Failure to follow this recommendation could alter designed water flow piping configuration and prevent proper unit operation.

To accommodate lifting apparatus, a nut is welded to each evaporator water box to enable attachment of a 3/4" [19 mm] eyebolt (field supplied). Condenser water boxes are provided with 1/2" [13 mm] tapped holes that allow installation of the eyebolt included in the unit's loose parts-box.

If the water boxes on any of the shells are exchanged end-for-end, be sure to reinstall them right side up to maintain the correct baffle arrangements. Use a new gasket with each water box cover.

Water Piping

Figure 2 – Typical Evaporator Water Piping Circuit



Notes:
1. Flow switch 5S1 (Item 7 in Legend of Components) may be installed in either the entering or leaving leg of the chilled water circuit.
2. It is recommended to pipe the (Item 1) gauge between entering and leaving pipes. A shutoff valve on each side of the gauge allows the operator to read either entering or leaving water pressure.

Legend of Field-Supplied and Installed Components

1. Pressure Gauge
2. Thermometer(s) (If field supplied)
3. Union(s) or Flanged Connection(s)
4. 1/2" [13 mm] NPT Couplings
5. Balancing Valve
6. Gate (Isolation) Valve(s) or Ball Valve(s)
7. Chilled Water Flow Switch (5S1)
8. Strainer
9. Evaporator Water Pump

Water Piping

Figure 3 – Typical Condenser Water Piping Circuits

Notes:
1. The Flow Switch 5S2 (Item 7 in Legend of Components) may be installed in either the entering or leaving leg of the chilled water circuit.
2. It is recommended to pipe a single gauge between entering and leaving pipes.
3. Some type of field-supplied temperature control device may be required to regulate the temperature of the heat-recovery condenser water circuit. For application recommendations, see Trane Application Manual, "AM-FND-8", titled "Heat-Recovery Engineering Seminar".
4. Install a bypass valve system to avoid circulating water through the auxiliary shell when the unit is shut down.

Legend of Field-Supplied and Installed Components

1. Pressure Gauge
2. Thermometer(s) (If field supplied)
3. Union(s) or Flanged Connection(s)
4. 1/2" [13 mm] NPT Couplings
5. Balancing Valve
6. Gate (Isolation) Valve(s) or Ball Valve(s)
7. Condenser Water Flow Switch

9. Condenser Water Pump
10. Strainer

Water Piping

Water Piping Connections

For CVHEs beginning with design sequence "1D," all units (except those with 032 through 050 condenser shells with 150 psig [1035 kPa] non-marine water boxes) use cut-groove end NSP Victaulic style pipe connections. All CVHGs beginning with "1A" and later design sequences. All CVHF units, "A" and later design sequences, use grooved-pipe connections. See Figure 4.

Piping joined using grooved type couplings, like all types of piping systems, requires proper support to carry the weight of pipes and equipment. The support methods used must eliminate undue stresses on joints, piping and other components; allow movement where required, and provide for any other special requirements (i.e., drainage, etc.).

Table 1 – Evaporator Water Piping Connection Sizes

	Nominal Pipe Size (inch/mm)					
	1 Pass		2 Pass		3 Pass	
EVSZ	Inch	mm	Inch	mm	Inch	mm
032	8	219.1	6	168.3	5	141.3
050	10	273.0	8	219.1	6	168.3
080	12	323.4	10	273.0	8	219.1
142	16	406.4	12	323.9	10	273.0

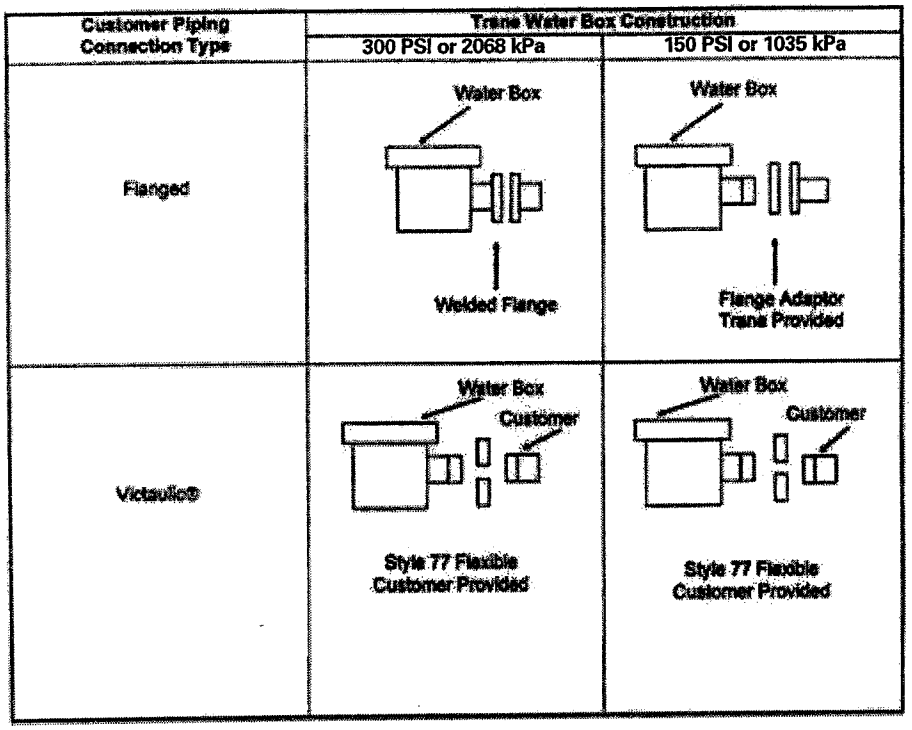
Water Piping

Table 3 – Water Piping Connection Components

		Customer Piping Connection	
Unit Model	Unit Connection Type	Victaulic™	Flanged
CVHE and CVHG	Flanged (Condenser 032-050 150 psig and 1035 kPa non-marine only)	Trane provided Victaulic-to-Flange Adapter	No Adapter Required
CVHE, CVHF and CVHG	Victaulic (All others)	Customer provided Victaulic Coupling	Trane provided Victaulic-to-Flange Adapter



Grooved Pipe Coupling

A customer-supplied, standard flexible grooved pipe coupling (Victaulic Style 77 or equivalent) should be used to complete the Victaulic connection for both 150 psig or 1035 kPa and 300 psig or 2068 kPa water boxes. See Table 3.

When a flexible coupling such as this is installed at the water box connections (Figure 5), other flexible piping connectors (i.e., braided-steel, elastomeric arch, etc.) are usually not required to attenuate vibration and/or prevent stress on the connections.

Note: Flexible coupling gaskets require proper lubrication before installation to provide a good seal. Refer to the coupling manufacturer's guidelines for proper lubricant type and application.

Figure 5 – Customer Piping Alternatives for Water Connections

Water Piping

Flange-Connection Adapters

When flat-face flange connections are specified, flange-to-groove adapters are provided (Victaulic™ Style 741 for 150 psig or 1035 kPa systems; Style 743 for 300 psig or 2068 kPa systems). Welded flanged connections are available only as a design special unless ordered as such, flange to groove adapters are provided if flat faced flange connections are specified. The adapters are shipped bolted to one of the chiller end-supports (Figure 6). Adapter weights are given in Tables 1 and 2, The flange adapters provide a direct, rigid connection of flanged components to the grooved-pipe chiller water box connections,

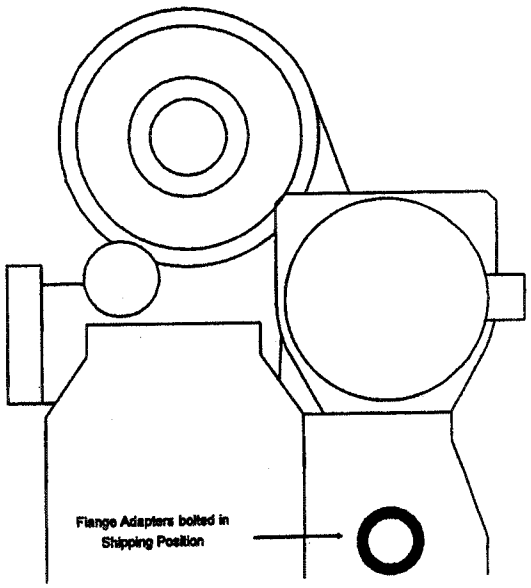
In this case, the use of flexible type connectors (i.e., braided steel, elastomeric arch, etc.) is recommended to attenuate vibration and prevent stress at the water box connections. Flange adapters are not provided for CVHE/F/G units with 300 psig or 2068 kPa water boxes that have 14" [356 mm] or 16" [406 mm] piping connections.

All flange-to-flange assembly bolts must be provided by the installer. Bolt sizes and number required are given in Tables 1 and 2.

The four draw-bolts needed for the 14" [356 mm] and 16" [406 mm] Style 741 (150 psig or 1035 kPa) adapters are provided. The Style 741, 150 psig or 1035 kPa flange adapter requires a smooth, hard surface for a good seal.

Connection to other type flange faces (i.e., raised, serrated, rubber, etc.) will require the use of a flange washer between the faces. Refer to the flange adapter manufacturer's guidelines for specific information.

The Style 743, 300 psig or 2068 kPa flange adapters are designed to mate with raised-face flanges. They can be used with flat-faced flanges, however, if the raised projections on the outside face of the adapter are removed (Figure 8.)



Note: The flange-adapter gasket must be placed with the color-coded lip on the pipe and the other lip facing the mating flange.

GASKET-CONTACT SURFACES OF ADAPTER MUST BE FREE OF GOUGES, UNDULATIONS, OR DEFORMITIES. Failure to do so may not provide an effective seal.

Victaulic Gasket Installation

1. Check gasket and lubricate: Check gasket supplied to be certain it is suited for intended service. Code identifies gasket grade. Apply a thin coat of silicone lubricant to gasket tips and outside of gasket.
2. Install Gasket: Place gasket over pipe end, being sure gasket lip does not overhang pipe end. See Figure 7 for gasket configuration.
3. Join pipe ends: Align and bring two pipe ends together and slide gasket into position centered between the grooves on each pipe. No portion of the gasket should extend into the groove on either pipe.
4. **Apply Vic-Flange™**: Open fully and place hinged flange around the grooved pipe end with the circular key section locating into the groove.
5. Insert bolt: Insert a standard bolt through the mating holes of the Vic-Flange to secure the flange firmly in the groove.
6. Tighten nuts: Tighten nuts alternately and equally until housing bolt pads are firmly together (metal to metal). Excessive nut tightening is not necessary. **Note:** Uneven tightening may cause gasket to pinch.

Water Piping

Bolt-Tightening Sequence for Water Piping Connections

A bolt-tightening sequence for flanges with flat gaskets or O-rings is described below and shown in Figure 9. Remember that improperly tightened flanges may leak.

Note: Before tightening any of the bolts, align the flanges. Flange bolt torque requirements are given in Table 6.

Flanges with 4, 8 or 12 Bolts

See Figure 9. Tighten all bolts to a snug tightness, following the appropriate numerical sequence for the flange. Repeat this sequence to apply the final torque to each bolt.

Flanges with 16, 20 or 24 Bolts

See Figure 9. Following the appropriate numbered sequence, tighten only the first half of the total number of bolts to a snug tightness. Next, sequentially tighten the remaining half of the bolts in the proper order.

Flanges with More than 24 Bolts

Refer to Figure 9 and sequentially tighten the first 12 bolts to a snug tightness. Tighten the next 12 consecutively numbered bolts in sequence, to the final torque.

Then, apply final torque to the first 12 bolts and the bolts not yet tightened (i.e., unnumbered bolts in Figure 9). Be sure to start with bolt "1" and move progressively around the flange in a clockwise direction.

Evaporator Water Box Covers

See Figure 9. Ensure that the water box head rests tightly against the tube sheet; then snugly tighten the 26 bolts in sequential order.

If excessive tube sheet crown prevents the head from contacting the tube sheet, tighten the bolts located where the greatest gaps occur. Be sure to use an equal number of bolt turns from side to side.

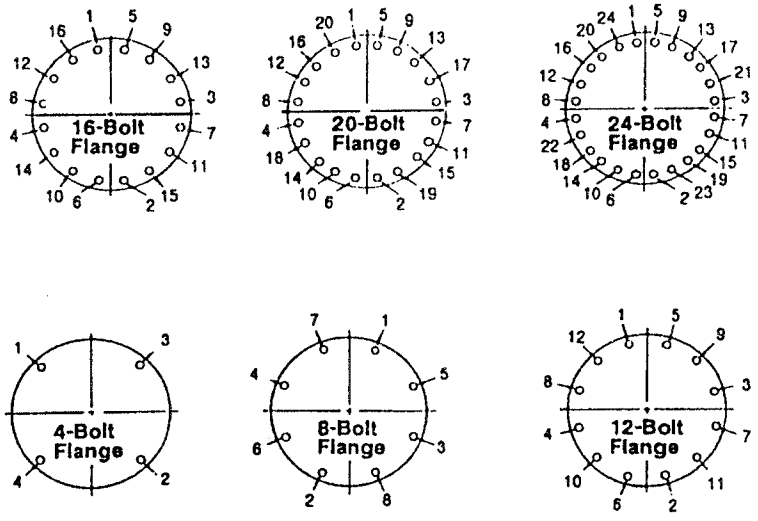

Table 6 – Flange Bolt Torque Recommendations for O-Ring and Flat-Gasket Piping Connections

Bolt Size		Gasket Type	
Inch	(mm)	O-Ring	Flat
3/8"	9.5	25 (34)	12-18 (16-24)
1/2"	13	70 (95)	33-50 (45-68)
5/8"	16	150 (203)	70-90 (95-122)
3/4"	19	250 (339)	105-155 (142-210)

Flanges with more than 24 bolts

Evaporator Water Box Covers

Purge Piping

EarthWise Purge Requirements Purge Installation

For certain CenTraVacs, the purge system is not mounted on the chiller when it ships. For 800-ton heat recovery chillers and 1250 and 1400 ton chillers with auxiliary condensers, the EarthWise Purge is shipped in a separate container that is secured to the chiller shipping skid.

Install the purge system in accordance with the following instructions.

1. Remove purge from its shipping brackets or container.
2. Disconnect purge gas and liquid lines and conduit from shipping bracket that spans purge supports on top of the heating or auxiliary condenser.
3. Remove shipping bracket and screws from purge supports and discard.
4. Locate purge on top of supports (purge base goes outside supports).
5. Secure the purge to the supports with the hardware provided.
6. Using proper brazing techniques as per American Welding society (A.W.S.) braze the following four copper lines at the factory disassembly points:
   - Purge suction line (larger)
   - Purge liquid drain line
   - Regeneration line
   - High pressure cutout switch

   Note: Verify that the high-pressure cutout switch is connected to the line, which proceeds to the chiller condenser. (Check the copper tube routing to verify.)
   - Assure braze joints are leak free
7. Remove purge panel cover and connect the unit wiring per the unit wiring diagrams:
   - Interprocessor communications bus (IPC).
   - Chiller motor temperature sensor wires to motor temperature module.
   - Conduit to control panel and interconnecting wires.
   - After inspection of terminations reassemble purge panel cover.
8. With completion of brazing and electrical connections, the unit valves can be opened for unit operation.

Vent Piping

Refrigerant Vent-Line

General Recommendations
Both the purge and rupture disc vent lines must be routed to outside atmosphere. Use only material compatible with the refrigerant in use. The use of Poly Vinyl Chloride (PVC) (not Chlorinated Poly Vinyl Chloride (CPVC) piping is acceptable if the pipe joint is properly primed and if the adhesive used has been tested for refrigerant compatibility. Testing conducted in Trane laboratories has approved the use of the following materials for PVC pipe construction.

Primer - Hercules, PVC Primer #60-465, RectorSeal PVC Cleaner -Smiling Sam CL3 Adhesive-Hercules, Clear PVC, Medium Body, Medium Set, #60-020 RectorSeal PVC Cement-Green Gene 104.

Consult with the manufacturers of any field-provided components or materials added to the refrigerant-side of the machine for acceptable material compatibility.

During vent line construction, provide a drip leg on the line that is of sufficient length to accommodate a minimum of one gallon of liquid. Provide a standard capped refrigerant service valve to facilitate liquid removal. Accumulated liquid must be drained from the drip leg into an evacuated waste container once every six months, at a minimum, and more often if the purge operates excessively.

Purge Discharge Vent Line

On CVHE, CVHF and CVHG units, the purge discharge is factory-piped downstream of the rupture disc on the unit.

Rupture Disc Vent Installation

All CenTraVac™ chillers are equipped with carbon rupture discs. A cross-section of the rupture disc assembly appears in Figure 10 along with an illustration indicating the location of the rupture disc on the suction elbow.

If refrigerant pressure within the evaporator exceeds 15 psig, the rupture disc breaks, shell pressure is relieved as refrigerant escapes from the chiller.

When constructing the rupture disc vent line, be sure to consult local codes for applicable guidelines and constraints.

Several general recommendations for rupture disc vent line installation are outlined below.

1. Verify that the vacuum support side of the rupture disc is positioned as shown in the cross-section view that appears in Figure 10.

   Note: If the rupture disc was removed for any reason, it must be reinstalled as shown.

2. Do not apply threading torque to the outside pipe assembly when installing the connecting pipe.

Do not apply threading torque to the outside pipe. Failure to do so may damage the rupture disc assembly.

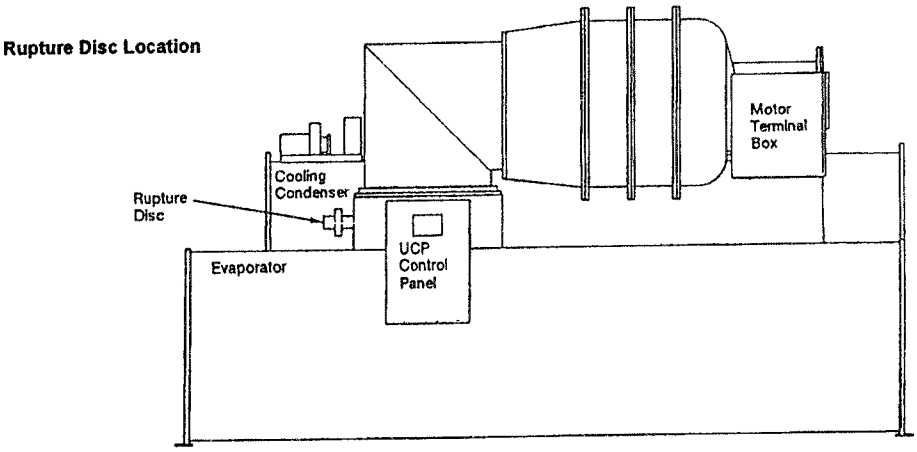
3. Support the vent piping, use a flexible connection to avoid placing stress on the rupture disc. (Stress can alter rupture pressure and cause the disc to break prematurely.)

Vent Piping

The flexible connector used to isolate the rupture disc from excessive vent line vibration must be compatible with the refrigerant in use. Use a flexible, steel connector such as the stainless-steel type (from Vibration Mounting and Control, Inc.) or equivalent.

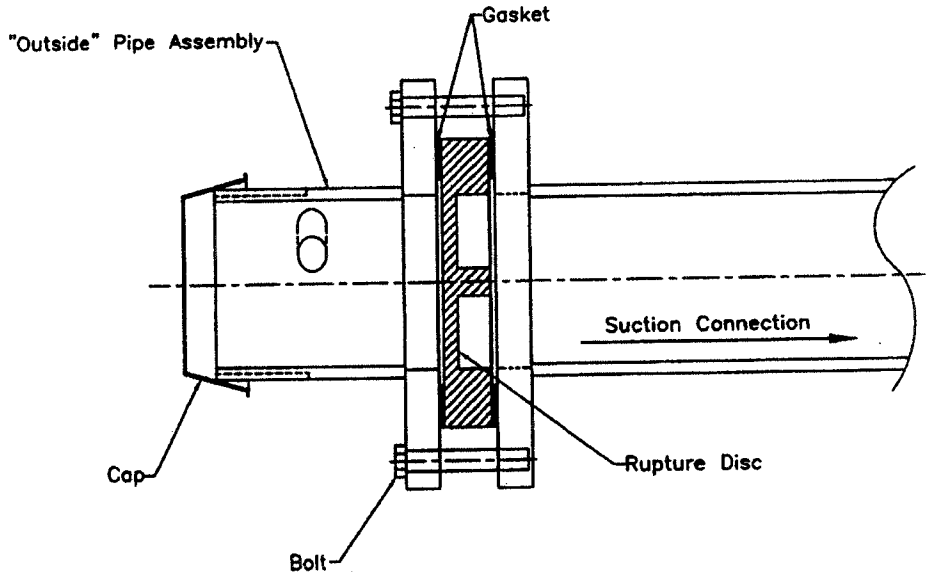
See Figure 11 for a recommended relief piping arrangement.

Important: Vent pipe size must conform to ANSI and ASHRAE Standard 15, which discusses vent pipe sizing.



Use Table 7 and then Figure 12 to determine proper vent pipe size.

Note: To determine the total "C" value for a specific unit, add the appropriate "C" values for the evaporator, standard condenser and economizer. If the unit is equipped with any options (e.g., heat recovery, free cooling, or an auxiliary condenser), add the applicable "C" value(s) to this total.



With this new sum, refer to Figure 12 to determine the vent line pipe diameter needed to handle flow.

4. Normally, where multiple chillers are used, install a separate rupture disc vent line for each unit.
5. Consult local regulations for any special relief line requirements and refer to Refrigerant Handling Guidelines.
6. The discharge of the vent line outside should not be in the general vicinity of any fresh air intakes to the building. Any gas venting from the vent line should not be allowed to re-enter the building.

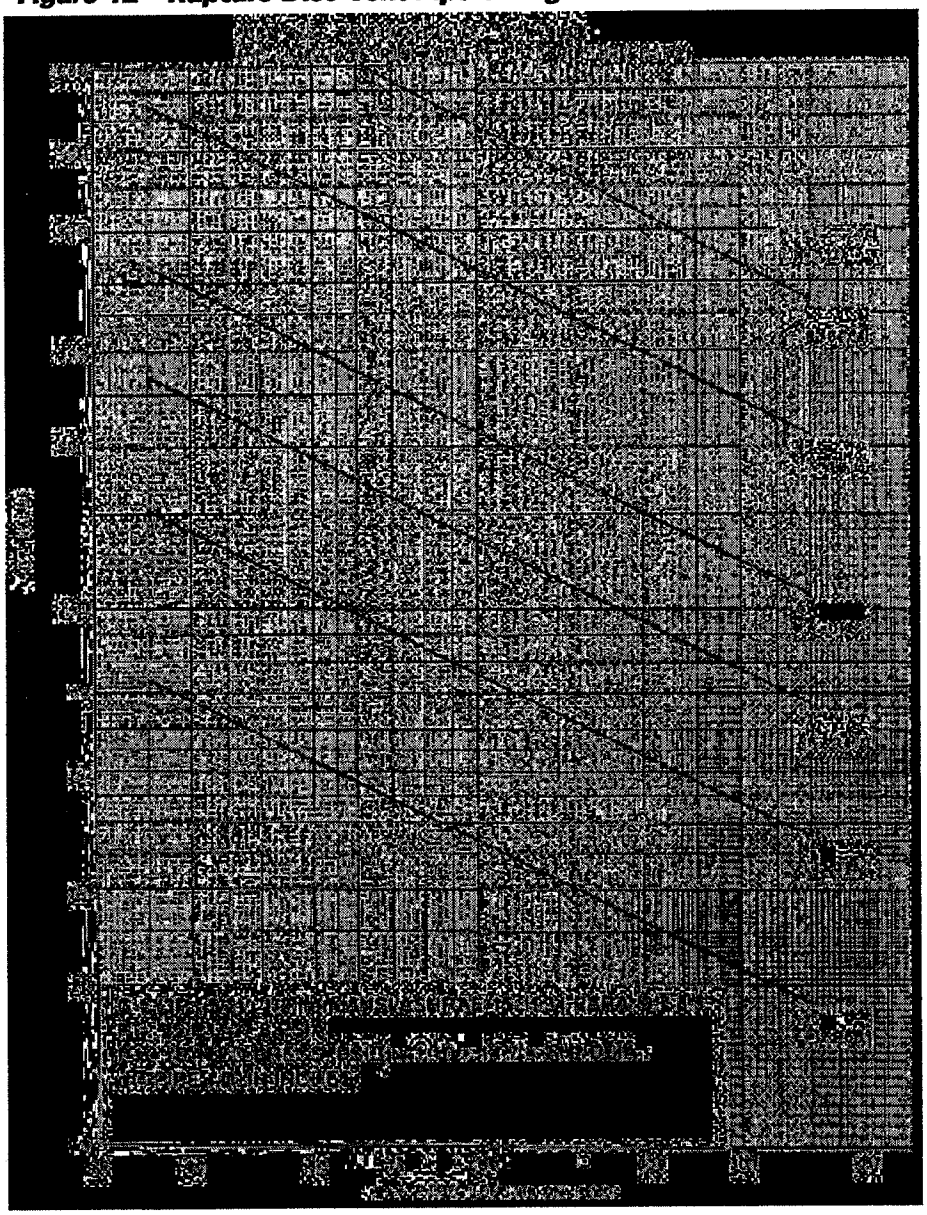
Evaporator Size (EVSZ) (3)	Condenser Size (CDSZ) (4)	"C" Values for Unit Components							
		Rupture Disc Diameter	Evaporator	Standard Condenser	Economizer	Short H.R. Condenser	Long H.R. Condenser	Auxiliary Condenser	With Free Cooling
032S	032S	3" (76 mm)	26.25	18.87	4.85	18.87	25.19	15.28	4.16
032S	032L	3" (76 mm)	26.25	25.19					
032L	032L	3" (76 mm)	35.04	25.19					
050S	050S	3" (76 mm)	33.05	23.56	7.44	23.56	31.45	15.28	6.16
050S	050L	3" (76 mm)	33.05	31.45					
050L	050L	3" (76 mm)	44.13	31.45					
080S	080S	3" (76 mm)	45.59	29.06	11.63	29.06	38.80	15.28	5.87
080S	080L	3" (76 mm)	45.59	38.80					
080L	080L	3" (76 mm)	60.86	38.80					
142E	142L	3" (76 mm)	74.30	50.50	17.40	N/A*	Design Special	15.28	Design Special
142M	142L	3" (76 mm)	58.47	50.50			50.50		7.10
142L	142L	3" (76 mm)	68.86	50.50			N/A*		
210L	210L	3" (76 mm)	75.16	56.72			56.72		
250E	250L	3" (76 mm)	93.81	62.12					



Notes:

1. To determine the total "C" value for a specific unit, add the appropriate ""C" values for the evaporator, standard condenser and economizer. If the unit is equipped with any options (e.g., heat recovery, free cooling or an auxiliary condenser, add the applicable "C" values to this total. With this new sum, refer to Figure 12 to determine the vent line pipe diameter.
2. If piping multiple rupture discs (multiple units) to a common vent line, first determine the total "C" value for each unit, and then; add all "C" values together and apply the result to the "vent pipe sizing chart" in Figure 12.
3. EVSZ = Evaporator Shell Size;
   S = Short Shell
   L = Long Shell
   E = Extended Shell
   M = Medium
4. CDSZ = Condenser Shell Size;
   S = Short Shell
   L = Long Shell
   E = Extended Shell

Insulation

Unit Insulation Requirements

Factory-installed insulation is available as an option for all CVHE, CVHF and CVHG units.

In those instances where the chiller is not factory-insulated, install insulation over the areas shaded in Figure 13. It may also be necessary to insulate the compressor suction cover and motor barrel if the unit is installed in an area subjected to high humidities.

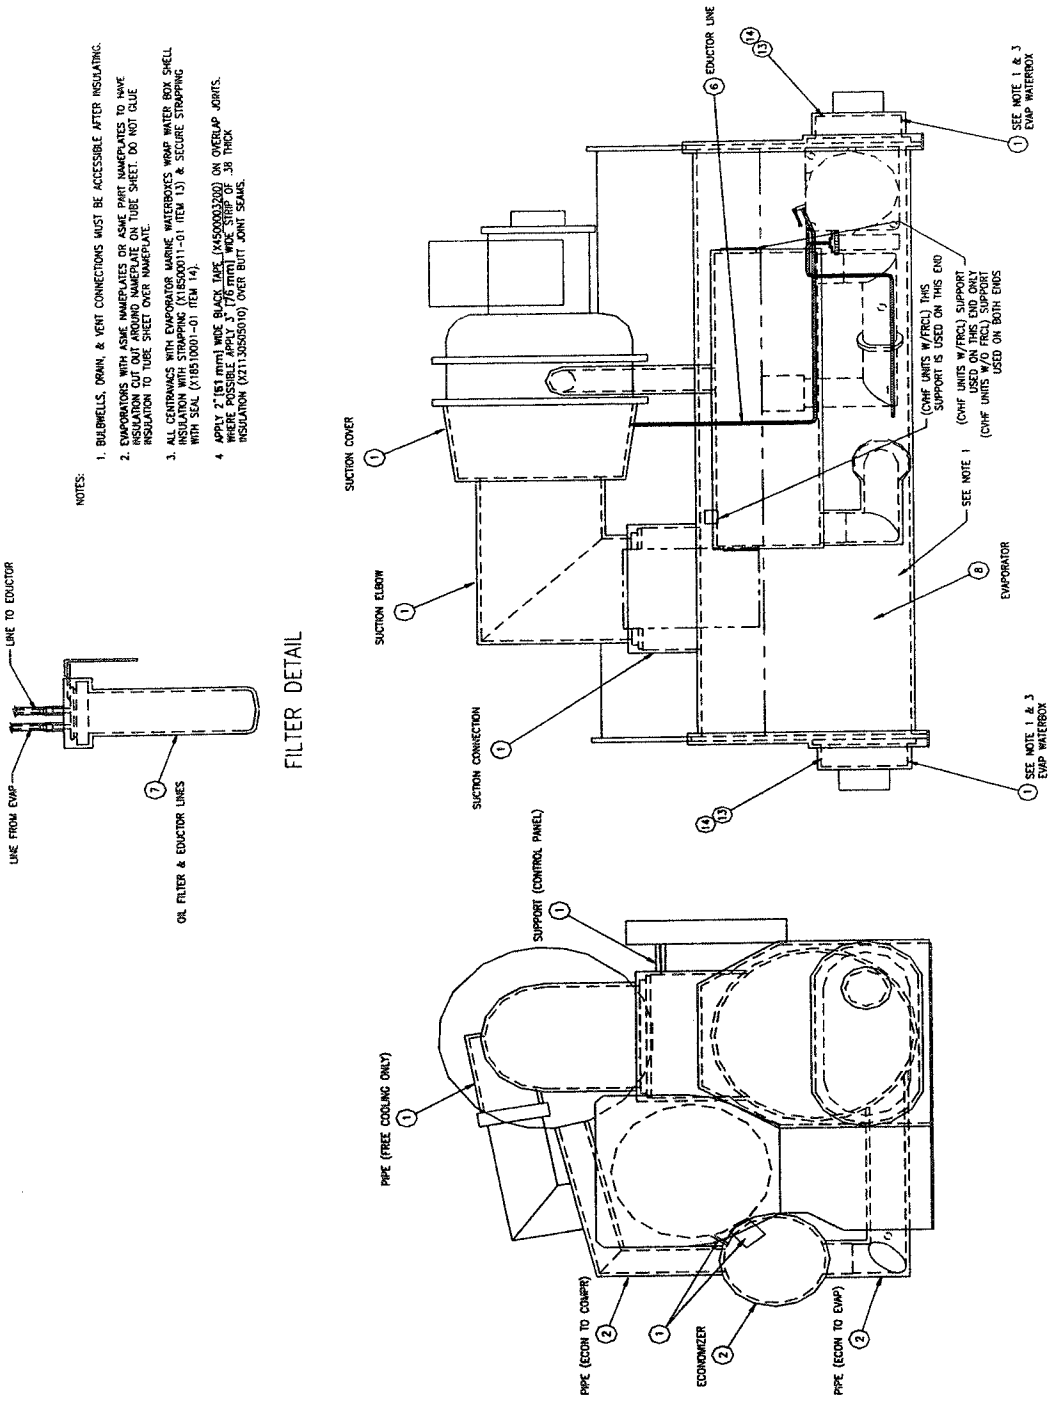
Insulate both 1/4" [6.4 mm] eductor lines, one from the suction cover and one from the evaporator to prevent sweating.

The quantities of installation required based on unit size and insulation thickness are listed in Table 8. Insulation thickness is determined at normal design conditions which are:
- 85°
- 75% Relative Humidity

Note: If the unit is not factory-insulated: Install insulation around the evaporator bulbwells; and, ensure that the bulbwells and connections for the water box drains and vents are still accessible after insulation is applied.

Table 8 – CVHE, CVHF and CVHG Evaporator Insulation Requirements

EVSZ (Note 1)	Standard Unit		Free Cooling	
	3/4" [19 mm] Insulation (Note 2) (Square Feet)	3/8" [9.5 mm] Insulation (Note 3) (Square Feet)	3/4" [19 mm] Insulation (Note 2) (Square Feet)	3/8" [9.5 mm] Insulation (Note 3) (Square Feet)
032S	337	52	347	74
032L	365	52	377	74
050S	385	63	398	72
050L	420	63	436	72
080S	505	84	515	97
080L	553	84	566	97
142M	555	98	555	133
142L	578	98	578	133
142E	603	104	629	133
210L	700	98	710	133
210 D	1220	193	Not Available	Not Available
250 D	1308	193	Not Available	Not Available
250 E	770	97	Not Available	Not Available



Notes:
1. EVSZ = Evaporator Shell Size, L = Long Shell, S = Short Shell
2. D = Duplex, M = Medium, E = Extended
3. 3/4" [19 mm] sheet insulation is installed on the evaporator, evaporator water boxes, compressor motor, suction elbow and suction cover as indicated in Figure 13.
4. 3/8" [9.5 mm] sheet insulation is installed on all economizers. All liquid lines and other pipes require the use of 1/2" [13 mm] pipe insulation or 3/8" [9.5 mm] sheet insulation. Copper oil eductor tube lines require pipe insulation.
5. Refrigerant Pump units are NOT insulated on the motor or refrigerant drain lines.

TO PREVENT DAMAGE TO FACTORY-INSTALLED INSULATION, do not allow the insulation to be exposed to excessive sunlight. Failure to do so may damage insulation.

IF THE INSULATION WILL BE PAINTED IN THE FIELD, USE ONLY WATER-BASED LATEX PAINTS. Failure to do so results in damage because thinners and solvents used or other types of paints may cause seams in the insulation to open as a result of shrinkage.

Insulation

Water Piping

Overview

Several water piping circuits must be installed and connected to the chiller.

Note: Field Piping must be arranged and supported to avoid stress on the equipment. It is strongly recommended that the piping contractor refrain from piping closer than 3' [.91 m] minimum to the equipment. This will allow for proper fit-up upon arrival of the unit at the job site. Any adjustment that is necessary can be made to the piping at that time.

(a) Pipe the evaporator into the chilled water circuit;

(b) Pipe the condenser into the condenser water circuit;

(c) A heat-recovery condenser water circuit, (optional);

(d) An auxiliary condenser water circuit, (optional)

Piping suggestions for each of the four water circuits listed above are outlined later in this section. General recommendations for the installation of field supplied piping components (e.g., valves, flow switches, etc.) common to most chiller water circuits are listed below.

Water Treatment

Since the use of untreated or improperly treated water in a CenTraVac™ may result in inefficient operation and possible tube damage, be sure to engage the services of a qualified water treatment specialist if needed. A label with the following disclaimer note is affixed to each unit.

Customer Note
The use of improperly treated or untreated water in this equipment may result in scaling, erosion, corrosion, algae or slime. The services of a qualified water treatment specialist should be engaged to determine what treatment, if any, is advisable. The Trane warranty specifically excludes liability for corrosion, erosion or deterioration of Trane equipment. Trane assumes no responsibilities for the results of the use of untreated or improperly treat water, or saline or brackish water.

CAUTION

Proper Water Treatment!

The use of untreated or improperly treated water in a CenTraVac may result in scaling, erosion, corrosion, algae or slime. It is recommended that the services of a qualified water treatment specialist be engaged to determine what water treatment, if any, is required. Trane assumes no responsibility for equipment failures which result from untreated or improperly treated water, or saline or brackish water.

Pressure Gauges

Locate pressure gauge taps in a straight run of pipe. Place tap a minimum of one pipe diameter downstream of any elbow, orifice etc. Example, for a 6" [152 mm] pipe, the tap would be at least 6" [152 mm] from any elbow, orifice, etc.

Valves

1. Install field-supplied air vents and drain valves on the water boxes. Each water box is provided with a 3/4" [19 mm] National Pipe Thread Female (NPTF) vent and drain connection.

   Plastic plugs are factory-installed in both openings for shipment; remove and discard these plugs as you install the water box vents and drain valves.

2. If necessary for the application, install pressure-relief valves at the drain connections on the evaporator and condenser water boxes. To do so, add a tee with the relief valve attached to the drain valve.

   To determine whether or not pressure relief valves are needed for a specific application, keep in mind that:

   (a) Vessels with close-coupled shutoff valves may cause high potentially damaging hydrostatic pressures as fluid temperature rises; and,

   (b) Relief valves are required by American Society of Mechanical Engineers (ASME) codes when the shell waterside is ASME. Follow ASME guidelines or other applicable codes to assure proper relief valve installation.

CAUTION

INSTALL PRESSURE-RELIEF VALVES IN THE CONDENSER AND EVAPORATOR WATER CIRCUITS, failure to do may result in shell damage due to hydrostatic expansion.

Strainers

Install a strainer in the entering side of each piping circuit to avoid possible tube plugging in the chiller with debris.

CAUTION

Use Piping Strainers!

To prevent evaporator or condenser damage, pipe strainers must be installed in the water supplies to protect components from water born debris. Trane is not responsible for equipment-only-damage caused by water born debris.

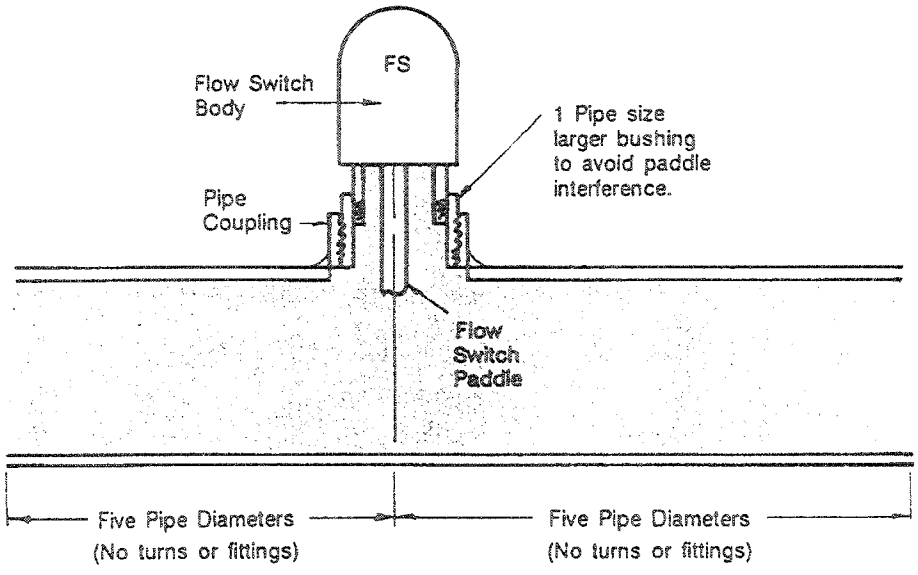
Water Piping

Required Flow-Sensing Devices

Use either flow switches or differential pressure switches in conjunction with the pump interlocks to verify evaporator and condenser water flows.

To assure adequate chiller protection, wire the chilled-water and condenser-water flow switches in series with the appropriate water pump interlock. Refer to the wiring diagrams that shipped with the unit for specific electrical connections.

Unless stated otherwise, all flow sensing devices must be field supplied. Be sure to follow the manufacturer's recommendations for device selection and installation.



Also, review the general flow switch installation guidelines listed below.

1. Mount the flow switch upright in horizontal section of pipe. Allow at least five pipe diameters of straight, horizontal run on each side of the switch.
2. To assure that the flow switch operates as designed, adjust the length of the flow switch paddle to compensate for the pipe diameter and the height of the coupling tee used to install the switch.
3. Install the flow switch using a coupling that is large enough to allow the insertion of a bushing one pipe diameter larger than the flow switch base (Figure 1). This will prevent interference with the flow switch paddle.
4. Verify that the direction-of-flow arrow on the switch points in the same direction as actual water flow through the piping circuit.
5. Remove all air from the piping circuit to prevent possible flow switch "fluttering."
6. Adjust the flow switch to open when water flow is less than normal.

CAUTION

EVAPORATOR AND CONDENSER "PROOF OF FLOW" SWITCHES (EITHER FLOW OR DELTA-P) ARE REQUIRED IN SERIES WITH THE PUMP CONTACTOR AUXILIARY SHOWN ON WIRING DIAGRAMS. THESE SWITCHES ARE USED WITH CONTROL LOGIC TO CONFIRM FLOW PRIOR TO STARTING A UNIT AND TO STOP A RUNNING UNIT IF FLOW IS LOST. FOR TROUBLE SHOOTING, A VIEWABLE DIAGNOSTIC IS GENERATED IF A "PROOF OF FLOW" SWITCH DOES NOT CLOSE WHEN FLOW IS REQUIRED. Failure to include the condenser "proof of flow" switch and "jumping out" this switch could cause the unit to stop on a secondary level of protection such as high condenser pressure. Frequent cycling on these higher level diagnostic devices could cause excessive thermal and pressure cycling of unit components (O-rings, gaskets, sensors, motors, controls, etc.) resulting in premature failure.

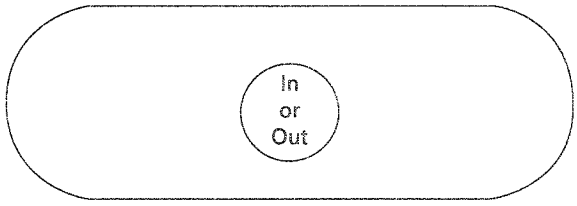
Figure 1. Flow switch installation

Water Piping

Evaporator and Condenser Water Piping

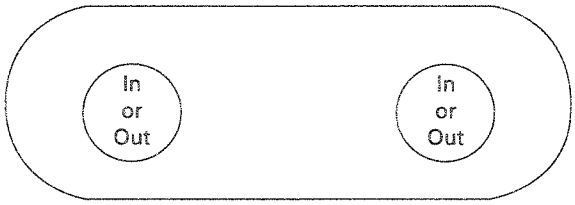
Figures 3 and 4 illustrate the typical water piping arrangements recommended for the evaporator and condenser.

Note: It is strongly recommended that the piping contractor refrain from piping closer than 3' [.91 m] minimum to the equipment. This will allow for proper fit-up upon arrival of the unit at the job site. Any adjustment that is necessary can be made to the piping at that time. Expenses that result from a failure to follow this recommendation will not be paid by Trane.



Water piping connection sizes are identified in Tables 1, 2 and 3. Remember that entering and leaving evaporator water can be piped to either water box connection since the tube bundles are split vertically.

Note: To assure that the evaporator water piping is clear, check it after the chilled water pump is operated but before initial chiller start-up. If any partial blockages exist, they can be detected and removed to prevent possible tube damage resulting from evaporator freeze-up or erosion.



Note: Arrange the water piping so that the water supply enters the shell at the lower connection, and exits from the top connection. (Operational problems may result if this is not obeyed) Some shells may be piped as desired since both connections are at the same level. Ref. Fig. 2.

Water Piping

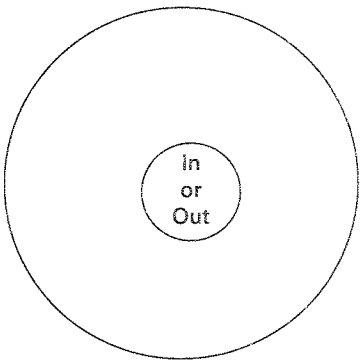


Figure 2. Standard waterbox connections

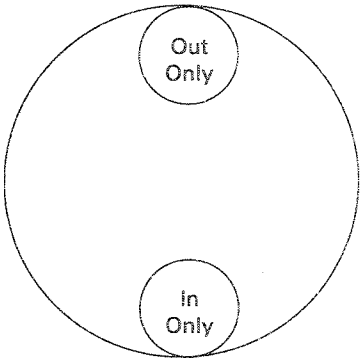
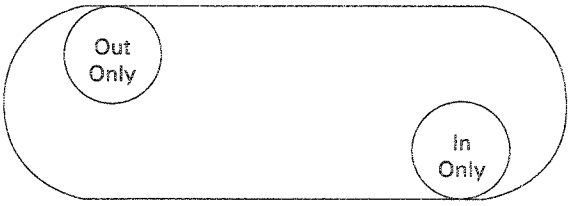
Typical Single Pass Evaporator



Standard Two Pass Evaporator



Standard Single Pass Condenser

Large Two Pass Evaporator

Standard Two Pass Condenser

Large Two Pass Evaporator

Water Piping

For applications that include an "infinite source" or "multiple-use", cooling condenser water supply, install a valved bypass "leg" (optional) between the supply and return pipes; see Figure 4. This valved bypass allows the operator to short-circuit water flow through the cooling condenser when the supply water temperature is too low.

See "Condenser Water Temperature Control for CenTraVac® Centrifugal Chiller Systems" Engineering Bulletin (CTV-PRB006-EN) for additional application information.

CAUTION

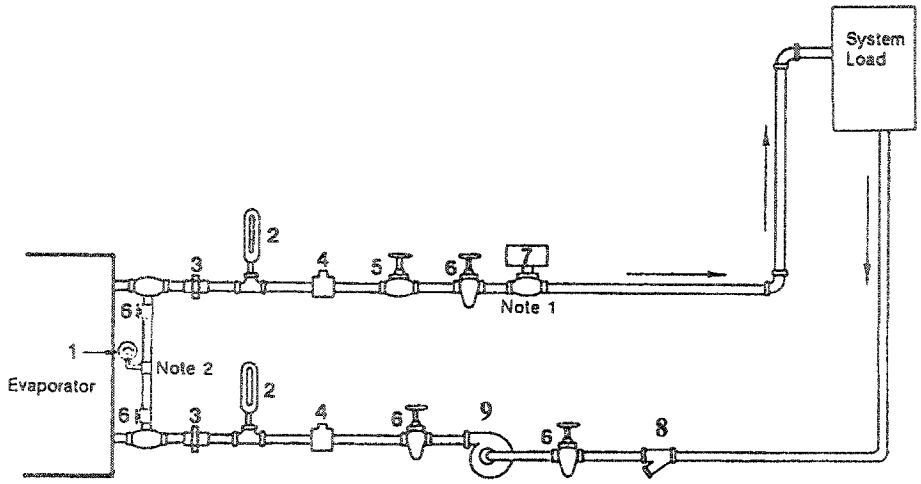
SYSTEM PRESSURE DIFFERENTIAL MUST BE MAINTAINED ABOVE 5 PSID [34 kPa] AT ALL TIMES. Failure to do so could result in operating problems.

Note: Whenever a CVHE, CVHF and CVHG unit is equipped with an auxiliary condenser, use a bypass valve system to avoid circulating water through the auxiliary shell during unit shutdown.

Water Box Locations

If necessary, the non-marine-style water boxes on each shell whether evaporator or condenser can be switched end-for-end to obtain the desired piping arrangement. Contact Trane LBU Marketing for switching of marine-style boxes.

CAUTION



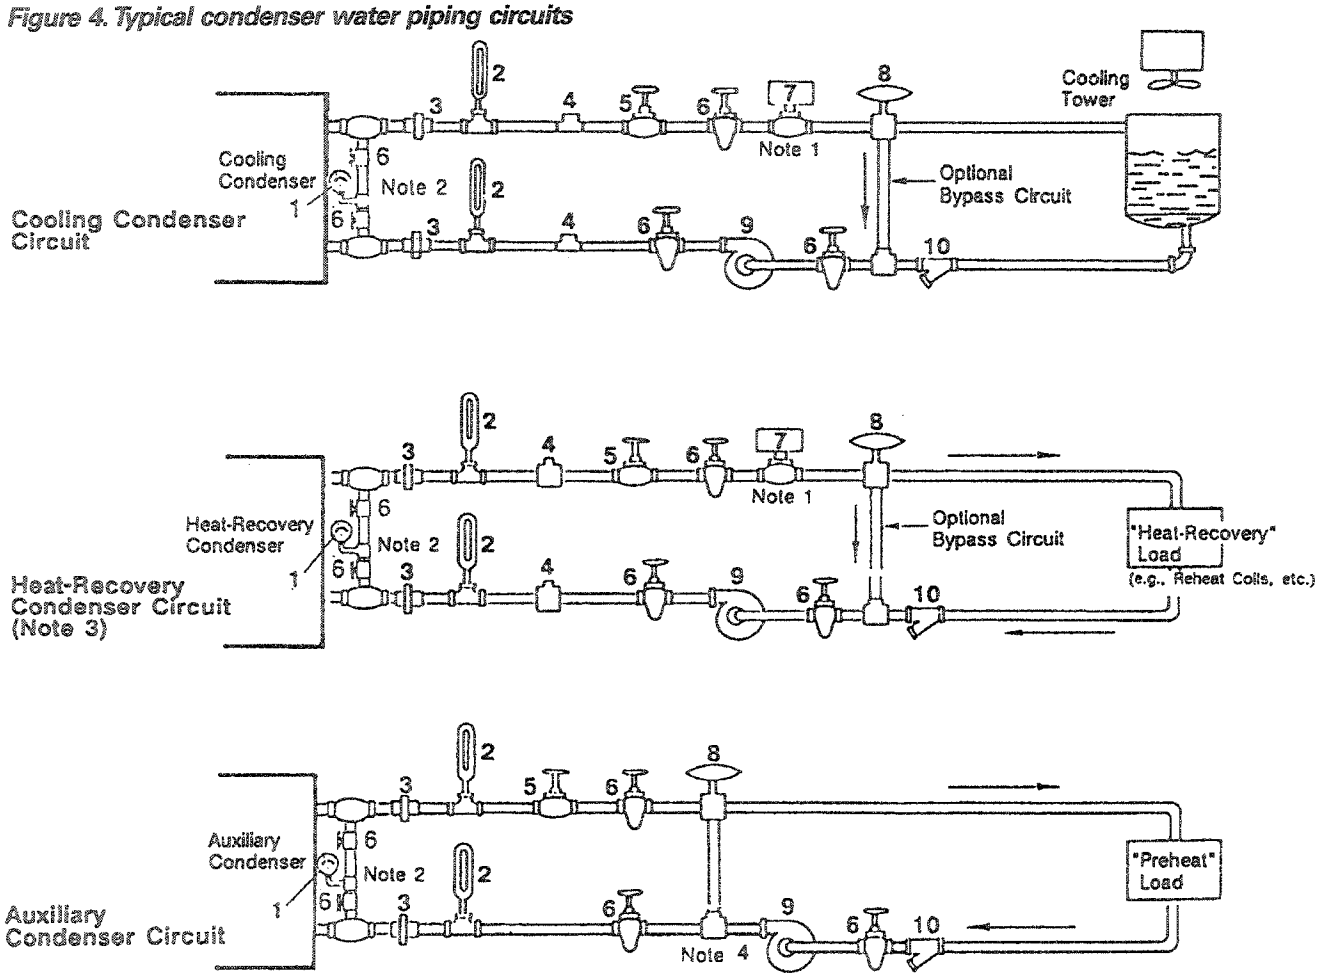
DO NOT EXCHANGE POSITIONS OF MARINE-STYLE WATER BOXES. Failure to follow this recommendation could alter designed water flow piping configuration and prevent proper unit operation.

To accommodate lifting apparatus, a nut is welded to each evaporator water box to enable attachment of a 3/4" [19 mm] eyebolt (field supplied). Condenser water boxes are provided with 1/2" [13 mm] tapped holes that allow installation of the eyebolt included in the unit's loose parts-box.

If the water boxes on any of the shells are exchanged end-for-end, be sure to reinstall them right side up to maintain the correct baffle arrangements. Use a new gasket with each water box cover.

Water Piping

Figure 3. Typical evaporator water piping circuit



Notes:
1. Flow switch 5S1 (Item 7 in Legend of Components) may be installed in either the entering or leaving leg of the chilled water circuit.
2. It is recommended to pipe the (Item 1) gauge between entering and leaving pipes. A shutoff valve on each side of the gauge allows the operator to read either entering or leaving water pressure.

8. Strainer
9. Evaporator Water Pump

Water Piping

Figure 4. Typical condenser water piping circuits

Notes:
1. The Flow Switch 5S2 (Item 7 in Legend of Components) may be installed in either the entering or leaving leg of the chilled water circuit.
2. It is recommended to pipe a single gauge between entering and leaving pipes.
3. Some type of field-supplied temperature control device may be required to regulate the temperature of the heat-recovery condenser water circuit. For application recommendations, see Trane Application Manual, "AM-FND-8," titled "Heat-Recovery Engineering Seminar."
4. Install a bypass valve system to avoid circulating water through the auxiliary shell when the unit is shut down.
5. On multiple pass condensers, entering condenser water must enter at the lowest nozzle.

Water Piping

Water Piping Connections

For CVHEs beginning with design sequence "1D," all units (except those with 032 through 050 condenser shells with 150 psig [1035 kPa] non-marine water boxes) use cut-groove end NSP Victaulic style pipe connections. All CVHGs beginning with "1A" and later design sequences. All CVHF units, "A" and later design sequences, use grooved-pipe connections. See Figure 5.

Piping joined using grooved type couplings, like all types of piping systems, requires proper support to carry the weight of pipes and equipment. The support methods used must eliminate undue stresses on joints, piping and other components; allow movement where required, and provide for any other special requirements (i.e., drainage, etc.).

Table 1. Evaporator water piping connection sizes

	Nominal Pipe Size (inch/mm)					
	1 Pass		2 Pass		3 Pass	
EVSZ	Inch	mm	Inch	mm	Inch	mm
032	8	219.1	6	168.3	5	141.3

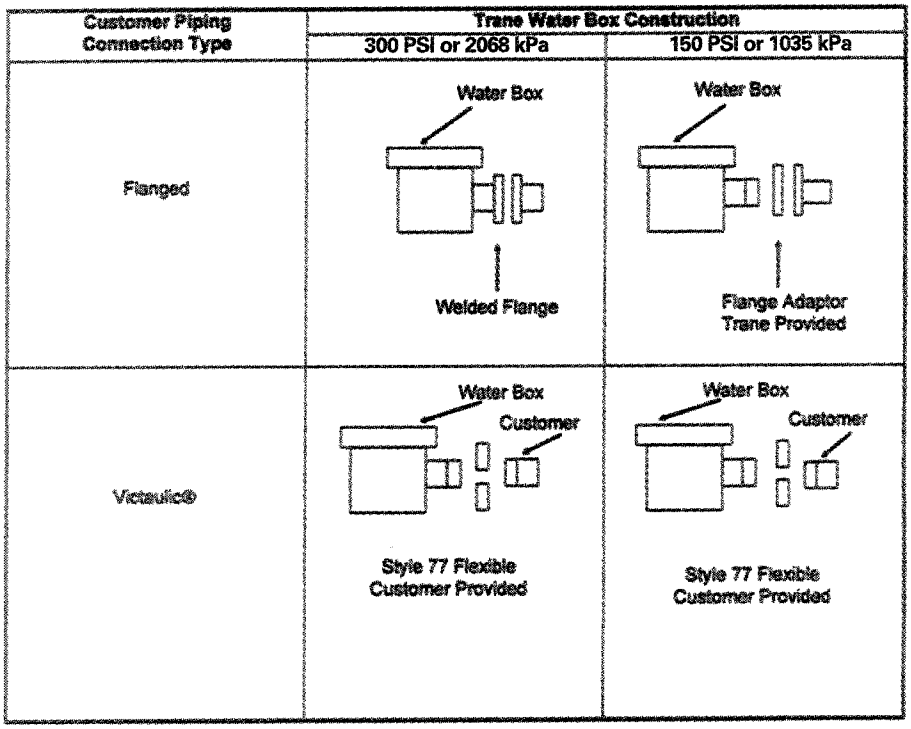
Figure 5. Typical CVHE grooved pipe connection

Water Piping

Table 3. Water piping connection components

		Customer Piping Connection	
Unit Model	Unit Connection Type	Victualic™	Flanged
CVHE and CVHG	Flanged (Condenser 032-050 150 psig and 1035 kPa non-marine only)	Trane provided Victaulic-to-Flange Adapter	No Adapter Required
CVHE, CVHF and CVHG	Victaulic (All others)	Customer provided Victaulic Coupling	Trane provided Victaulic-to-Flange Adapter



Grooved Pipe Coupling

A customer-supplied, standard flexible grooved pipe coupling (Victaulic Style 77 or equivalent) should be used to complete the Victaulic connection for both 150 psig or 1035 kPa and 300 psig or 2068 kPa water boxes. See Table 3.

When a flexible coupling such as this is installed at the water box connections (Figure 6), other flexible piping connectors (i.e., braided-steel, elastomeric arch, etc.) are usually not required to attenuate vibration and/or prevent stress on the connections.

Note: Flexible coupling gaskets require proper lubrication before installation to provide a good seal. Refer to the coupling manufacturer's guidelines for proper lubricant type and application.

Figure 6. Customer piping alternatives for water connections

Water Piping

Flange-Connection Adapters

When flat-face flange connections are specified, flange-to-groove adapters are provided (Victaulic™ Style 741 for 150 psig or 1035 kPa systems; Style 743 for 300 psig or 2068 kPa systems). Welded flanged connections are available only as a design special unless ordered as such, flange to groove adapters are provided if flat faced flange connections are specified. The adapters are shipped bolted to one of the chiller end-supports (Figure 7). Adapter weights are given in Tables 1 and 2, The flange adapters provide a direct, rigid connection of flanged components to the grooved-pipe chiller water box connections.

In this case, the use of flexible type connectors (i.e., braided steel, elastomeric arch, etc.) are recommended to attenuate vibration and prevent stress at the water box connections. Flange adapters are not provided for CVHE/F/G units with 300 psig or 2068 kPa water boxes that have 14" [356 mm] or 16" [406 mm] piping connections.

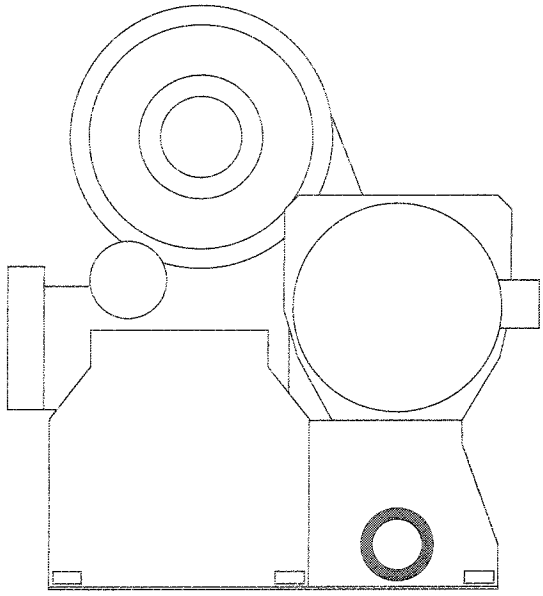
All flange-to-flange assembly bolts must be provided by the installer. Bolt sizes and number required are given in Tables 1 and 2.

The four draw-bolts needed for the 14" [356 mm] and 16" [406 mm] Style 741 (150 psig or 1035 kPa) adapters are provided. The Style 741, 150 psig or 1035 kPa flange adapter requires a smooth, hard surface for a good seal.

Connection to other type flange faces (i.e., raised, serrated, rubber, etc.) will require the use of a flange washer between the faces. Refer to the flange adapter manufacturer's guidelines for specific information.

The Style 743, 300 psig or 2068 kPa flange adapters are designed to mate with raised-face flanges. They can be used with flat-faced flanges, however, if the raised projections on the outside face of the adapter are removed (Figure 9.)

Note: The flange-adapter gasket must be placed with the color-coded lip on the pipe and the other lip facing the mating flange.



CAUTION

GASKET-CONTACT SURFACES OF ADAPTER MUST BE FREE OF GOUGES, UNDULATIONS, OR DEFORMITIES. Failure to do so may not provide an effective seal.

Victaulic Gasket Installation

1. Check gasket and lubricate: Check gasket supplied to be certain it is suited for intended service. Code identifies gasket grade. Apply a thin coat of silicone lubricant to gasket tips and outside of gasket.
2. Install Gasket: Place gasket over pipe end, being sure gasket lip does not overhang pipe end. See Figure 8 for gasket configuration.
3. Join pipe ends: Align and bring two pipe ends together and slide gasket into position centered between the grooves on each pipe. No portion of the gasket should extend into the groove on either pipe.
4. **Apply Vic-Flange™**: Open fully and place hinged flange around the grooved pipe end with the circular key section locating into the groove.
5. Insert bolt: Insert a standard bolt through the mating holes of the Vic-Flange to secure the flange firmly in the groove.
6. Tighten nuts: Tighten nuts alternately and equally until housing bolt pads are firmly together (metal to metal). Excessive nut tightening is not necessary. **Note:** Uneven tightening may cause gasket to pinch.

*Or equivalent supplied by others.

Water Piping

Bolt-Tightening Sequence for Water Piping Connections

A bolt-tightening sequence for flanges with flat gaskets or O-rings is described below and shown in Figure 10. Remember that improperly tightened flanges may leak.

Note: Before tightening any of the bolts, align the flanges. Flange bolt torque requirements are given in Table 6.

Flanges with 4, 8 or 12 Bolts

See Figure 10. Tighten all bolts to a snug tightness, following the appropriate numerical sequence for the flange. Repeat this sequence to apply the final torque to each bolt.

Flanges with 16, 20 or 24 Bolts

See Figure 10. Following the appropriate numbered sequence, tighten only the first half of the total number of bolts to a snug tightness. Next, sequentially tighten the remaining half of the bolts in the proper order.

Flanges with More than 24 Bolts

Refer to Figure 10 and sequentially tighten the first 12 bolts to a snug tightness. Tighten the next 12 consecutively numbered bolts in sequence, to the final torque.

Then, apply final torque to the first 12 bolts and the bolts not yet tightened (i.e., unnumbered bolts in Figure 10). Be sure to start with bolt "1" and move progressively around the flange in a clockwise direction.

Evaporator Water Box Covers

See Figure 10. Ensure that the water box head rests tightly against the tube sheet; then snugly tighten the 26 bolts in sequential order.

If excessive tube sheet crown prevents the head from contacting the tube sheet, tighten the bolts located where the greatest gaps occur. Be sure to use an equal number of bolt turns from side to side.

Pressure Testing Waterside Piping

Water side design pressure is either 150 or 300 Psig

⚠ WARNING

Do not over pressurize the system or exceed design pressure. Over pressurization can result in equipment damage. Always perform as a hydro pressure test with water present in piping and water boxes.

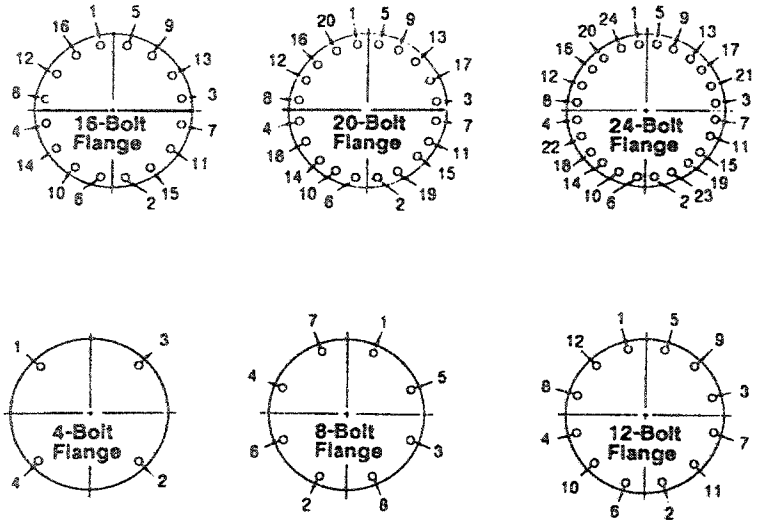

Table 6. Flange bolt torque recommendations for o-ring and flat-gasket piping connections

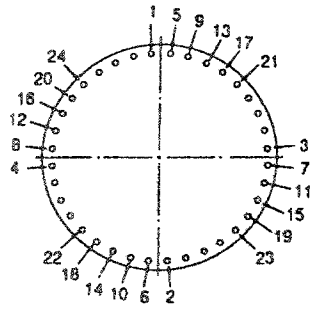
Bolt Size		Gasket Type	
Inch	(mm)	O-Ring	Flat
3/8"	9.5	25 (34)	12-18 (16-24)
1 /2"	13	70 (95)	33-50 (45-68)
5/8"	16	150 (203)	70-90 (95-122)
3/4"	19	250 (339)	105-155 (142-210)



Note: Torques provided in Ft/Lbs. (Newton/metres) Bolt size is determined by the diameter of bolt shank.

Water Piping

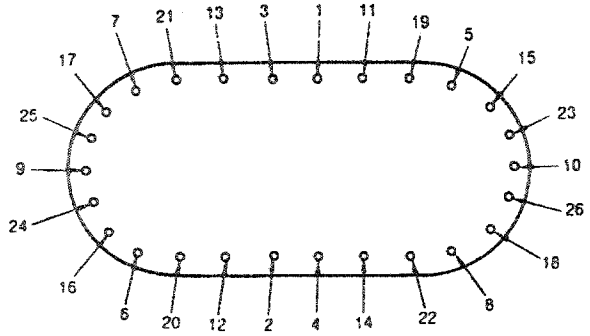


Figure 10. Bolt rightening sequences for water piping flanges and water boxes

Flanges with more than 24 bolts

Evaporator Water Box Covers

Purge Piping

EarthWise Purge Requirements Purge Installation

For certain CenTraVacs, the purge system is not mounted on the chiller when it ships. For 800-ton heat recovery chillers and 1250 and 1400 ton chillers with auxiliary condensers, the EarthWise Purge is shipped in a separate container that is secured to the chiller shipping skid.

Install the purge system in accordance with the following instructions.

1. Remove purge from its shipping brackets or container.
2. Disconnect purge gas and liquid lines and conduit from shipping bracket that spans purge supports on top of the heating or auxiliary condenser.
3. Remove shipping bracket and screws from purge supports and discard.
4. Locate purge on top of supports (purge base goes outside supports).
5. Secure the purge to the supports with the hardware provided.
6. Using proper brazing techniques as per American Welding society (A.W.S.) braze the following four copper lines at the factory disassembly points:
   - Purge suction line (larger)
   - Purge liquid drain line
   - Regeneration line
   - High pressure cutout switch

   Note: Verify that the high-pressure cutout switch is connected to the line, which proceeds to the chiller condenser. (Check the copper tube routing to verify.)
   - Assure braze joints are leak free
7. Remove purge panel cover and connect the unit wiring per the unit wiring diagrams:
   - Interprocessor communications bus (IPC).
   - Chiller motor temperature sensor wires to motor temperature module.
   - Conduit to control panel and interconnecting wires.
   - After inspection of terminations reassemble purge panel cover.
8. With completion of brazing and electrical connections, the unit valves can be opened for unit operation.

Vent Piping

Refrigerant Vent-Line

General Recommendations

Both the purge and rupture disc vent lines must be routed to outside atmosphere. Use only material compatible with the refrigerant in use. The use of Poly Vinyl Chloride (PVC) (not Chlorinated Poly Vinyl Chloride (CPVC) piping is acceptable if the pipe joint is properly primed and if the adhesive used has been tested for refrigerant compatibility. Testing conducted in Trane laboratories has approved the use of the following materials for PVC pipe construction.

Primer - Hercules, PVC Primer #60-465, RectorSeal PVC Cleaner -Smiling Sam CL3 Adhesive-Hercules, Clear PVC, Medium Body, Medium Set, #60-020 RectorSeal PVC Cement-Green Gene 104.

Consult with the manufacturers of any field-provided components or materials added to the refrigerant-side of the machine for acceptable material compatibility.

During vent line construction, provide a drip leg on the line that is of sufficient length to accommodate a minimum of one gallon of liquid. Provide a standard capped refrigerant service valve to facilitate liquid removal. Accumulated liquid must be drained from the drip leg into an evacuated waste container once every six months, at a minimum, and more often if the purge operates excessively.

Purge Discharge Vent Line

On CVHE, CVHF and CVHG units, the purge discharge is factory-piped downstream of the rupture disc on the unit.

Rupture Disc Vent Installation

All CenTraVac™ chillers are equipped with carbon rupture discs. A cross-section of the rupture disc assembly appears in Figure 10 along with an illustration indicating the location of the rupture disc on the suction elbow.

If refrigerant pressure within the evaporator exceeds 15 psig, the rupture disc breaks, shell pressure is relieved as refrigerant escapes from the chiller.

When constructing the rupture disc vent line, be sure to consult local codes for applicable guidelines and constraints.

Several general recommendations for rupture disc vent line installation are outlined below.

1. Verify that the vacuum support side of the rupture disc is positioned as shown in the cross-section view that appears in Figure 10.

   Note: If the rupture disc was removed for any reason, it must be reinstalled as shown.

2. Do not apply threading torque to the outside pipe assembly when installing the connecting pipe.

CAUTION

Do not apply threading torque to the outside pipe. Failure to do so may damage the rupture disc assembly.

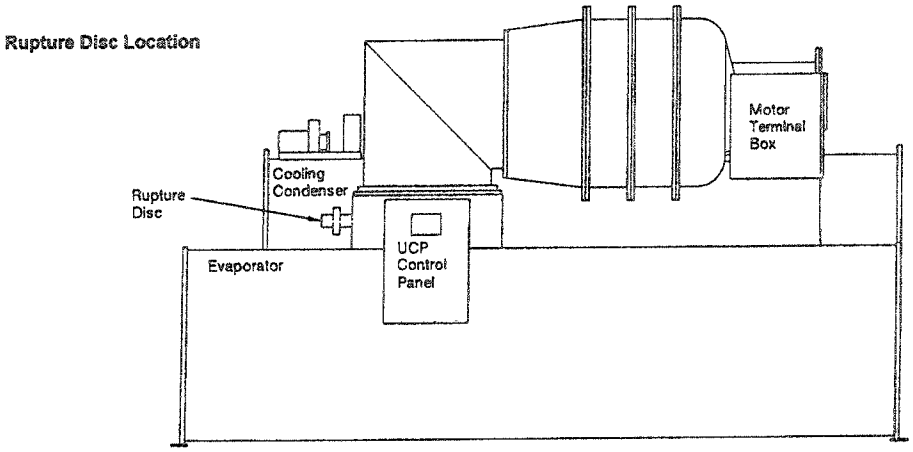
3. Support the vent piping, use a flexible connection to avoid placing stress on the rupture disc. (Stress can alter rupture pressure and cause the disc to break prematurely.)

Vent Piping

The flexible connector used to isolate the rupture disc from excessive vent line vibration must be compatible with the refrigerant in use. Use a flexible, steel connector such as the stainless-steel type (from Vibration Mounting and Control, Inc.) or equivalent.

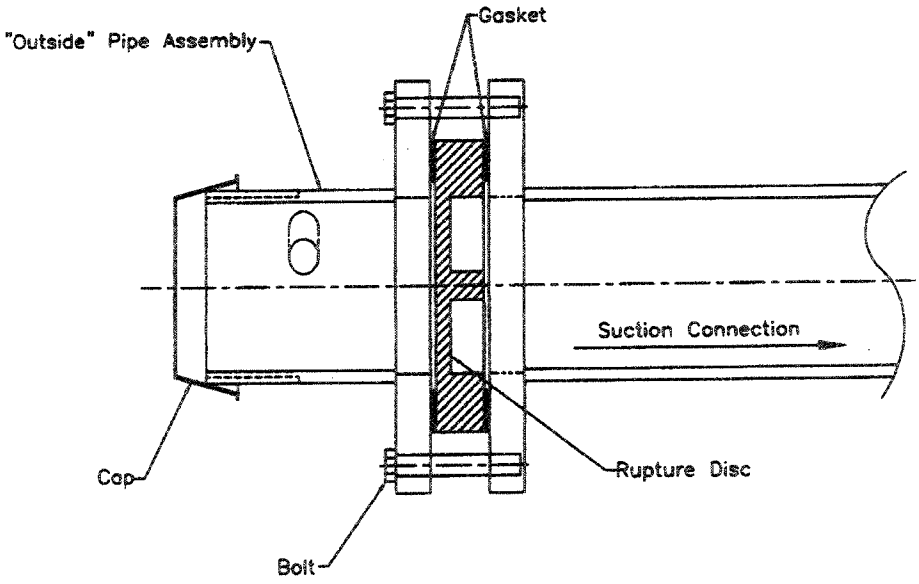
See Figure 12 for a recommended relief piping arrangement.

Important: Vent pipe size must conform to ANSI and ASHRAE Standard 15, which discusses vent pipe sizing.



Use Table 7 and then Figure 13 to determine proper vent pipe size.

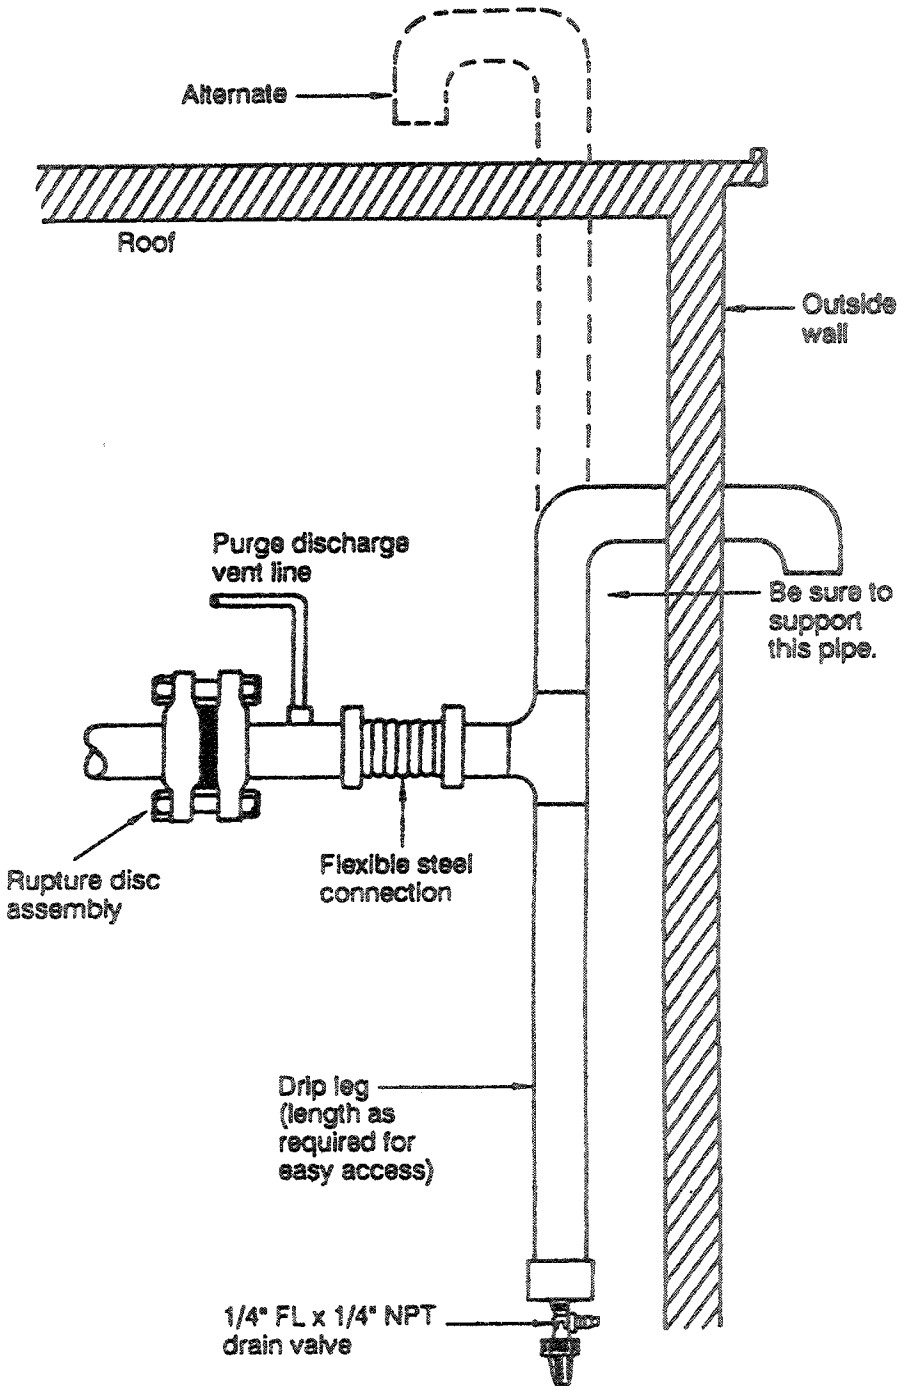
Note: To determine the total "C" value for a specific unit, add the appropriate "C" values for the evaporator, standard condenser and economizer. If the unit is equipped with any options (e.g., heat recovery, free cooling, or an auxiliary condenser), add the applicable "C" value(s) to this total.



With this new sum, refer to Figure 13 to determine the vent line pipe diameter needed to handle flow.

4. Normally, where multiple chillers are used, install a separate rupture disc vent line for each unit.
5. Consult local regulations for any special relief line requirements and refer to Refrigerant Handling Guidelines.
6. The discharge of the vent line outside should not be in the general vicinity of any fresh air intakes to the building. Any gas venting from the vent line should not be allowed to re-enter the building.

Figure 11. Illustrates rupture disc location, cross section of rupture disc and recommended rupture disc relief piping



Cross Section of Rupture Disc

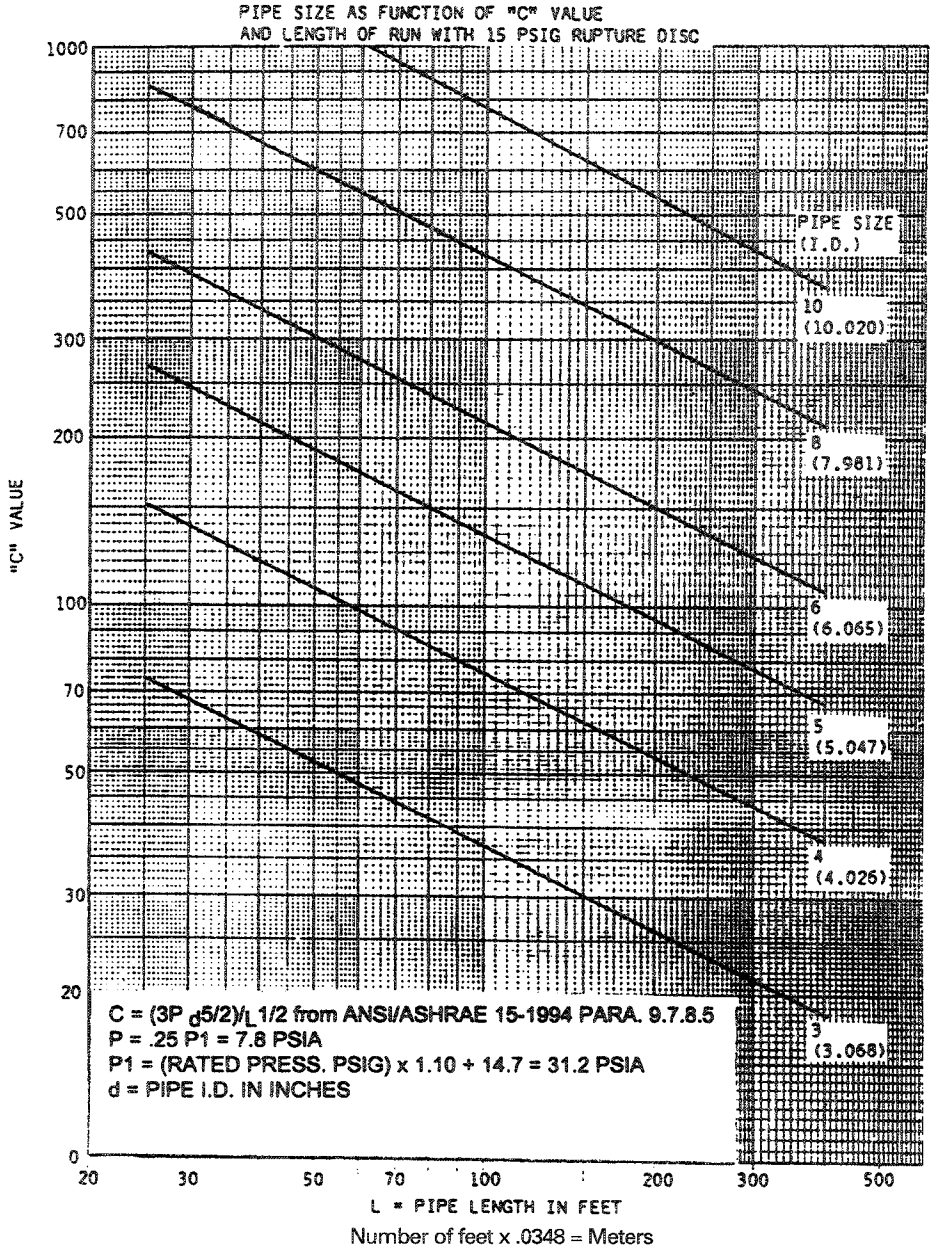
Vent Piping

Figure 12. Arrangement for rupture disc relief piping

Vent Piping

Table 7. "C" values used to determine rupture disc vent line sizes – CVHE, CVHF and CVHG

Evaporator Size (EVSZ) (3)	Condenser Size (CDSZ) (4)	"C" Values for Unit Components							
		Rupture Disc Diameter	Evaporator	Standard Condenser	Economizer	Short H.R. Condenser	Long H.R. Condenser	Auxiliary Condenser	With Free Cooling
032S	032S	3" (76 mm)	26.25	18.87	4.85	18.87	25.19	15.28	4.16
032S	032L	3" (76 mm)	26.25	25.19					
032L	032L	3" (76 mm)	35.04	25.19					
050S	050S	3" (76 mm)	33.05	23.56	7.44	23.56	31.45	15.28	6.16
050S	050L	3" (76 mm)	33.05	31.45					
050L	050L	3" (76 mm)	44.13	31.45					
080S	080S	3" (76 mm)	45.59	29.06	11.63	29.06	38.80	15.28	5.87
080S	080L	3" (76 mm)	45.59	38.80					
080L	080L	3" (76 mm)	60.86	38.80					
142E	142L	3" (76 mm)	74.30	50.50	17.40	N/A*	Design Special	15.28	Design Special
142M	142L	3" (76 mm)	58.47	50.50					
142L	142L	3" (76 mm)	68.86	50.50			50.50		7.10
210L	210L	3" (76 mm)	75.16	56.72			N/A*		
250E	250L	3" (76 mm)	93.81	62.12			56.72		



Notes:

1. To determine the total "C" value for a specific unit, add the appropriate ""C" values for the evaporator, standard condenser and economizer. If the unit is equipped with any options (e.g., heat recovery, free cooling or an auxiliary condenser, add the applicable "C" values to this total. With this new sum, refer to Figure 12 to determine the vent line pipe diameter.
2. If piping multiple rupture discs (multiple units) to a common vent line, first determine the total "C" value for each unit, and then; add all "C" values together and apply the result to the "vent pipe sizing chart" in Figure 12.
3. EVSZ = Evaporator Shell Size;
   S = Short Shell
   L = Long Shell
   E = Extended Shell
   M = Medium
4. CDSZ = Condenser Shell Size;
   S = Short Shell
   L = Long Shell
   E = Extended Shell

Insulation

Unit Insulation Requirements

Factory-installed insulation is available as an option for all CVHE, CVHF and CVHG units.

In those instances where the chiller is not factory-insulated, install insulation over the areas outlined and highlighted with dashed lines Figure 14. It may also be necessary to insulate the compressor suction cover and motor barrel if the unit is installed in an area subjected to high humidities.

Insulate both 1/4" [6.4 mm] eductor lines, one from the suction cover and one from the evaporator to prevent sweating.

The quantities of installation required based on unit size and insulation thickness are listed in Table 8. Insulation thickness is determined at normal design conditions which are:
- 85°
- 75% Relative Humidity

Note: If the unit is not factory-insulated: Install insulation around the evaporator bulbwells; and, ensure that the bulbwells and connections for the water box drains and vents are still accessible after insulation is applied. The sensor modules (LLID's) and interconnecting four wire cable (IPC Buss) must be raised up above the field installed insulation. Secure the IPC Buss to the insulation top/ outer surface after insulation is completed. Do not insulate over the wiring or sensor devices.

Table 8. CVHE, CVHF and CVHG evaporator insulation requirements

EVSZ (Note 1)	Standard Unit		Free Cooling	
	3/4" [19 mm] Insulation (Note 2) (Square Feet)	3/8" [9.5 mm] Insulation (Note 3) (Square Feet)	3/4" [19 mm] Insulation (Note 2) (Square Feet)	3/8" [9.5 mm] Insulation (Note 3) (Square Feet)
032S	337	52	347	74
032L	365	52	377	74
050S	385	63	398	72
050L	420	63	436	72
080S	505	84	515	97
080L	553	84	566	97
142M	555	98	555	133
142L	578	98	578	133
142E	603	104	629	133
210L	700	98	710	133
210 D	1220	193	Not Available	Not Available
250 D	1308	193	Not Available	Not Available
250 E	770	97	Not Available	Not Available

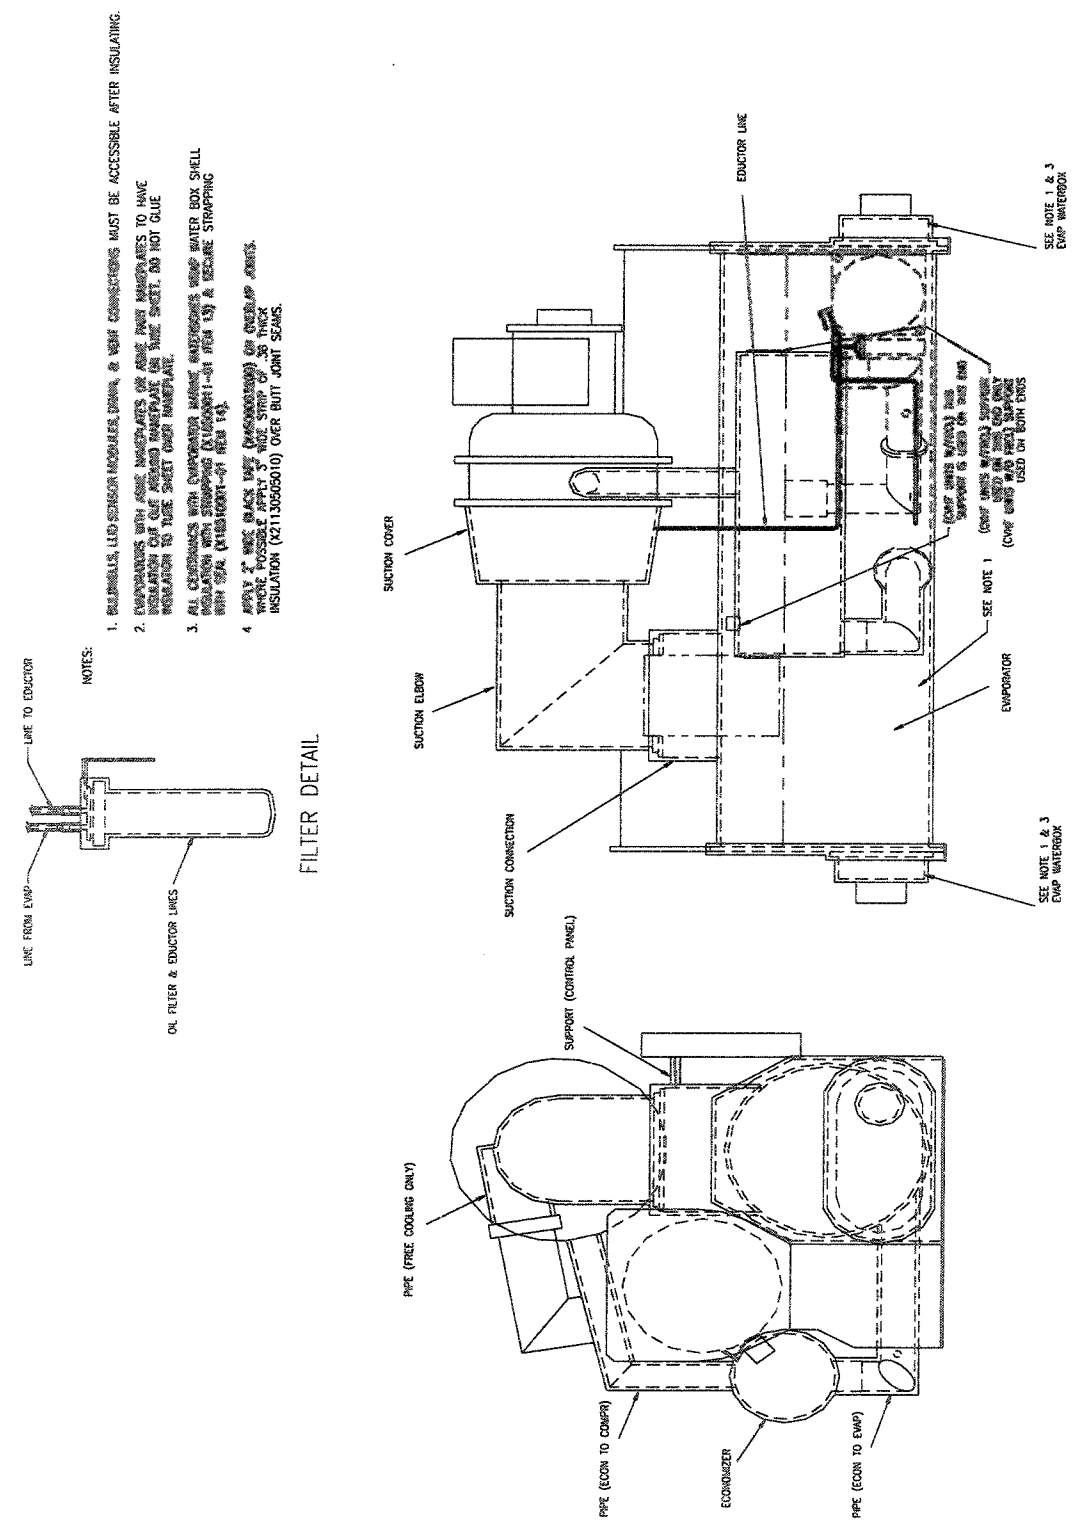
Notes:
1. EVSZ = Evaporator Shell Size, L = Long Shell, S = Short Shell
2. D = Duplex, M = Medium, E = Extended
3. 3/4" [19 mm] sheet insulation is installed on the evaporator, evaporator water boxes, compressor motor, suction elbow and suction cover as indicated in Figure 13.
4. 3/8" [9.5 mm] sheet insulation is installed on all economizers. All liquid lines and other pipes require the use of 1/2" [13 mm] pipe insulation or 3/8" [9.5 mm] sheet insulation. Copper oil eductor tube lines require pipe insulation.
5. Refrigerant Pump units are NOT insulated on the motor or refrigerant drain lines.

Insulation Thickness Requirements

Factory applied insulation. All low temperature surfaces are covered with 3/4" (19mm) Armaflex II or equal (thermal conductivity = 0.28 BTU/hr-ft sq.) (1.59 W/m2-K), including the evaporator, water boxes and suction elbow. The economizer and motor cooling lines are insulated with 3/8" (10mm) and 1/2" (13mm) insulation respectively.

Insulation is Armaflex or equivalent closed cell elastomeric insulation, to prevent sweating up to a dew point rating of 74°F K = 0.25. Chillers in high humidity areas or ice storage, low leaving water temperature (less than 36 degree chilled water temperature/glycol) units may require double thickness to prevent sweating.

CAUTION



TO PREVENT DAMAGE TO FACTORY-INSTALLED INSULATION, do not allow the insulation to be exposed to excessive sunlight. Failure to do so may damage insulation.

CAUTION

IF THE INSULATION WILL BE PAINTED IN THE FIELD, USE ONLY WATER-BASED LATEX PAINTS. Failure to do so results in damage because thinners and solvents used or other types of paints may cause seams in the insulation to open as a result of shrinkage.

Insulation

Warnings and Cautions

NOTICE

Warnings and Cautions appear at appropriate locations throughout this manual.

Read these carefully.

Warning: Indicates a potentially hazardous situation which, if not avoided, could result in death or serious injury.

CAUTION: Indicates a potentially hazardous situation which, if not avoided, may result in minor or moderate injury. It may also be used to alert against unsafe practices and where property-damage only accidents could occur.

Product Coding Definition

The CVHE, CVHF and CVHG models are defined using the product definition and selection (PDS) system. This system describes the product offerings in terms of a product coding block which is made up of feature categories and feature codes.

The operating components and options for any Model CVHE, CVHF and CVHG CenTraVac® units can be identified by referring to the alpha-numeric product identification coding block located on the nameplate for the unit. The coding block precisely identifies all characteristics of a unit. Be sure to refer to the service model when ordering replacements parts or requesting service. An example of a typical product code is given on this page.

Note: Unit-mounted starters are identified by a separate number found on the starter.

Typical Product Description Block

MODL CVHE	DSEQ 2R	NTON 320	VOLT 575	REF 123
HRTZ 60	TYPE SNGL	CPKW 142	CPIM 222	TEST AIR
EVTM IECU	EVTH 28	EVSZ 032S	EVBS 280	
EVWC STD	EVWP 2	EVWT NMAR	EVPR 150	
EVCO VICT	EVWA LELE	CDTM IECU	CDTH 28	
CDSZ 032S	CDBS 250	CDWC STD	CDWP 2

HHOP NO	GENR NO	GNSL NO	SOPT SPSH	
ACCY ISLS	HGBP WO	LUBE SNGL	AGLT CUL	
CNIF UCP2	SRTY USTR	SRRL 207	PNCO TERM	

MODL
Unit Model
CVHE = 3 stage direct drive
CVHF = 2 stage direct drive
CVHG = 3 stage direct drive

DSEQ
Design Sequence

EER
Energy Efficiency Rating

EEV
Energy Efficiency Verification

GENR
Gas Powered Chiller
YES = Yes gas powered chiller
NO = No gas powered chiller

HRTZ
Unit Hertz
60 = 60 Hertz
50 = 50 Hertz

NTON
Nominal Tons
190 = 190 Nominal Tons
210 = 210 Nominal Tons
230 = 230 Nominal Tons
240 = 240 Nominal Tons
250 = 250 Nominal Tons
270 = 270 Nominal Tons
280 = 280 Nominal Tons
300 = 300 Nominal Tons
320 = 320 Nominal Tons
330 = 330 Nominal Tons
350 = 350 Nominal Tons
360 = 360 Nominal Tons
370 = 370 Nominal Tons
400 = 400 Nominal Tons
410 = 410 Nominal Tons
420 = 420 Nominal Tons
450 = 450 Nominal Tons
470 = 470 Nominal Tons
480 = 480 Nominal Tons
485 = 485 Nominal Tons
500 = 500 Nominal Tons
530 = 530 Nominal Tons
555 = 555 Nominal Tons
560 = 560 Nominal Tons
565 = 565 Nominal Tons
590 = 590 Nominal Tons
630 = 630 Nominal Tons
640 = 640 Nominal Tons
650 = 650 Nominal Tons
660 = 660 Nominal Tons
670 = 670 Nominal Tons
710 = 710 Nominal Tons
770 = 770 Nominal Tons
780 = 780 Nominal Tons
800 = 800 Nominal Tons
910 = 910 Nominal Tons
920 = 920 Nominal Tons
1060 = 1060 Nominal Tons
1067 = 1067 Nominal Tons
1280 = 1280 Nominal Tons
1470 = 1470 Nominal Tons
1720 = 1720 Nominal Tons

VOLT
Unit Voltage
208 = 208 Volt 3 Phase
380 = 380 Volt 3 Phase
400 = 400 Volt 3 Phase
415 = 415 Volt 3 Phase
440 = 440 Volt 3 Phase
460 = 460 Volt 3 Phase
480 = 480 Volt 3 Phase
575 = 575 Volt 3 Phase
600 = 600 Volt 3 Phase
2300 = 2300 Volt 3 Phase
2400 = 2400 Volt 3 Phase
3300 = 3300 Volt 3 Phase
4160 = 4160 Volt 3 Phase
6000 = 6000 Volt 3 Phase
6600 = 6600 Volt 3 Phase

CVHE-OM-8 - May 1999

About this manual

Information regarding 032 and 050 shell sizes on models CVHE, CVHF and CVHG is in this manual. Extended capacity, available only on models CVHF 1470 and 1720, has been added to this manual. The operation and maintenance of 50 and 60 Hz. CVHE, CVHF and CVHG centrifugal chillers equipped with micro-computer-based control systems, whether standard cooling or heat recovery, is described.

Important: *All diagnostic information is provided in the latest revision of the clear language display manual, CVHE-CLD-1A or latest revision which ships with the unit or is available at the nearest trane office.*

By carefully reviewing this information and following the instructions given, the owner/operator can successfully operate and maintain a CVHE, CVHF or CVHG unit.

If mechanical problems do occur, however, contact a qualified service organization to ensure proper diagnosis and repair of the unit.

Commonly Used Acronyms

For convenience, a number of acronyms are used throughout this manual. These acronyms are listed alphabetically below, along with the "translation" of each:

For your convenience, a number of acronyms are used throughout this manual. These acronyms are listed alphabetically below, along with the "translation" of each:

AFDB = Adaptive Frequency Drive

ASME = American Society of Mechanical Engineers

ASHRAE = American Society of Heating, Refrigerating and Air Conditioning Engineers

BAS = Building Automation System

CABS = Auxiliary Condenser Tube-Bundle S

CDBS = Condenser Bundle Size

CDSZ = Condenser Shell Size

CLD = Clear Language Display

CWR = Chilled Water Reset

DTFL = Design Delta-T at Full Load (i.e., the difference between entering and leaving chilled water temperatures)

ENT = Entering Chilled Water Temperature

FC = Free Cooling

GPM = Gallons-per-minute

HGBP = Hot Gas Bypass

HVAC = Heating, Ventilating, and Air Conditioning

IE = Internally-Enhanced Tubes

IPC = Interprocessor Communication

LBU = La Crosse Business Unit

LCD = Liquid Crystal Display

LED = Light Emitting Diode
PFCC = Power Factor Correction Capacitor

LCD = Liquid Crystal Display

LED = Light Emitting Diode

PFCC = Power Factor Correction Capacitor

PSID = Pounds-per-Square-Inch (differential pressure)

PSIG = Pounds-per-Square-Inch (gauge pressure)

RCLD = Remote Clear Language Display

UCP2 = Chiller Control Panel for CenTraVacs

General Information

Warnings and Cautions

Notice that warnings and cautions appear at appropriate intervals throughout this manual. Warnings are provided to alert installing contractors to potential hazards that could result in personal injury or death, while cautions are designed to alert personnel to conditions that could result in equipment damage.

Your personal safety and the proper operation of this machine depend upon the strict observance of these precautions.

Unit Nameplate Information

The unit nameplate is located on the left side of the unit control panel (UCP). The following information is provided on the unit nameplate.

1. Service model and size descriptor
2. Unit serial number
3. Identifies unit electrical requirements
4. Correct operating charges and type of refrigerant
5. Unit Test Pressures and Maximum Operating Pressures
6. Identifies unit Installation and Operation and Maintenance manuals
7. Product Description Block (Identifies all unit components and unit "design sequence" used to order literature and make other inquiries about the unit).
8. Drawing numbers for Unit Wiring Diagrams.

Mechanical Operation - CVHE, CVHG

Overview

THE FOLLOWING INFORMATION APPLIES TO THE TRANE MODEL CVHE AND CVHG CENTRIFUGAL CHILLER ONLY. CVHF INFORMATION IS DISCUSSED IN ANOTHER SECTION OF THIS MANUAL. Refer to the appropriate operation manual for refrigeration cycle descriptions of other models.

Each CVHE, CVHG unit is composed of 5 basic components.

-- the evaporator,
-- 3-stage compressor,
-- water-cooled condenser,
-- 2-stage economizer,
-- related interconnecting piping.

A heat-recovery or auxiliary condenser can be factory-added to the basic unit assembly to provide a heat-recovery cycle.

Figure 1 illustrates the general component layout of a typical CVHE, CVHG chiller.

CVHE, CVHG cooling-only and heat recovery modes of operation are described in the following sections. A pressure enthalpy diagram (shown in Figure 2) is provided to further illustrate unit operation.

Cooling-Only Cycle

When the CVHE or CVHG is functioning in the cooling mode, liquid refrigerant is distributed along the length of the evaporator and sprayed through small holes in a distributor (i.e., running the entire length of the shell) to uniformly coat each evaporator tube. Here, the liquid refrigerant absorbs enough heat from the system water circulating through the evaporator tubes to vaporize.

The gaseous refrigerant is then drawn through the eliminators (which remove droplets of liquid refrigerant from the gas) and first-stage variable inlet guide vanes, and into the first stage impeller.

Note: Inlet guide vanes are designed to modulate the flow of gaseous refrigerant to meet system capacity requirements; they also prorate the gas, allowing it to enter the impeller at an optimal angle that maximizes efficiency at all load conditions.

Compressed gas from the first-stage impeller flows through the fixed, second-stage inlet vanes and into the second-stage impeller.

Here, the refrigerant gas is again compressed, and then discharged through the third-stage variable guide vanes and into the third-stage impeller.

Once the gas is compressed a third time, it is discharged into the condenser. Baffles within the condenser shell distribute the compressed refrigerant gas evenly across the condenser tube bundle. Cooling tower water circulated through the condenser tubes absorbs heat from the refrigerant, causing it to condense. The liquid refrigerant then passes through orifice plate "A" and into the economizer.

The economizer reduces the energy requirements of the refrigerant cycle by eliminating the need to pass all gaseous refrigerant through three stages of compression. See Figure 3. Notice that some of the liquid refrigerant flashes to a gas because of the pressure drop created by the orifice plates, thus further cooling the liquid refrigerant. This flash gas is then drawn directly from the first (Chamber A) and second (Chamber B) stages of the economizer into the third-and second-stage impellers of the compressor, respectively.

All remaining liquid refrigerant flows through another orifice plate "C" to the evaporator.

Units With Refrigeration Pump

Compressor Lubrication System - CVHE and CVHG

A schematic diagram of the compressor lubrication system is illustrated in Figure 4 for the CVHE and CVHG.

Oil is pumped from the oil tank (i.e., by a pump and motor located within the tank) through an oil pressure-regulating valve designed to maintain a net oil pressure of 18 to 22 psid. It is then filtered and sent to the oil cooler located in the Economizer and on to the bearings.

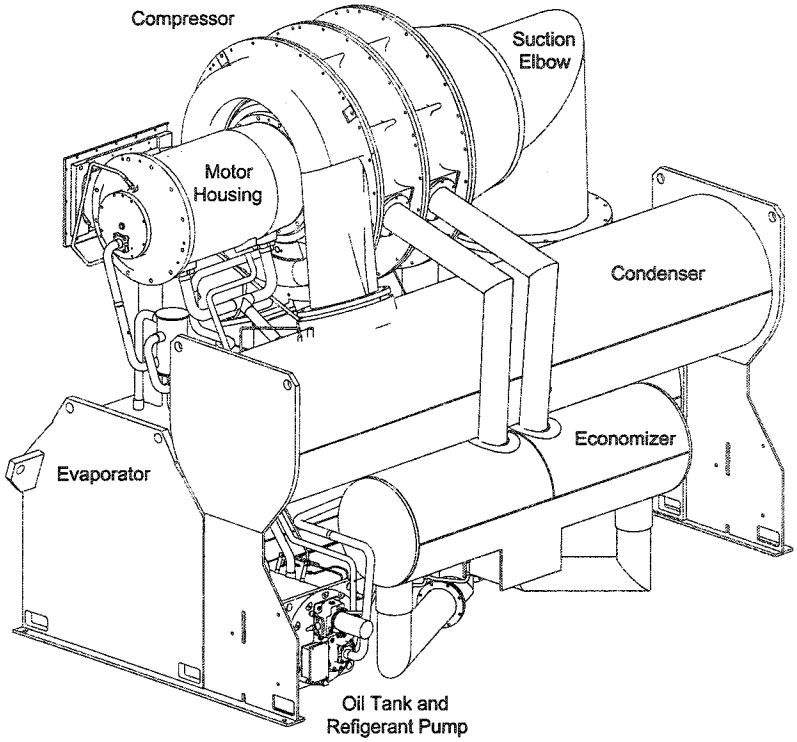
From the bearings, the oil drains back to the manifold under the motor and then on to the oil tank.

⚠ WARNING
SURFACE TEMPERATURES MAY EXCEED 150°F. Use caution while working on certain areas of the unit, failure to do so may result in death or personal injury.

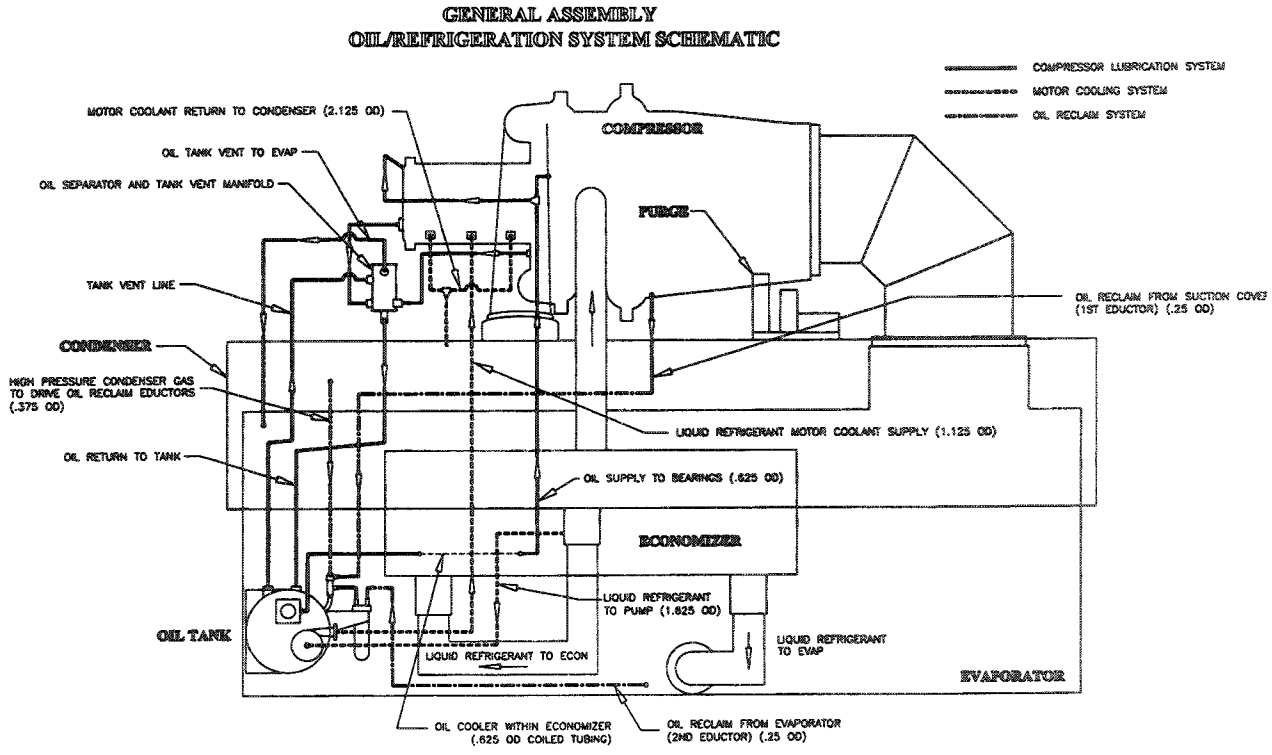
To ensure proper lubrication and prevent refrigerant from condensing in the oil tank, a 750-watt heater is immersed in the oil tank and is used to warm the oil while the unit is off. When the unit starts, the oil heater is de-energized. This heater energizes as needed to maintain 140° to 145° F (60-63 C) when the chiller is not running.

When the chiller is operating, the temperature of the oil tank is typically 115° to 160°F (46-72 C). The oil return lines from the thrust and journal bearings, transport oil and some seal leakage refrigerant. The oil return lines are routed into a manifold under the motor. Gas flow exits the top of the manifold and is vented to the Evaporator. A vent line solenoid is not needed with the refrigerant pump. Oil exits the bottom of the manifold and returns to the tank. Separation of the seal leakage gas in the manifold keeps this gas out of the tank.

A duel eductor system is used to reclaim oil from the suction cover and the evaporator, and deposit it back into the oil tank. these eductors use high pressure condenser gas to draw the oil from the suction cover and evaporator back to the eductors and then discharged into the oil tank. The evaporator eductor line has a shut off valve mounted by the evaporator and ships with two turns open.



Liquid refrigerant is used to cool the oil supply to both the Thrust bearing and Journal bearings. On refrigerant pump units the oil cooler is located inside the economizer and uses refrigerant passing from the condenser to evaporator to cool the oil . Oil leaves the oil cooler and flows to both the thrust and journal bearings.



Motor Cooling System

Compressor motors are cooled with liquid refrigerant, see Figure 4.

The refrigerant pump is located on the front of the oil tank (motor inside the oil tank). the refrigerant pump inlet is connected to the well at the bottom of the condenser. The connection is on the side where a weir assures a preferential supply of liquid. refrigerant is delivered to the motor via the pump. Motor refrigerant drain lines are routed to the condenser.
